ASM HANDBOOK®

VOLUME
15
Casting

ASM INTERNATIONAL ®
The Materials Information Company

Publication Information and Contributors

Casting was published in 1988 as Volume 15 of the 9th Edition *Metals Handbook*. With the second printing (1992), the series title was changed to *ASM Handbook*. The Volume was prepared under the direction of the ASM Handbook Committee.

Volume Chair

The Volume Chair was D.M. Stefanescu.

Authors and Reviewers

- **Rafael Menezes Nunes** UFRGS
- **G. J. Abbaschian** University of Florida
- **Harvey Abramowitz** Purdue University
- **R. Agarwal** General Motors Technical Center
- **Mark J. Alcini** Williams International
- **Robert L. Allen** Deere & Company
- **Richard L. Anderson** Arnold Engineering Company
- **John Andrews** Camden Castings Center
- **James J. Archibald** Ashland Chemical Company
- **Shigeo Asai** Nagoya University (Japan)
- **William H. Bailey** Cleveland Pneumatic Company
- **Leo J. Baran** American Foundrymen's Society, Inc.
- **W.J. Barice** Precision Castparts Corporation
- **Charles E. Bates** Southern Research Institute
- **Robert J. Bayuzick** Vanderbilt University
- **J. Beech** University of Sheffield (Great Britain)
- **V.G. Behal** Dofasco Inc. (Canada)
- **P. Belding** Columbia Steel Casting Company

Foreword

The subject of metal casting was covered--along with forging--in Volume 5 of the 8th Edition of *Metals Handbook*. Volume 15 of the 9th Edition, a stand-alone volume on the subject, is evidence of the strong commitment of ASM International to the advancement of casting technology.

The decision to devote an entire Handbook to the subject of casting was based on the veritable explosion of improved or entirely new molding, melting, metal treatment, and casting processes that has occurred in the 18 years since the publication of Volume 5. New casting materials, such as cast metal-matrix composites, also have been developed in that time, and computers are being used increasingly by the foundry industry. An entire section of this Handbook is devoted to the application of computers to metal casting, in particular to the study of phenomena associated with the solidification of molten metals.

Coverage of the depth and scope provided in Volume 15 is made possible only by the collective efforts of many individuals. In this case, the effort was an international one, with participants in 12 nations. The driving force behind the entire project was volume chairman Doru M. Stefanescu of the University of Alabama, who along with his section chairmen recruited more than 200 of the leading experts in the world to author articles for this Handbook. We are indebted to all of them, as well as to the members of the ASM Handbook Committee and the Handbook editorial staff. Their hard work and dedication have culminated in the publication of this, the most comprehensive single-volume reference on casting technology yet published.

William G. Wood

President, ASM International

Edward L. Langer

Managing Director, ASM International

Preface

The story of metal casting is as glamorous as it is ancient, beginning with the dawn of human civilization and interwoven with legends of fantastic weapons and exquisite artworks made of precious metals. It was and is involved in the two main activities of humans since they began walking the earth: producing and defending wealth. Civilization as we know it would not have been possible without metal casting. Metal casting must have emerged from the darkness of antiquity first as magic, later to evolve as an art, then as a technology, and finally as a complex, interdisciplinary science.

As with most other industries, the body of knowledge in metal casting has doubled over the last ten years. A modern text on the subject should discuss not only the new developments in the field but also the applications of some fundamental sciences such as physical chemistry, heat transfer, and fluid flow in metal casting. The task of reviewing such an extensive amount of information and of documenting the knowledge currently involved in the various branches of this manufacturing industry is almost impossible. Nevertheless, this is the goal of this Volume. For such an endeavor to succeed, only one avenue was possible--to involve in the preparation of the manuscripts as well as in the review process the top metal casting engineers and scientists in the international community. Indeed, nearly 350 dedicated experts from industry and academe worldwide contributed to this Handbook. This magnificent pool of talent was instrumental in putting together what I believe to be the most complete text on metal casting available in the English language today.

The Handbook is structured in ten Sections, along with a Glossary of Terms. The reader is first introduced to the historical development of metal casting, as well as to the advantages of castings over parts produced by other manufacturing processes, their applications, and the current market size of the industry. Then, the thermodynamic relationships and properties of liquid metals and the physical chemistry of gases and impurities in liquid metals are discussed. A rather extensive Section reviews the fundamentals of the science of solidification as applied to cast alloys, including nucleation kinetics, fundamentals of growth, and the more practical subject of interpretation of cooling curves. Traditional subjects such as patterns, molding and casting processes, foundry equipment, and processing and design considerations are extensively covered in the following Sections. Considerable attention has been paid to new and emerging processes, such as the Hitchiner process, directional solidification, squeeze casting, and semisolid metal forming. The metallurgy of ferrous and nonferrous alloys is extensively covered in two separate Sections. Finally, there is detailed information on the most modern approach to metal casting, namely, computer applications. The basic principles of modeling of heat transfer, fluid flow, and microstructural evolution are discussed, and typical examples are given.

It is hoped that the reader can find in this Handbook not only the technical information that he or she may seek, but also the prevailing message that the metal casting industry is mature but not aging. It is part of human civilization and will remain so for centuries to come. Make no mistake. A country cannot hold its own in the international marketplace without a modern, competitive metal casting industry.

It is a great pleasure to acknowledge the collective effort of the many contributors to this Handbook. The chairmen of the ten Sections and the authors of the articles are easily acknowledged, since their names are duly listed throughout the Volume. Less obvious but of tremendous importance in maintaining a uniform, high-quality text is the contribution of the reviewers. The Handbook staff of ASM INTERNATIONAL must also be commended for their dauntless and painstaking efforts in making this Volume not only accurate but also beautiful. Last but not least, I would like to acknowledge the precious assistance of my secretary, Mrs. Donna Snow, who had the patience to cope gracefully with the many tasks involved in such a complex project.

Prof. D.M. Stefanescu

Volume Chairman

General Information

Officers and Trustees of ASM International

Officers

- **William G. Wood** President and Trustee Kolene Corporation
- **Richard K. Pitler** Vice President and Trustee Allegheny Ludlum Corporation (retired)
- **Raymond F. Decker** Immediate Past President and Trustee University Science Partners, Inc.
- **Frank J. Waldeck** Treasurer Lindberg Corporation

Trustees

- **Stephen M. Copley** University of Southern California
- **Herbert S. Kalish** Adamas Carbide Corporation
- **H. Joseph Klein** Haynes International, Inc.
- **William P. Koster** Metcut Research Associates, Inc.
- **Robert E. Luetje** Kolene Corporation
- **Gunvant N. Maniar** Carpenter Technology Corporation
- **Larry A. Morris** Falconbridge Limited
- **William E. Quist** Boeing Commercial Airplane Company
- **Daniel S. Zamborsky** Aerobraze Corporation
- **Edward L. Langer** Managing Director ASM International

Members of the ASM Handbook Committee (1987-1988)

- **Dennis D. Huffman** (Chairman 1986-; Member 1983-) The Timken Company
- **Roger J. Austin** (1984-) Astro Met Associates, Inc.
- **Roy G. Baggerly** (1987-) Kenworth Truck Company
- **Peter Beardmore** (1986-) Ford Motor Company
- **Robert D. Caligiuri** (1986-) Failure Analysis Associates
- **Richard S. Cremisio** (1986-) Rescorp International, Inc.
- **Thomas A. Freitag** (1985-1988) The Aerospace Corporation
- **Charles David Himmelblau** (1985-1988) Lockheed Missiles & Space Company, Inc.
- **J. Ernesto Indacochea** (1987-) University of Illinois at Chicago
- **Eli Levy** (1987-) The De Havilland Aircraft Company of Canada
- **Arnold R. Marder** (1987-) Lehigh University
- **L.E. Roy Meade** (1986-) Lockheed-Georgia Company
- **Merrill L. Minges** (1986-) Air Force Wright Aeronautical Laboratories
- **David V. Neff** (1986-) Metaullics Systems
- **David LeRoy Olson** (1982-1988) Colorado School of Mines
- **Ned W. Polan** (1987-) Olin Corporation
- **Paul E. Rempes** (1986-) Williams International
- **E. Scala** (1986-) Cortland Cable Company, Inc.
- **David A. Thomas** (1986-) Lehigh University

Previous Chairmen of the ASM Handbook Committee

- **R.S. Archer** (1940-1942) (Member, 1937-1942)
- **L.B. Case** (1931-1933) (Member, 1927-1933)
- **T.D. Cooper** (1984-1986) (Member, 1981-1986)
- **E.O. Dixon** (1952-1954) (Member, 1947-1955)
- **R.L. Dowdell** (1938-1939) (Member, 1935-1939)
- **J.P. Gill** (1937) (Member, 1934-1937)

- **J.D. Graham** (1966-1968) (Member, 1961-1970)
- **J.F. Harper** (1923-1926) (Member, 1923-1926)
- **C.H. Herty, Jr.** (1934-1936) (Member, 1930-1936)
- **J.B. Johnson** (1948-1951) (Member, 1944-1951)
- **L.J. Korb** (1983) (Member, 1978-1983)
- **R.W.E. Leiter** (1962-1963) (Member, 1955-1958, 1960-1964)
- **G.V. Luerssen** (1943-1947) (Member, 1942-1947)
- **G.N. Maniar** (1979-1980) (Member, 1974-1980)
- **J.L. McCall** (1982) (Member, 1977-1982)
- **W.J. Merten** (1927-1930) (Member, 1923-1933)
- **N.E. Promisel** (1955-1961) (Member, 1954-1963)
- **G.J. Shubat** (1973-1975) (Member, 1966-1975)
- **W.A. Stadtler** (1969-1972) (Member, 1962-1972)
- **R. Ward** (1976-1978) (Member, 1972-1978)
- **M.G.H. Wells** (1981) (Member, 1976-1981)
- **D.J. Wright** (1964-1965) (Member, 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Kathleen M. Mills, Manager of Editorial Operations; Joseph R. Davis, Senior Editor; James D. Destefani, Technical Editor; Theodore B. Zorc, Technical Editor; Heather J. Frissell, Editorial Supervisor; George M. Crankovic, Assistant Editor; Alice W. Ronke, Assistant Editor; Diane M. Jenkins, Word Processing Specialist; and Karen Lynn O'Keefe, Word Processing Specialist. Editorial assistance was provided by Lois A. Abel, Robert T. Kiepura, Penelope Thomas, and Nikki D. Wheaton. The Volume was prepared under the direction of Robert L. Stedfeld, Director of Reference Publications.

Conversion to Electronic Files

ASM Handbook, Volume 15, *Casting* was converted to electronic files in 1998. The conversion was based on the fourth printing (1998). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

History of Casting

Martha Goodway, Smithsonian Institution

Introduction

THE CASTING OF METAL is a prehistoric technology, but one that appears relatively late in the archaeological record. There were many earlier fire-using technologies, collectively called by Wertime pyrotechnology, which provided a basis for the development of metal casting. Among these were the heat treatment of stone to make it more workable, the burning of lime to make plaster, and the firing of clay to produce ceramics. At first, it did not include smelting, for the metal of the earliest castings appears to have been native.

The earliest objects now known to have been have of metal are more than 10,000 years old (see Table 1) and were wrought, not cast. They are small, decorative pendants and beads, which were hammered to shape from nuggets of native copper and required no joining. The copper was beaten flat into the shape of leaves or was rolled to form small tubular beads. The archaeological period in which this metalworking took place was the Neolithic, beginning some time during the Aceramic Neolithic, before the appearance of pottery in the archaeological record.

Table 1 Chronological list of developments in the use of materials

Date	Development	Location
9000 B.C.	Earliest metal objects of wrought native copper	Near East

6500 B.C.	Earliest life-size statues, of plaster	Jordan
5000-3000 B.C.	Chalcolithic period: melting of copper; experimentation with smelting	Near East
3000-1500 B.C.	Bronze Age: arsenical copper and tin bronze alloys	Near East
3000-2500 B.C.	Lost wax casting of small objects	Near East
2500 B.C.	Granulation of gold and silver and their alloys	Near East
2400-2200 B.C.	Copper statue of Pharoah Pepi I	Egypt
2000 B.C.	Bronze Age	Far East
1500 B.C.	Iron Age (wrought iron)	Near East
700-600 B.C.	Etruscan dust granulation	Italy
600 B.C.	Cast iron	China
224 B.C.	Colossus of Rhodes destroyed	Greece
200-300 A.D.	Use of mercury in gilding (amalgam gilding)	Roman world
1200-1450 A.D.	Introduction of cast iron (exact date and place unknown)	Europe
Circa 1122 A.D.	Theophilus's *On Divers Arts,* the first monograph on metalworking written by a craftsman	Germany
1252 A.D.	*Diabutsu* (Great Buddha) cast at Kamakura	Japan
Circa 1400 A.D.	Great Bell of Beijing cast	China
16th century	Sand introduced as mold material	France
1709	Cast iron produced with coke as fuel, Coalbrookdale	England
1715	Boring mill or cannon developed	Switzerland
1735	Great Bell of the Kremlin cast	Russia
1740	Cast steel developed by Benjamin Huntsman	England

1779	Cast iron used as architectural material, Ironbridge Gorge	England
1826	Zinc statuary	France
1838	Electrodeposition of copper	Russia, England
1884	Electrolytic refining of aluminum	United States, France

Native metals were then perhaps considered simply another kind of stone, and the methods that had been found useful in shaping stone were attempted with metal nuggets. It seems likely that the copper being worked was also being annealed, because this was a treatment that already being given store. Proof of annealing could be obtained from the microstructures of these early copper artifacts were it not for their generally corroded condition (some are totally mineralized) and the natural reluctance to use destructive methods in studying very rare objects.

The appearance of plasters and ceramics in the Neolithic period is evidence that the use of fire was being extended to materials other than stone. Exactly when the casting of metals began is not known. Archaeologists give the name Chalcolithic to the period in which metals were first being mastered and the date this period, which immediately preceded the Bronze Age, very approximately to between 5000 and 3000 B.C. Analyses of early cast axes and other objects give chemical compositions consistent with their having been cast from native copper and are the basis for the conclusion that the melting of metals had been mastered before smelting was developed. The furnaces were rudimentary. It has been shown by experiment that it was possible to smelt copper, for example, in a crucible. Nevertheless, the evidence for casting demonstrates an increasing ability to manage and direct fire in order to achieve the required melting temperatures. The fuel employed was charcoal, which tended to supply a reducing atmosphere where the fire was enclosed in an effort to reduce the loss of heat. Smelting followed.

The molds were of stone (Fig. 1). The tradition of stone carving was longer than any of the pyrotechnologies, and the level of skill allowed very finely detailed work. The stone carved was usually of a smooth texture such as steatite or andesite, and the molds produced are themselves often very fine objects, which can be viewed in museums and archaeological exhibitions. Many are open molds, although they were not necessarily intended for flat objects. Elaborate filigree for jewelry was cast in open molds and then shaped by bending into bracelets and headpieces, or cast in parts and then assembled. Certain molds, described by the archaeologist as multifaceted, have cavities carved in each side of a rectangular block of stone. Such multifaceted molds would have been more portable than separate ones and suggest itinerant founding, but they may simply represent economy in the use of a suitable piece of stone.

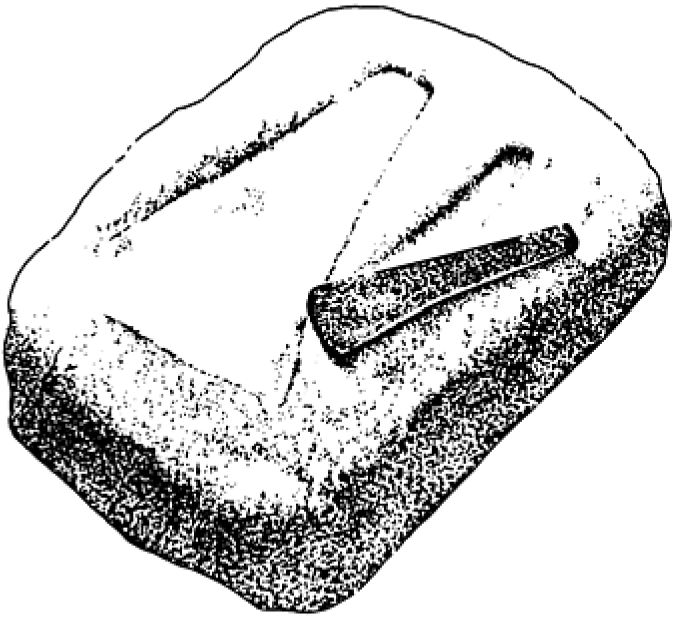

Fig. 1 Bronze Age stone mold with axe.

The Bronze Age

The Bronze Age began in the Near East before 3000 B.C. The first bronze that could be called a standard alloy was arsenical copper, usually containing up to 4% As, although a few objects contain 12% or more. This alloy was in widespread use and occurs in objects from Europe and the British Isles (Fig. 2) as well as the Near East. The metal can sometimes be recognized as arsenical copper by the silvery appearance of the surface, which occurred as a result of inverse segregation of the arsenic-rich low-melting phase to the surface. This is the same phenomenon that produces tin sweat on tin bronzes, and it led earlier excavators to describe these artifacts as silver plated. A few examples of arsenic plating on tin bronze can be seen on objects from Anatolia and Egypt, but the plating method is not known.

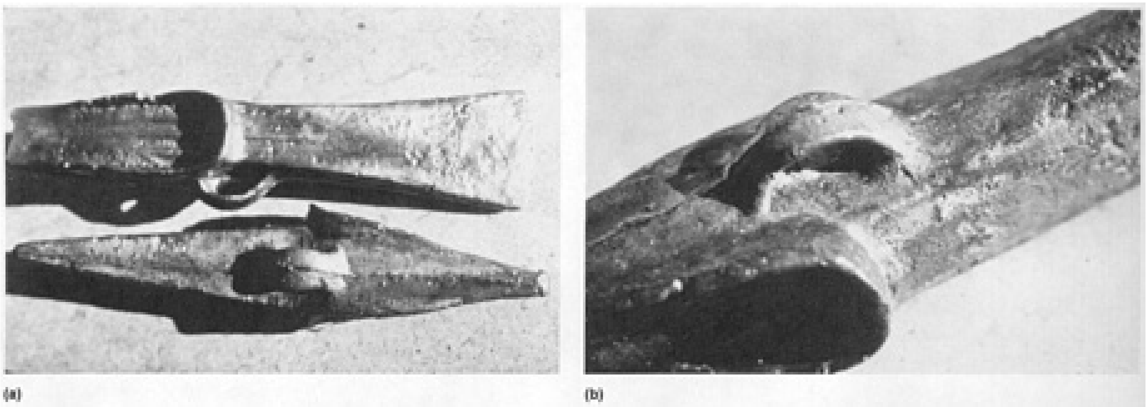

Fig. 2 Top and side view (a) of arsenical copper axes from Oxfordshire, England, that appear silver plated due to inverse segregation. (b) Detail of one of the arsenical copper axes showing the joint of the bivalve (permanent two-part) mold, placed so that no core was necessary.

The use of 5 to 10% Sn as an alloying element for copper has the obvious advantages of lowering the melting point, deoxidizing the melt, improving strength, and producing a beautiful, easily polished cast surface that reproduces the features of the mold with exceptional fidelity--vitality important properties for art castings (Fig. 3). There are several

hypotheses to explain the development of tin bronze. One is that of the so-called natural alloy, that is, metal smelted from a mixed ore of copper and tin. Another suggests the stream tin (tin ore in the form of cassiterite) may have been added directly to molten copper. The more vexing question has been the sources of the tin, copper, and silver that have been excavated from sites in such areas as Mesopotamia, which lack local metal resources. Cornwall or Afghanistan was long thought to have been the source of this early tin, but more recent investigations have located stream tin in the Eastern Desert of Egypt and sources of copper and silver as well as tin in the Taurus mountains of south central Anatolia in modern Turkey.

Fig. 3 Bronze panel by Giacomo Manzu for the Doors of Death to St. Peter's Basilica, the Vatican. The bronze alloy faithfully renders the texture of the surface as well as the form of the sculptor's model.

Recent experiments have shown that metal cast into an open mold is sounder if the open face is covered after the mold has been filled. This observation may have led to the use of bivalve (permanent two-part) molds. They were in common use for objects having bilateral symmetry, such as axes of various designs and swords. The molds were made such that the flash occurred at the edge, which required finishing to sharpen (Fig. 4). These edges are often harder than the body of the object, evidence of deliberate work hardening. There is also evidence in the third millennium B.C. for the lost wax casting of small objects of bronze and silver, such as the stag from Alaça Hoyük, now in Ankara. This small object is also of interest because the casting sprues were left in place attached to the feet, clearly showing how the object was cast.

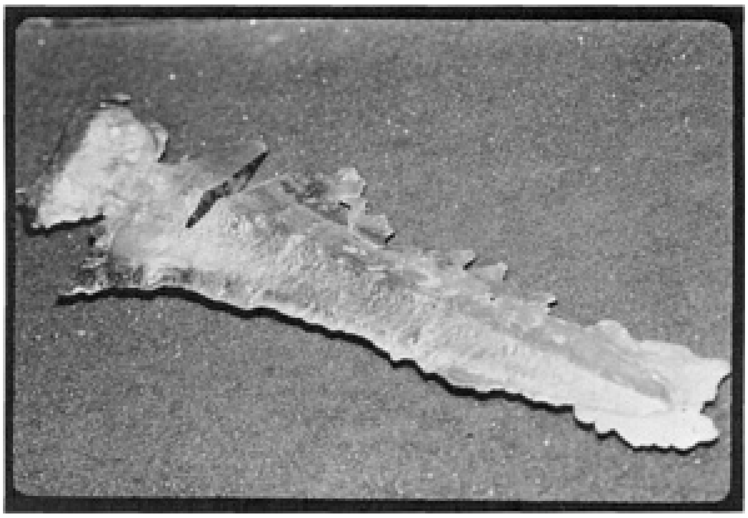

Fig. 4 A sword of typical Bronze Age design replicated by Dr. Peter Northover, Oxford, in arsenical copper using a bivalve mold. It has a silvery surface due to inverse segregation. The flash at the mold joint demonstrates the

excellent fluidity of the alloy.

Although there is abundant evidence from such objects that lost wax casting was employed early in the Bronze Age, the remnants of the process, such as broken investment and master molds, have eluded researchers. Wax may well have been the material of the model; other material may have been used, but no surviving evidence of any of these materials has been recognized. Similarly, the mold dressings used then and later remain unknown. Nevertheless, discoveries are occasionally made that greatly enlarge the geographical area in which lost wax casting in thought to have taken place. One of these discoveries occurred in 1972 at a site in England called Gussage All Saints.

At Gussage, an Iron Age (first century B.C.) factory was excavated. The lost wax process was used in this factory for the mass production of bronze bridle bits and other metal fittings for harnesses and chariots. More than 7000 fragments of clay investment molds were recovered (Fig. 5), along with crucible fragments, charcoal slag, and other debris thought to represent the output of single season. The bronze was leaded and in one case had been used to bronze plate a ring of carbon steel by dipping. This is the first site in Great Britain where direct evidence of lost wax casting has been found, yet the maturity of the industry suggests that earlier sites remain to be located.

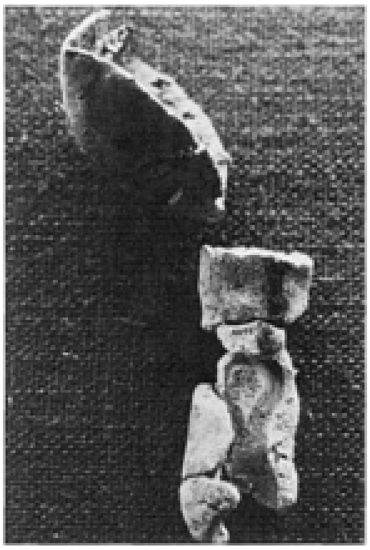

Fig. 5 Fragments of a crucible (top) and a lost wax investment excavated at Gussage All Saints.

The Far East

The Bronze Age in the Far East began in about 2000 B.C. more than a millennium after its origin in the Near East. It is not yet clear whether this occurred in China or elsewhere in southeast Asia, and there are vigorous efforts underway to discover and interpret early metallurgical sites in Thailand. The later date for the development of metallurgy in the Far East let to an obvious assumption that the knowledge of metal smelting and working had entered the area by diffusion from the West. This assumption was countered by mapping the geographical distribution of dated metallurgical sites in China, which indicates development in a generally east-to-west direction. The question of independent origin for the metallurgy of southeast Asia remains open.

Casting was the predominant forming method in the Far East. There is little evidence of other methods of metalworking in China before about 500 B.C. Antique Chinese cast bronze ritual vessels were of such complexity that it was the opinion until recently that these must have been cast by the lost wax method. This had also been the opinion of Chinese scholars in recent centuries. In the 1920s, however, a number of mold fragments were unearthed at Anyang, prompting reevaluation of the lost wax hypothesis. The molds were ceramic, and they were piece molds.

Very early Bronze Age sites, approximately 2000 B.C., in Thailand present similar evidence. At one of these sites a burial was unearthed that contained the broken pieces of an apparently unused ceramic bivalve mold. The bronze founder had been buried with a piece of the mold in each hand.

The Chinese mold was a ceramic piece mold, typically of many separate parts. The wall sections of the vessels cast in these molds are quite thin and testify to very fine control over the design of the molds and pouring of the metal. The metal, usually a leaded tin bronze, was used to great effect but also in an economical manner. Parts, such as legs, which could have been cast solid, were instead cast around a ceramic core held in position in the mold by chaplets. The chaplets took several forms; some were cross shaped, others square. They were of the same alloy as the vessel but can clearly be seen in radiographs. They have occasionally become visible on the surface because their patina appears slightly different from that of the rest of the vessel.

Metal parts that in the Western tradition would have been made separately and then joined by soldering or welding were incorporated into Chinese vessels by a sequence of casting on. Handles and legs might be cast first, the finished parts set in the mold, and the body of the vessel then poured (Fig. 6). Elaborate designs demanded several such steps. An unusual feature of this way of thinking about mold making and casting metal is the deliberate incorporation of flash into the design elements.

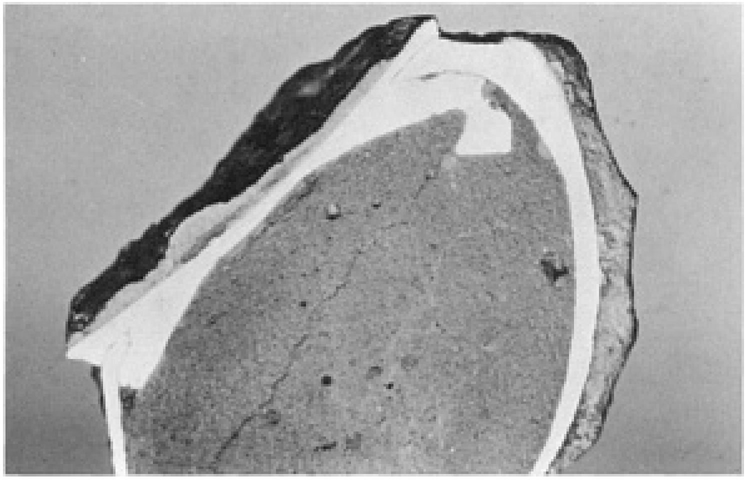

Fig. 6 Cross section of a leg and part of the attached bowl of a Chinese *ting,* a footed cauldron of the type used for cooking in China for at least 3000 years. The leg was cast around a core, which is still in place. Part of this core was excavated to allow a mechanical as well as a metallurgical joint when the leg was placed in the mold and the bowl of the vessel cast on. Source: Ref 1.

The surface decoration of the vessels sometimes employed inlay or gilding, but even in these examples much of the decoration is cast in. Various decorative elements may have been molded from a master model, impressed into the mold with loose pieces, or incorporated by casting on metal elements. By using a leaded tin bronze, the founder increased the fluidity of the melt and consequently the soundness of the casting even in the usual thin sections. However, such a fluid melt also has a greater tendency to penetrate the joints between the pieces of the mold so as to produce flash. If the surface of the bronze is meant to be smooth, the flash must be trimmed away. The Chinese founders eventually took this casting flaw and made it a deliberate element of their design. The joints of the mold were placed in relation to the rest of the surface decoration such that the flash needed only to be trimmed to an even height to be accepted as part of the cast-in decoration.

Cast Iron

Cast iron appeared in China in about 600 B.C. Its use was not limited to strictly practical applications, and there are many examples of Chinese cast iron statuary. Most Chinese cast irons were unusually high in phosphorus, and, because coal was often used in smelting, high in sulfur as well. These irons, therefore, have melting points that are similar to those of bronze and when molten are unusually fluid. The iron castings, like the Chinese cast bronzes, are often remarked upon for the thinness of their wall sections.

There is some dispute concerning the date of the introduction of cast iron into Europe and the route by which it came. There is less disagreement about the assumption that it was brought from the East. The generally agreed upon date for the introduction of cast iron smelting into Europe is the 15th century A.D.; it may have been earlier. At this time, cast iron was less appreciated as a casting alloy than as the raw material needed for "fining" to wrought iron, the form in which iron could be used by the local blacksmith.

The mass production of cast iron in the West, as well as its subsequent use as an important structural material, began in the 18th century at Coalbrookdale in England. Here Abraham Darby devised a method of smelting iron with coal by first coking the coal. He was successful because the local ores fortuitously contained enough manganese to scavenge the sulfur that the coke contributed to the iron. The vastly greater amounts of cast iron that could be produced by using coke rather than charcoal from dwindling supplies of timber were eventually put to use nearby in erecting the famous Iron Bridge (Fig. 7) and led to many other architectural uses of cast iron.

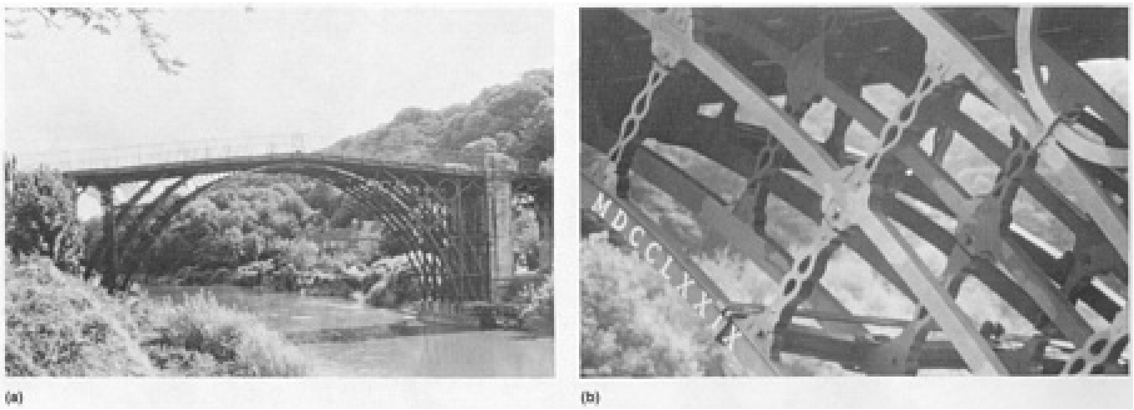

Fig. 7 The Iron Bridge (a) across the Severn River at Ironbridge Gorge. The structure was cast from iron smelted by Abraham Darby at Coalbrookdale. (b) Detail of the Iron Bridge showing the date, 1779. This was the first important use of cast iron as a structural material.

The dome of the United States Capitol Building is an example, as is the staircase designed by Louis Sullivan for the Chicago Stock Exchange now at the Metropolitan Museum in New York City. Cast iron architectural elements were usually painted; the Capitol dome is painted to resemble the masonry of the rest of the building. Finishes other than paint were also used. The Sullivan staircase was copper plated and then patinated to give it the appearance of having been cast in bronze. Another method suitable for interior iron work was the treatment of the surface by deliberate light rusting, followed by hydrogen reduction of the rust. This produced a velvety black adherent layer of magnetite (Fe_3O_4) that was both attractive and durable.

Granulation

Not all casting requires a shaped mold. The exploitation of surface tension led to granulation. The tiny spheres produced when small amounts of molten metal solidified without restraint were being used as decoration in gold jewelry by 2500 B.C. Granulation was primarily done in gold, silver, or the native alloy of gold and silver called electrum. Some granules were attached to copper or gilt-silver substrates. The finest work in granulation was done by the Etruscans in about the seventh century B.C. Its fineness has given it the name "dust granulation," the granules being less than 0.2 mm (0.008 in.) in diameter. Many thousands of granules were used to create the design on a single object. The Etruscan alloy was gold

with about 30% Ag and a few percent of copper. The method of joining the granules varied. Sweating or soldering have both been observed, but the exact method used is often still a matter of dispute.

Tumbaga

New World metallurgy is a metallurgy almost without iron. The exception was the use of meteoric iron, which was most important among the Eskimos, who traded it all across the North. Copper-using cultures flourished further south until the sources of native copper were exhausted. There is no evidence of smelting among the native population of what is now the United States until the arrival of the Europeans.

In South America, however, the story is quite different. Early European explorers were overwhelmed by the amount of gold and silver objects they found. Many of these objects were of sheet gold or its alloys, and it has been suggested that sheet metal was viewed then as a kind of textile, as textiles in these cultures were not limited to clothing and were used for weapons and armor. The most interesting castings are of an alloy called tumbaga, which contained gold, silver, and copper in various proportions. Molds have been found (some never used) that were made by the lost wax process. After an object had been cast in tumbaga, it was pickled in a corrosive solution that attacked the silver and especially the copper and, when rinsed off, left a surface layer enriched in gold. This method of gilding is called *mise-en-couleur,* or "depletion gilding."

Africa

Africa, where sculpture is often the province of the blacksmith, presents several interesting traditions of casting. Among them are the famous Benin bronzes of Nigeria and the gold weights of Ghana, formerly the Gold Coast. Both of these traditions produced castings in brass, with the brass having a high enough zinc content to appear golden. The source of the brass, or at least that of the zinc, may well be indicated by the portrait of a Portuguese trader in a Benin bronze (Fig. 8). Recent discoveries of zinc furnaces and distillation retorts at Zawar, near Udaipur in India, as well as the very long trade routes that were opened in the 17th century, suggest the possibility that the metal may have been traded from India. The Benin bronzes were cast by the lost wax process, and the traditional method has been recorded on film.

Fig. 8 A Benin bronze plaque depicting a Portuguese trader of the time. The alloy is actually brass.

Lost wax was also used in Ghana to make gold weights and many types of small decorative objects. Once the mold and the crucible had been made, the crucible was charged with the brass, and both mold and crucible were invested (Fig. 9). While one end of the investment was heated to the casting temperature, the mold at the other extremity was being preheated, ready to receive the metal when the investment was inverted.

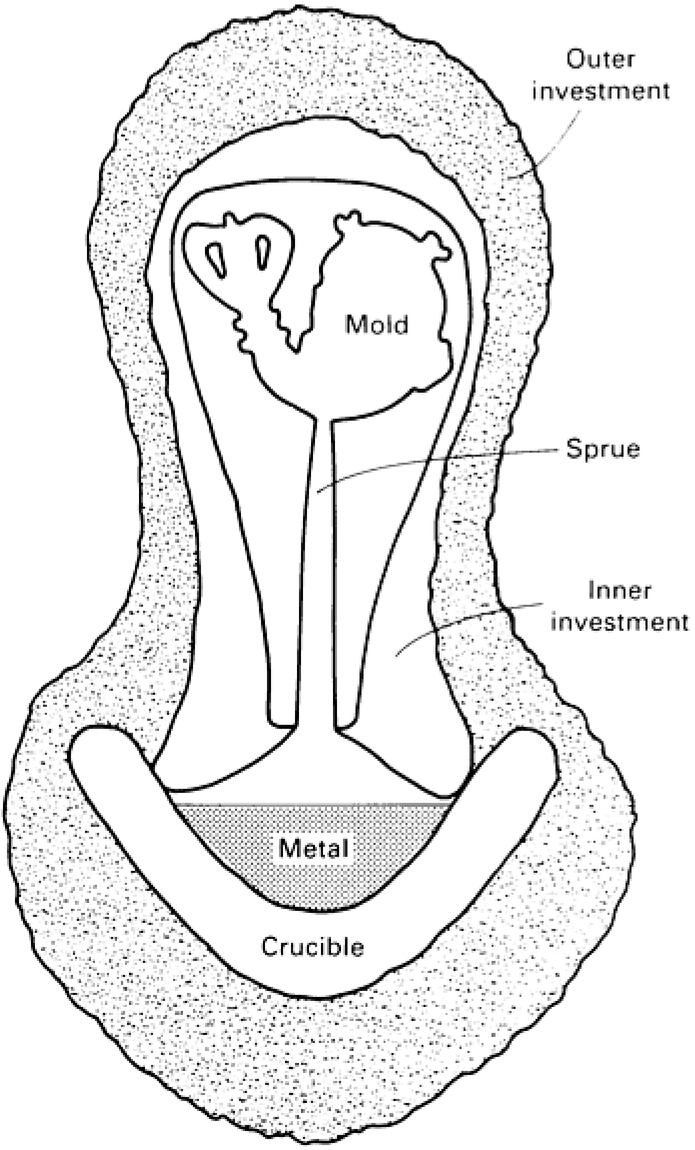

Fig. 9 Crucible and mold assembly for the lost wax casting of a small brass figure in Ghana. The metal is brought to the casting temperature, and the assembly is inverted to fill the mold. Source: Ref 2.

Bells and Guns

In general, large castings were made in sections that were then bolted or welded together or were cast on sequentially. However, neither bells nor guns function well if joined and so are cast in a single pour. Large bells have traditionally represented the limits of foundry capacity. The Great Bell in the Kremlin was cast in 1735 and weighs 175 Mg (193 tons). It is now cracked. The largest bell that still sounds is the Great Bell in Beijing. It was cast early in the Ming dynasty, about 1400, and weighs 42 Mg (46.5 tons). The alloy contains 15% Sn and 1% Pb. The loudness of this bell can reach 120 dB, and on a quiet evening it can be heard 20 km (12 miles) away.

According to Theophilus, in the 12th century bells were cast into clay molds made by the lost wax process using tallow instead of wax. The clay core had to be broken out before the metal cooled, or the bell would shrink tightly around the

core and crack. An iron staple to hold the clapper was placed in the mold and cast into the bell, a practice that caused many bells to crack when the iron rusted and expanded. Bell metal in Europe was a bronze usually containing 20 to 25% Sn, although bells in the Far East, which have a very different shape and sound, were cast with lower levels of tin. Recent research has indicated that the shape of the casting as well as its integrity has a much greater effect on the tone of a bell than its alloy, and in fact close attention was given the "bell scale," the correct proportions of a bell by both Theophilus and Biringuccio.

A reproduction of the Liberty Bell was recently cast by the same foundry that cast the original. The mold was made by the same cope and core method described by Biringuccio, who also described the welding of cracked bells. A clayey loam was shaped over bricks by a strickle rotating about the axis of the bell to shape the core, and another molding board was used to shape the cavity in the cope. The alloy, containing 23% Sn, was poured at 1100 °C (2010 °F). The mold took 16 min to fill. Traditionally, the pouring rate was controlled by the sound of the liquid metal in the mold. The bell, which weighs more than 4.5 Mg (5 tons), took a week to cool.

Although large bells are usually cast of bronze, other metals have been used. Bells were cast of white iron in China, Russia, and elsewhere. After Benjamin Huntsman's development of cast steel in 1740, bells of cast steel became a specialty of Sheffield, England.

Gun barrels have been made of many materials. Cannons, albeit small ones, exist that were made of laminated leather. Laminations of welded iron strip were used to make damascene gun barrels before these were routinely cast. Gunmetal was a bronze alloy containing 10% Sn, although additional tin was added late in the pour to make up for the effects of tin sweat. Biringuccio describes gun founding in 1540. Cannons were cast around a core to form the bore. Because of its size and weight, the core required elaborate reinforcement, and it was supported in the mold on iron chaplets. Later, in 1715, Johann Maritz in Burgdorf, Switzerland, developed the boring mill that made it possible to cast cannons solid. Because cannons were cast vertically, boring removed the shrinkage along the centerline of the casting, which led to increased reliability in service. The entire sequence from mold making to milling was recorded in detail in a set of 50 watercolor paintings made by an 18th century gun founder and are known as the Royal Brass Foundry Drawings.

Art Founding

Sculpture has been made of many different materials. The earliest known are the Paleolithic Venus figurines of bone and other materials. The earliest life-size statues are of plaster. They were excavated at Ain Ghazal in Jordan in 1985 and are dated to about 6500 B.C. Early metal sculpture, like the earliest metal objects, is of worked copper sheet. The oldest (and largest) metal statue from ancient Egypt is a life-size statue of Pharoah Pepi I of the Sixth Dynasty (about 2400 to 2200 B.C.). This statue was found at Hierakopolis and is now in Cairo. It was made in several sections and is part of a group that includes a smaller figure of the pharaoh's son. The metal is copper, but because of its highly mineralized condition, there remains some doubt as to whether it was wrought or cast. The copper relief from al'Ubaid, dating from about 2600 B.C., now in the British Museum, has figures of two stags whose tines were separately cast and attached. Statuary in the round from this site was made of wrought copper sheet over a bitumen core. Cast statuary of the late third millennium B.C. includes portrait busts such as the one of Sargon of Akkad now in Baghdad.

Classical Sculpture

Most surviving large classical sculpture is in stone, but a few of the life-size bronzes known to have been cast in antiquity have survived. Some have come to light as a result of excavation or underwater finds. Greek bronzes include the Charioteer of Delphi, the Poseidon of Artemision in Athens, and the youth attributed to Lysippos now in Los Angeles. Large sculptures were piece cast by lost wax and assembled by welding. The joints were skillfully hidden by, for example, placing them along folds in drapery (Fig. 10).

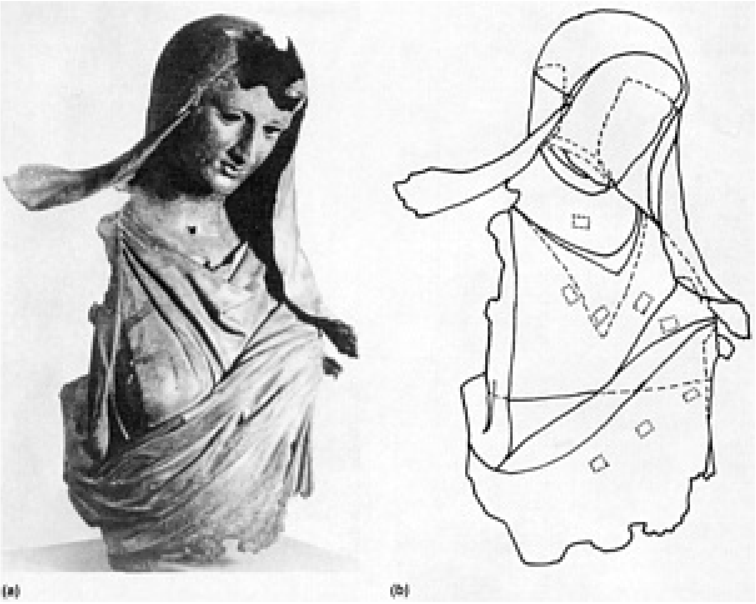

Fig. 10 Bronze statue (a), dated to the fourth century B.C., found off the coast of Turkey. Now in the museum at Izmir and known as the Lady From the Sea. (b) Assembly diagram for the precast pieces of the Lady From the Sea. Source: Ref 3.

Smaller classical statuettes, thought to have been intended as votive offerings, exist in large numbers. These figures were cast head down over a core, which is usually still intact. Occasionally the design called for an additional piece, such as an extended arm, to be joined. None of the molds has been found. Vessels that earlier had been wrought, such as ewers, were also cast, as were articles of households furniture such as tripods.

One use of cast metal in the art of classical antiquity that often goes unnoticed is the use of lead in building. Lead was a relatively plentiful by-product of silver smelting and refining. It was used to set the iron clamps and dowels holding the stone blocks in place, and it served to protect the stone from cracking under the pressure caused by the expansion of rusting iron. Lead was also cast as statuettes. Some classical statues were said to be cast in gold. These were more likely gilded.

Gilding

In addition to gilding by depletion, as in the case of tumbaga, gold was applied to the metal surface either as a foil or as an amalgam. Foil could be attached to the substrate in several ways. Various adhesives were used, including mercury, or the surface was given a texture so that the foil, when burnished, made a good mechanical bond with the substrate. Amalgam gilding is still being practiced (Fig. 11), although the risks of mercury poisoning have long been recognized. Experiments made while the famous Roman bronze horses from San Marco in Venice were being studied indicated that, to be successfully amalgam gilded, a bronze must be cast from an alloy low enough in tin so that the color of the metal is still coppery. Thus, a low tin analysis can be evidence that an ancient object now without gilding may have been gilded originally.

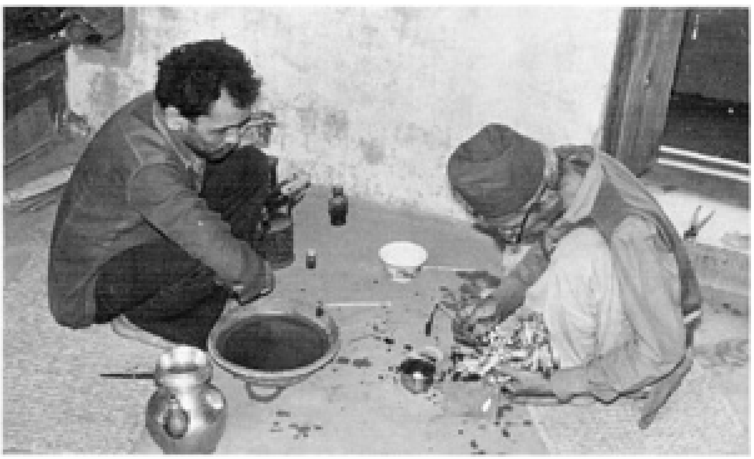

Fig. 11 Amalgam gilding in Patan, Nepal. The work, including heating of the amalgam to sublime the mercury, takes place in the open air on the roof of the workshop.

Colossal Statues

Cellini, in 1568, defined a colossal statue as one at least three times life size. The Colossus of Rhodes was a bronze statue that stood more than 30 m (100 ft) tall. Although filled with stone as ballast, it was destroyed in an earthquake in 224 B.C. The fragments remained where they fell until they were sold as scrap in 656 A.D. According to Pliny, other colossal statues were erected at Tarentum, Rome, and one at Appollonia that was later taken to Rome.

Japan boasts several *Diabutsu,* or Great Buddhas, in bronze. The Great Buddha at Nara, begun in the eighth century, is gilded and was therefore cast in a low-tin alloy. The Great Buddha at Kamakura (Fig. 12) was cast in the 13th century and contains 109 Mg (120 tons) of bronze, 18 Mg (20 tons) in the head alone. The alloy contains 9% Sn and 20% Pb. The statue was cast in place, with each section cast onto sections already in place (Fig. 13) using mechanically interlocking joints, a necessary precaution in an earthquake zone.

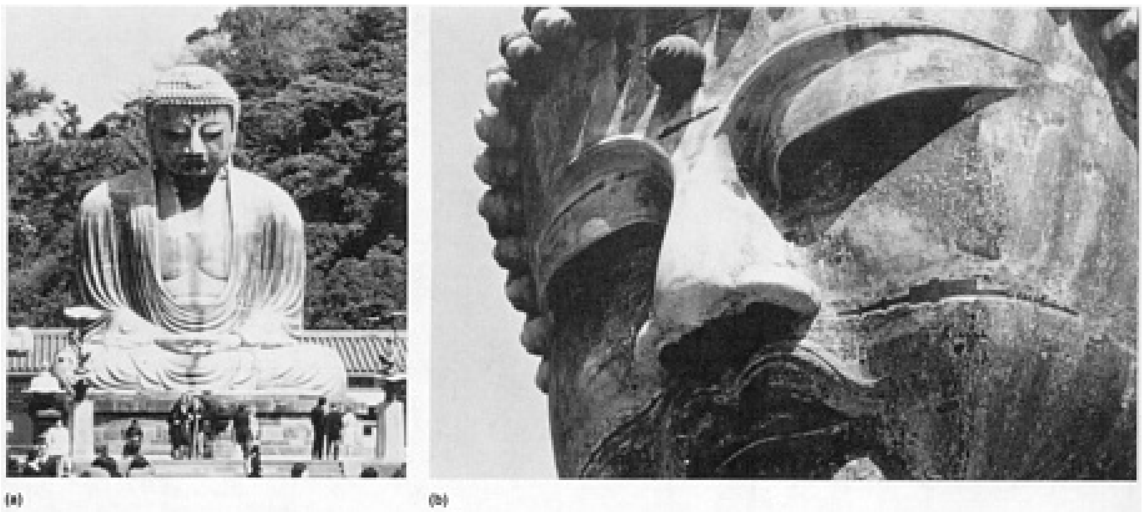

Fig. 12 Overall view (a) of the Great Buddha at Kamakura, Japan, cast in high-lead tin bronze in 1252. (b) View of the face of the Kamakura Buddha showing metal losses at the joints between separate casts.

Fig. 13 View of the interior of the Kamakura Buddha showing the interlocking joints between the casts.

Modern colossal statues of bronze are east in sections and bolted together. An example is the statue of William Penn atop the city hall in Philadelphia. Monuments very much larger than those of antiquity are wrought, net cast. Examples are the Statue of Liberty, which, like the earliest known metal object is of repoussé copper, and the Gateway Arch of St. Louis, which is of stainless steel.

Modern Statuary

With the Renaissance came a revival in bronze casting. Large single castings were attempted in lost wax. Cellini recommended the assistance of ordnance founders in casting them. Cellini also claimed a "secret" mold material of rotted rags in clay, although it is known that in the previous century pieces of cloth were added to the clay used for gun cores. Clearly, there was considerable exchange of techniques among the founding specialists despite the tradition of craft secrets. Sand for molding was newly introduced from a source near Paris, and "French sand" continued to be highly recommended into the 20th century.

The 19th century saw many technical innovations, including the electroplating of copper statues and architectural elements as large as domes. The electroplating of copper on less noble metals such as cast zinc or cast iron gave these metals the surface appearance of bronze. Cast zinc was referred to as white bronze, and zinc statuary for Civil War monuments, business emblems, and the like could be ordered relatively inexpensively from catalogs of standard designs. Aluminum was more expensive, costing about as much as silver until the Hall-Heroult refining process was invented. An aluminum casting, rather than stone, was used to cap the tip of the Washington Monument in 1884, and aluminum has been occasionally used since as a statuary material.

Traditional methods of art casting continue in the 20th century (Fig. 14), but the standard "three fives" statuary bronze alloy containing 5% each of Sn, Pb, and Zn, has been replaced for occupational health reasons by silicon bronzes. An interesting variation on lost wax casting uses standard foundry sand in place of the investment, and plastic foam in place of the wax. The method is called foam vaporization and has the advantage that the model remains in place when the metal is poured, vaporizing the foam. Post World War II alloys for art casting included stainless steel, although this was more often used as welded sheet, as were the weathering steels.

Introduction

THE ART OF IRON CASTING, as discussed in the article "History of Casting", was introduced to Europe from China, where iron castings were being produced as early as 600 B.C. Considerable progress took place in Europe from the time of this introduction in the 15th century to the 19th century. Virtually no foundry developments, however, can be found in the Americas before 1800, and the focus of this article will be the development of foundry technology in the United States.

Before the colonization of the Atlantic Seaboard of the United States and Canada by the English, Dutch, and French in the 16th and 17th centuries, castings were not produced in North America. The North American Indians had no knowledge of metallurgy. There is some evidence that the prehistoric mound builders who preceded the Indians may have worked with melted metals. The mounds located in what is now Ohio and the Mississippi Valley have yielded certain castings. Undoubtedly, the same methods were employed as those used by the prehistoric peoples of the Middle East. For all practical purposes, however, the New World was only beginning to emerge from the Stone Age when the first Europeans landed on these shores, bringing with them their knowledge of cast metals.

Early American Foundries

Records indicate that as a general rule, this hemisphere was explored for gold but colonized with iron. Iron first made its appearance as a result of a deliberate search by Sir Walter Raleigh, who advised of the presence of iron ore deposits on the Roanoake River in South Carolina. Samples were sent back to England, but no action was taken on the development of iron ore for nearly 40 years. In 1607, the first colony at Jamestown, Virginia, was established, and again iron ore samples were sent back to England for analysis. It was not until 1622 that there was an attempt to make use of this mineral. In that year, an iron blast furnace was established at Falling Creek, Virginia (near Richmond), with skilled melters and foundrymen from England. Unfortunately, this enterprise was completely wiped out by an Indian massacre before the furnace went into operation. Because there were no survivors, details of the project are missing.

The Saugus Iron Works

It fell to Massachusetts to have the honor in 1642, of becoming the birthplace of the first American casting. This original American foundry was established near Lynn, Massachusetts, on the Saugus River and has been referred to in history as the Saugus Iron Works. Some details of this operation provide a picture of the typical iron foundry of that period.

The founders of the enterprise were Thomas Dexter, the mechanic and builder, and Robert Bridges, the promoter of the project. It was Bridges who took the samples of Saugus area bog ore to England and obtained the necessary financial help

for starting operations. Thus was founded The Company of Undertakers for the Iron Works. The company in turn founded the small village of Hammersmith, so called because of the imported furnace and foundrymen from Hammersmith, England.

On October 14, 1642, the Saugus Iron Works was granted the exclusive right to make iron for 21 years, during which time it could freely mine or cut wood, dam streams, and set up furnaces. The Iron Works was also given public lands on which to operate tax free. The firm was allowed to sell and transport freely, and all employees were completely exempt from military duty. Members of the company could even refrain from attending church without losing their voting privileges.

With such a start, the Iron Works built a four-sided hollow stack 6 m (20 ft) high, 7.3 m (24 ft) square at its base, 2 m (6 ft) in diameter at its top, and 3 m (10 ft) in interior diameter. The blast was operated by a waterwheel. Because the wheel naturally could not function in freezing weather, no winter operations were possible. Bog ore dug from neighboring swamps was charged into the furnace, together with oyster shells for flux and charcoal for fuel. Capacity was estimated at 7.3 Mg (8 tons) of iron per week. It is interesting to note that the first metal of the new plant was made into a shaped casting. The company had retained Joseph Jenks as a master molder; he molded a cooking pot in a small mold buried in a hole in the ground. The resulting casting weighs about 1.4 kg (3 lb) and has an internal diameter of about 114 mm ($4 \frac{1}{2}$ in.). This Saugus pot casting has been preserved and is now the property of the city of Lynn, Massachusetts.

The Saugus Iron Works should be remembered on several historic scores. Jenks, the first molder, obtained the first patent granted in the colonies for his invention of the two-handed scythe, a tool that is still made in the same original shape. Jenks was also responsible for coining the first American money, the Pine Tree coinage of the Colony of Massachusetts. In addition, because of the interest of John Winthrop, Jr., son of the governor of Massachusetts, the first firefighting equipment for Boston was made in this plant in 1654. Although the Iron Works formed the start of an industry that would eventually number over 5000 plants, the company itself never achieved greatness. It failed in 1688 as a result of litigation, nuisance suits, and the reduction of timber resources, yet the Iron Works furnished an important beginning for the new colonies.

The Spread of Foundries

New England. From this early beginning, the direct-iron blast furnace foundry spread quickly. A second works was started at Braintree near Boston in 1645. In quick succession, plants were established at Taunton in 1653 and at Concord and Raleigh in 1657. By 1700, there were a dozen plants in eastern Massachusetts, including that of the Leonards at Raynham, and Massachusetts became the center of metalworking. Meanwhile, activity had spread to other states. John Winthrop, Jr., built Connecticut's first blast furnace foundry at New Haven. In 1658, Joseph Jenks, Jr., son of the first molder at the Saugus Iron Works, erected a plant in Pawtucket, Rhode Island. The plant burned down in 1675. Henry Leonard, who was from a noted foundry family, moved to New Jersey and established the industry in that state. Colonel Lewis Morris was also an early operator there and is said to have used the first cast iron cylinder compressed air blast in America.

Maryland and Virginia. In the southern part of Maryland and Virginia, no iron was produced for many years following the abortive attempt at Falling Creek, Virginia. However, in 1715, Virginia's governor, Colonel Alexander Spotswood, promoted iron foundry progress and established a furnace on the Rappahannock River at the junction of the Rapidan. Pig iron was hauled 24 km (15 miles) to Massaponax, where, by means of an air furnace, the metal was cast into firebacks, cooking utensils, andirons, and similar items. The quality of the iron produced by this remelt process surprised the British and is remarkable considering that the remelt process had only recently begun in France. Spotswood established another furnace at Fredericksville, Virginia in 1726, but his efforts never reached the limits of his planning. Of the iron furnaces that were constructed in the Delaware/Maryland/Virginia area (Fig. 1), one of the most interesting is the Principio Furnace and Forge because its founders included Augustine Washington, father of George Washington.

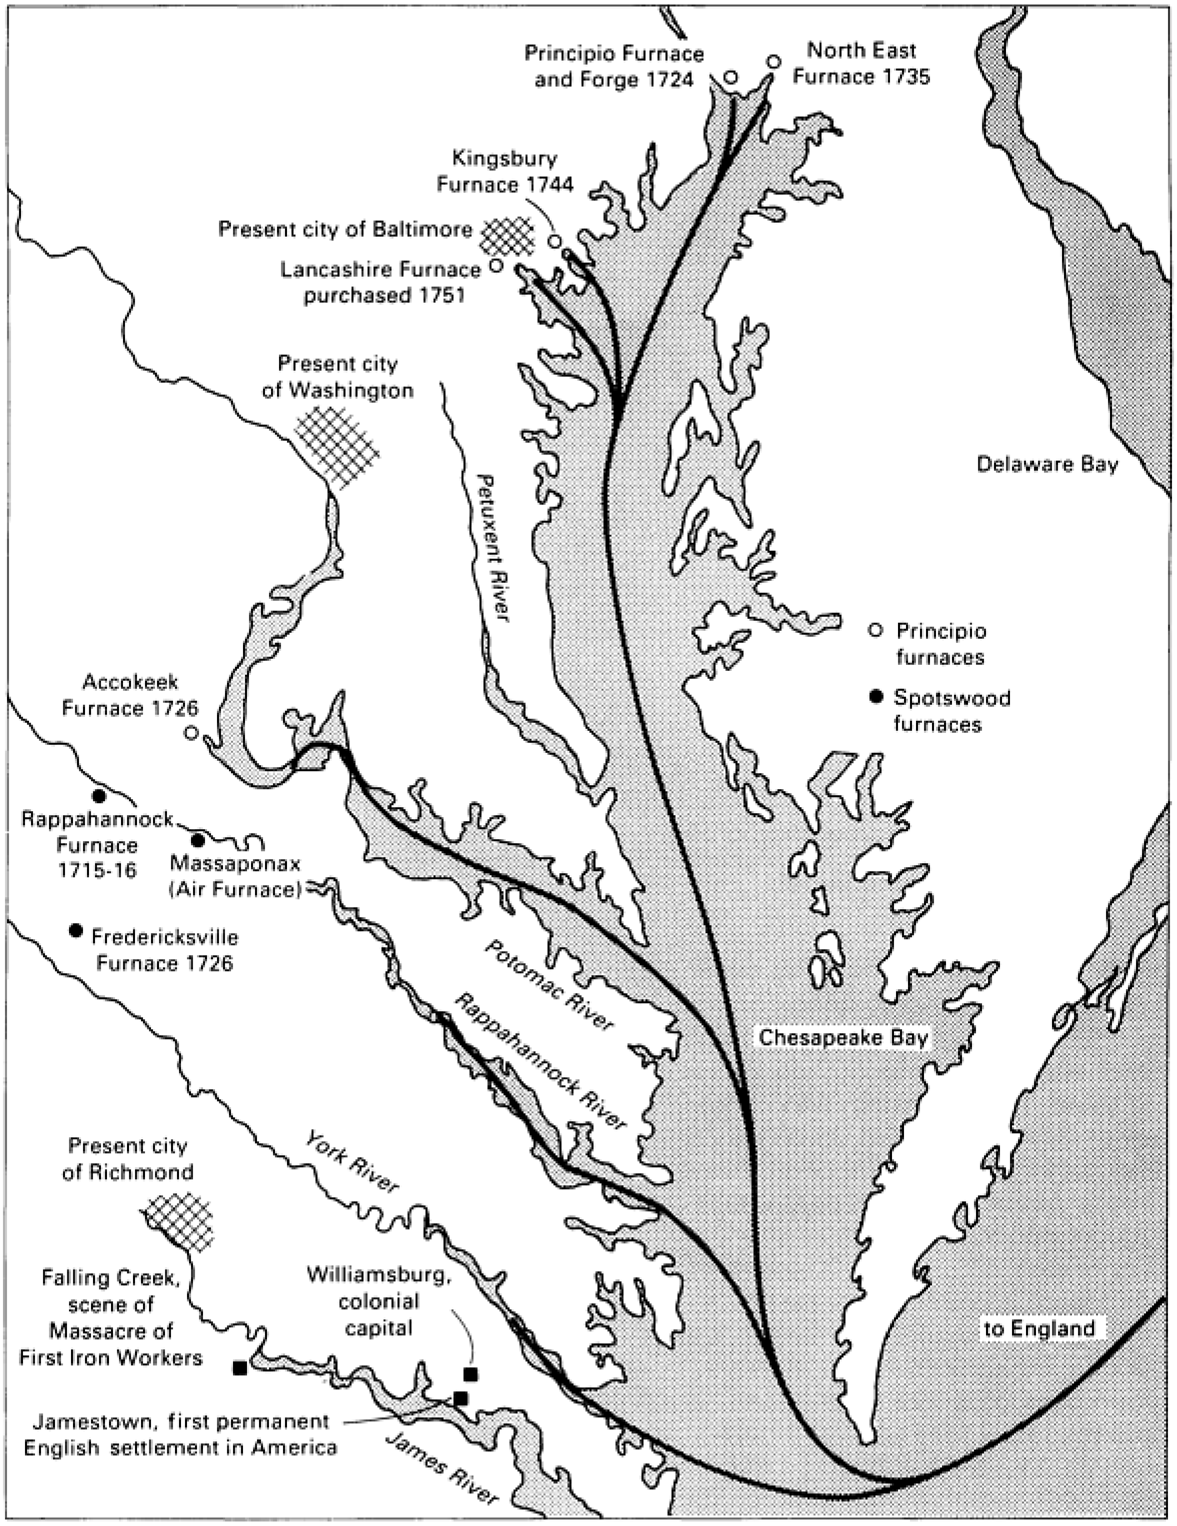

Fig. 1 Growth of iron furnaces in the Delaware, Maryland, Virginia area. Note the numerous Principio furnaces; George Washington's father, Augustine, was one of the founders of this company.

The Principio Company was to exist for 200 years. Augustine Washington built a furnace in 1724 at the head of the Chesapeake Bay in Maryland, and his company built a chain of plants in rapid succession in and around Baltimore and in northern Virginia. By 1750, Maryland had eight operating furnaces. This furnace expansion continued until 1754, and the company was successful for years as a commercial foundry and furnace enterprise. By this time, New Jersey and Pennsylvania had entered the race to produce the iron and other castings and these states were prominent metal producers by the middle of the 18th century.

The Union Furnace. One early New Jersey plant is particularly interesting in that it still exists as a foundry and traces its origin back to 1742. The Taylor-Wharton Iron and Steel Company of High Bridge, New Jersey, is the oldest foundry and probably the oldest industrial corporation of continuous existence in the United States. This plant had its beginnings in December 1742 when a foundry furnace was erected by William Allen and Joseph Turner under the name of the Union Furnace. Shortly afterward (in 1754), another furnace--the Amesbury Furnace--was built in the same area. In 1760, Robert Taylor became works manager of Union Furnace and subsequently took over the plant in 1780. During the revolutionary war, this furnace supplied the colonial troops with guns and shot. In 1860, the name of the plant was changed to Taylor and Lange. In 1868, it became the Taylor Iron Works and later the Taylor-Wharton Iron and Steel Company.

Pennsylvania was also moving rapidly to exploit its mineral resources. Again, iron became the predominant material because of the needs of the expanding frontier and because the inhabitants relied on iron castings to carve their homes out of the wilderness. Several ironworks in eastern Pennsylvania merit discussion. In 1742, Benjamin Franklin invented the Franklin stove; he obtained his castings from a foundry known as the Warwick Furnace, located near Warwick, Pennsylvania. This stove, an invention that was soon widely adopted, was made possible because of castings, and it increased cast metal tonnage. For example, in 1742, a furnace foundry known as the Mount Joy Forge was erected in Chester County, Pennsylvania, on Earl Valley Creek. The name was later changed to Valley Forge. This foundry, which was burned by the British in 1777, served as the encampment of the American army during the winter of 1777-1778. This furnace was later rebuilt, and important early experiments on steel castings were conducted there.

Iron Plantations. No history of the American foundry industry would be complete without a description of the iron plantations, great estates that existed principally in eastern Pennsylvania in the 18th century. Dozens of these semi-industrial and partly feudal facilities had been established by 1750. A typical enterprise was Hopewell Village near Birdsboro, Pennsylvania (Fig. 2). William Bird bought this tract of approximately 10,000 acres in 1743. In 1761, his son built the furnace and developed the plantation.

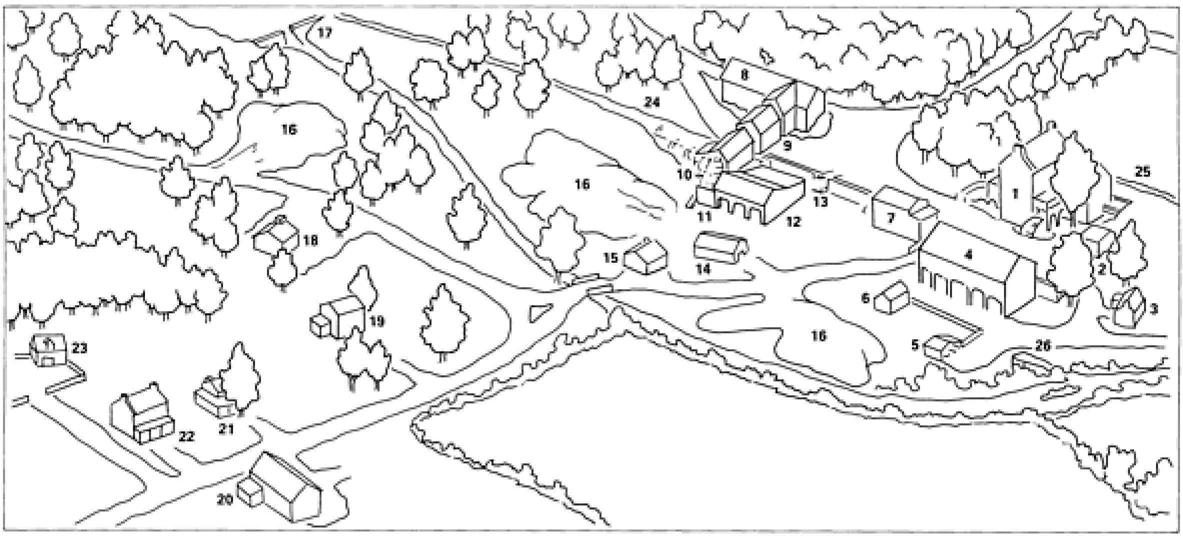

Fig. 2 Schematic of an 18th century iron plantation. 1, mansion house; 2, bakery; 3, spring house; 4, barn; 5, carriage house; 6, corn crib; 7, office; 8, charcoal storehouse; 9, furnace bridge; 10, mill wheel; 11, furnace; 12, casting house; 13, ore roaster; 14, wheelwright shop; 15, blacksmith shop; 16, slag; 17, dam; 18, schoolhouse; 19-22, tenant houses; 23, tenant barn; 24, west head race; 25, east head race; 26, tail race outlet.

At one time, nearly 1000 persons (including furnacemen, molders, miners, charcoal burners, wagonmen, and their families) lived there and derived their existence almost entirely from the production of pig iron and castings. The iron mine was located approximately $1\frac{1}{2}$ km (1 mile) from the furnace, and the ore was carted in. The furnace used charcoal in vast quantities, averaging around 1500 cords of wood a year. Most of the inhabitants were woodcutters and charcoal

burners, who prepared the charcoal in mounds in the forest. Iron and castings were sent to Philadelphia by boat or cart, but the inhabitants lived and worked on the plantation.

Westward Expansion. Toward the end of the 18th century, the furnaces and foundries of America began to move westward. The first ferrous foundry established west of the Alleghenies was built in Fayette County, Pennsylvania, in 1792 by William Turnbull. This foundry supplied guns and shot for General Wayne's expedition against the Indians. In the same year, the first plant in Pittsburgh was erected by George Anschultz, who made stove and grate castings. A furnace was also established at the same time on the Licking River in Bath County, Kentucky.

Far to the north, the first Canadian foundry had been installed years earlier, in 1730, at a location south of Three Rivers, Quebec. This foundry operated for 150 years.

Foundries and the Revolution. A final commentary on 18th century foundry operations in the United States concerns the connection between the foundry and the American Revolution. It is generally accepted that the stamp tax on tea and "taxation without representation" were the primary causes of the American Revolution. However, history reveals even more fundamental reasons that involve the casting of metals. In 1750, the English Parliament, envious of the growth of ironworking in the colonies, passed an act prohibiting the refining of pig iron or the casting of iron. This act also restricted the construction of any additional furnaces or forges. Pig iron could be made only if it was shipped to England, where a shortage of charcoal had seriously curtailed iron production. The act was openly resisted by early American foundrymen.

For the most part, the colonial founders joined the revolutionary cause and supported it with money, guns, and shot; other foundrymen supported it politically. Among the many foundrymen who fought in the Continental army as officers were Nathaniel Green (Rhode Island Furnace), who commanded at the Battle of Long Island; Ethan Allen (Connecticut Furnace), who commanded the Green Mountain Boys and forced the surrender of Fort Ticonderoga; and Lord Sterling (Sterling Iron Works), who served on General Washington's staff.

The production of war material was the principal task of the American foundries during the War for Independence. Many foundries made shot, shells, and cannons in great quantities, and it was through these efforts that supplies kept coming to Washington's troops. Frequently, these same founders remained unpaid. As always in time of war, foundries were military objectives, and the British directed their raids toward the destruction of the foundries. Undelivered cannons and shot were sometimes buried to keep them from falling into enemy hands in case the furnaces were captured.

During the Revolution, another figure appeared who is not usually associated with the casting of metals--Paul Revere. Before the Revolution, Revere had acquired experience in casting bronze and silver for bells and tableware and many iron articles. However, his primary metallurgical experience was obtained when he was assigned by the Continental government to work with Louis de Maresquelle (Louis Ansort), a French founder of exceptional ability. Ansort was able to soften iron by mixing metals, and he also introduced the completely bored, solid cast gun. Under this master founder, Paul Revere learned metallurgical techniques that later served him well in his further work on the malleability of copper.

After the war, Revere returned to his bell-and-fittings foundry in Boston. In an effort to improve the tonal quality of cast bells, Revere began to experiment with various coppers and copper alloys. His metallurgical success is well known today, and a company bearing his name is the direct descendant of Revere's original enterprise.

The Liberty Bell. No account of the relationship between bells and the American colonies would be complete without mention of the Liberty Bell, whose ringing in Philadelphia on July 4, 1776, announced the signing of the American Declaration of Independence. The Liberty Bell was cast by Thomas Lister of Whitechapel, London, to mark the 50th anniversary of the Commonwealth of Pennsylvania. The bell cracked twice during testing and was recast twice; its original tone has been considerably altered by the amount of copper added in the recasting. This bell casting weighs 943 kg (2080 lb) and is now preserved in Philadelphia, where it was originally hung.

The War of 1812

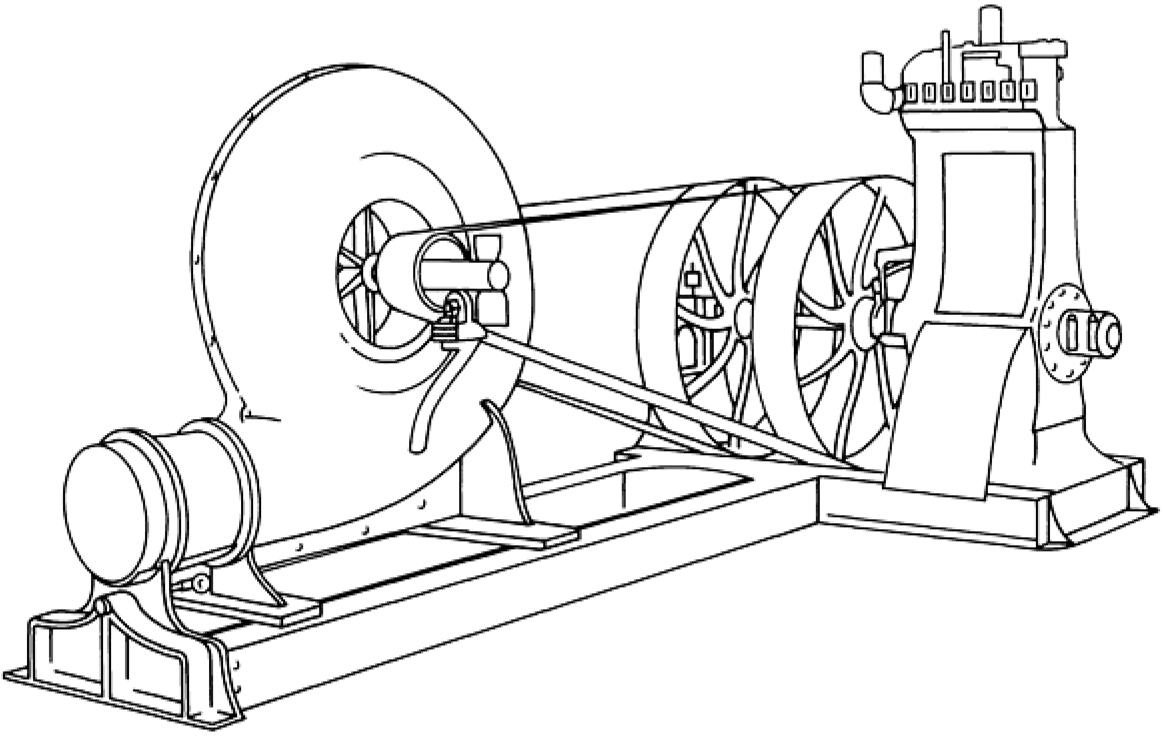
The War of 1812 also contributed to foundry history. During that conflict, Henry Foxall, a minister and foundryman, was making castings for the United States at Georgetown, Maryland. The British, after burning the White House in Washington, marched toward Georgetown to destroy the foundry, and Foxall vowed that if his foundry, were spared he would establish a new Methodist Church. A sudden electrical storm delayed the British and then prevented them from reaching the foundry. In 1815, Foxall built the Foundry Methodist Church in Washington, D.C.

Equipment Advances

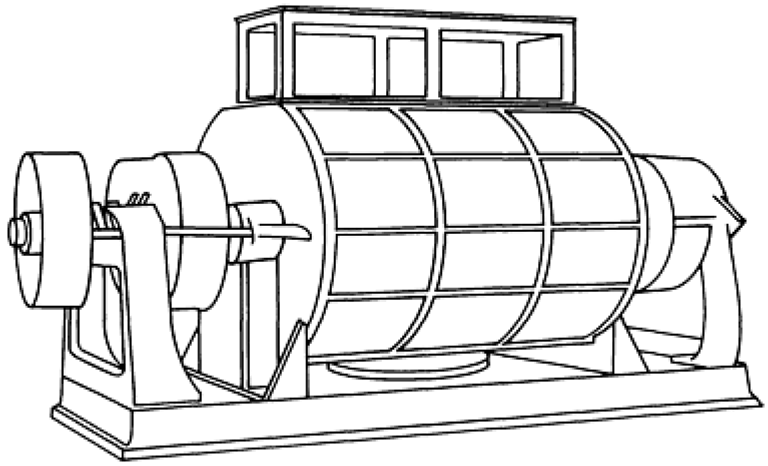
Continuous melting and furnace improvements over a period of approximately 80 years during the 19th century brought to foundrymen melting tools that were superior to any previously known. With efficient and economical melting equipment, the foundry industry was able to develop a metallurgical chemistry that, coupled with the art of casting, made it possible to produce high quality parts economically. The new furnaces introduced during the 19th century did not satisfy all of the needs of the industry, but fortunately other divisions of the foundry were also progressing rapidly. The new furnaces were soon complemented by better blowers, pouring devices, microscopic analysis of metals, molding equipment, mechanical chargers, and many other tools that are commonly accepted in modern foundry practice.

Metallography was developed by Henry Clifton Sorby of Sheffield, England, in 1863. Chemical analysis had been available before this time, but Sorby was the first to polish, etch, and microscopically examine metal surfaces for analysis. Sorby first became interested in and developed microscopy as an aid to the study of meteorites. His work on the surfaces of metals soon became much more important from an industrial point of view because it enabled practicing foundrymen to supply the missing element of knowledge and to supplement their rather sketchy experience with chemical analysis.

Blowers. Metals and melting were further aided by the development of blowers designed specifically to meet foundry needs. The steam engine and the water bellows had already proved to be of great benefit to the foundries because they permitted higher temperatures and shorter melting times. Mechanical blowers entered the foundry market as commercial devices sometime after the middle of the 19th century, although homemade equipment had preceded the standardized articles for many years. These blowers were of two types: the cyclone (for example, the sturtevant blower) and the Roots (a box-type blower). These are shown in Fig. 3. Both types are well known today.



(a)



(b)

Fig. 3 Two types of blowers developed for use in the foundry industry. (a) Cyclone type. (b) Box type.

Pouring Devices. Early in the development of pouring devices, numerous mechanical aids were invented that today are highly specialized and built with standard and interchangeable parts. The shanked ladle, adapted for use by two men, appeared later in the century. Still later came the one-man ladle equipped with wheels (Fig. 4). However, when it was realized that foundry flooring was not ideal for the smooth transportation of molten metal, foundrymen began to move their ladle overhead by crane or winch. As the demand for larger castings increased during the machine age, ladles of greater capacity were required, and this increased the hazards of metal pouring. Many accidents in foundries during the early 1800s were due to improper pouring devices.

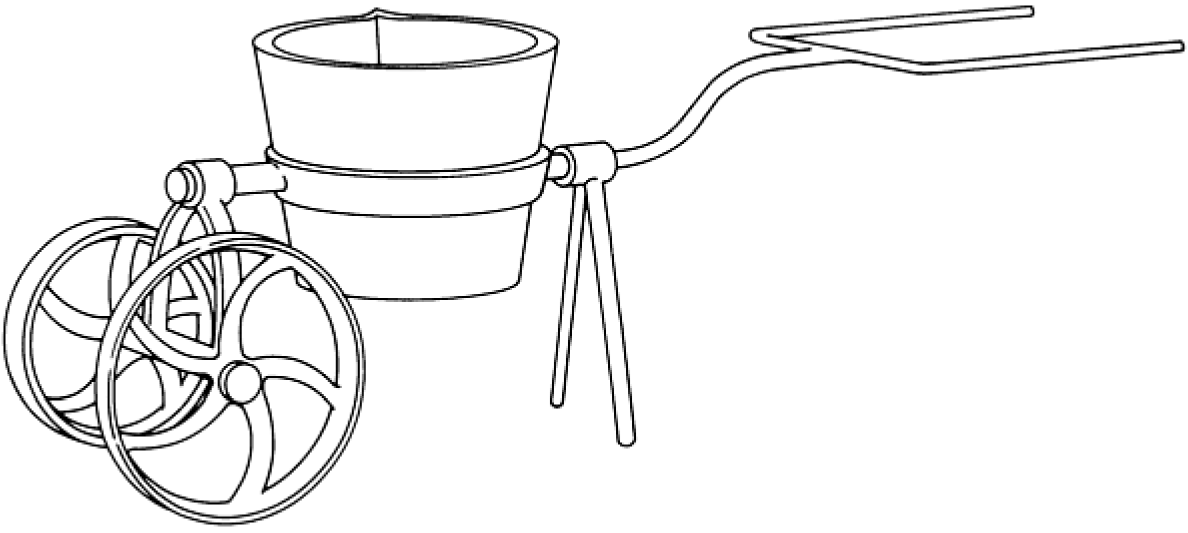


Fig. 4 Wheeled ladle for one-man operation used in the latter part of the 19th century.

In 1867, James Nasmythe, the inventor of the steam hammer, came forward with a ladle that undoubtedly prevented countless metal pouring accidents. He constructed a safety foundry ladle whose tilt was controlled by gearing (Fig. 5). On the basis of greater safety and economy, the foundry industry quickly adopted this device for pouring all sizes of castings.

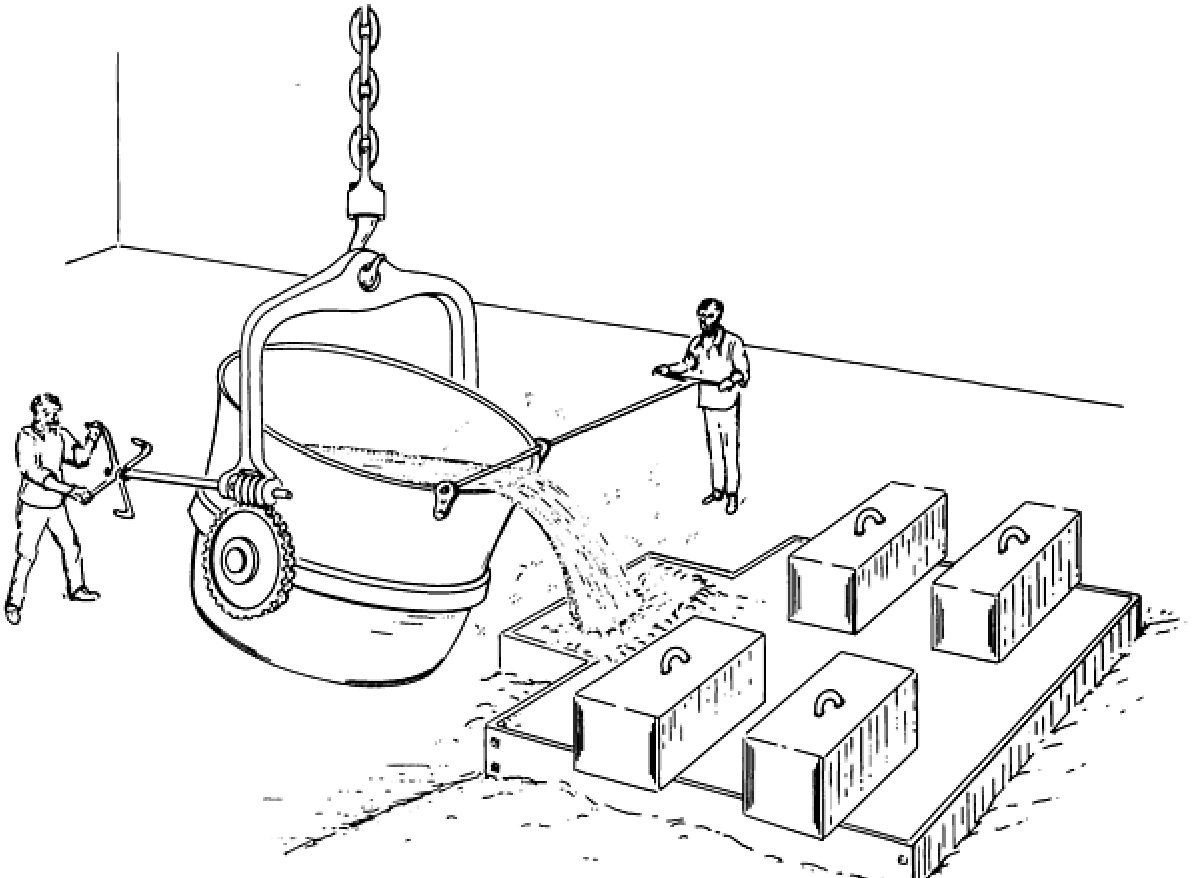

Fig. 5 Geared safety ladle as suggested by James Nasmythe in 1867.

Molding Machines. The most important development in foundry technology was the molding machine, without which the modern foundry would be incapable of its current large-scale production. Molding machines had been the foundryman's dream for centuries, but it was not until the 19th century that such equipment actually appeared. There is a record that an unknown Englishman developed a machine in 1800 for molding screws. In this device, the pattern was backed out of the sand by lead screws of the same pitch. However, in 1837, a dependable molding machine was finally placed on the market. This was a jarring type of machine that was first made and used by the S. Jarvis Adams Company, the forerunner of the Pittsburg Iron and Steel Foundries Company and later known as the Mackintosh-Hemphill Company. Although this machine was of rather crude design and was built for special work, it was successfully used in making a number of castings on one riser.

Molding machine designers subsequently created all manner of devices, many of which would be highly impractical today. But it was not until the 1880s that commercially viable equipment became available. These improved designs lightened the foundry task and enabled foundrymen to increase production, to produce more accurately and uniformly on a production basis, and to lower costs.

In 1896, nearly all molds were made from loose patterns and were molded by hand. The production of even one mold per hour was a laborious task. Molders used single loose patterns or gated patterns with a hard sand match. Molds were rammed by hand with sand-to-sand partings in flasks. The first high-production molding possibility came with the introduction of the drop machine, which was made for farm machinery. Sand was rammed by hand, but the half patterns (cope or drag) were drawn down through a contoured stripping plate. This the pattern without the aid of vibrators and made it easier to remove the mold with all the sand intact. The first machines functioned mechanically with levers and cams, but compressed air soon became the source of the jolt power.

The early squeezer machines were simple devices. The foundryman planted a vertical steel rail about 2 m (7 ft) long in the foundry floor. A cast iron table of convenient height was bolted to the rail, along with a squeeze head. The squeeze head was operated manually with a hand lever. The molds were not very hard, because of the tight (Albany) naturally bonded sands that were used. Millions of molds of stove plate were made in this manner. With the molder carefully pouring his own work, satisfactory castings were produced.

Another notable improvement in small casting work was the development of the match plate. First appearing in the literature in about 1910, match plates eliminated the hard sand match and the problems of sand-to-sand parting. Match plates, together with the air vibrator, made the jolt squeeze principle for small molds feasible. Snap flasks and steel bands were also introduced about this time.

Sandslingers. In 1914, Elmer Beardsley and Walter Piper operated a foundry in Klamath Falls, Oregon. They took a job that proved to be far beyond their capability to produce in the required time limit. They noticed, in hand molding, that when the molder had to lift out a pocket he always followed a set routine (riddle a small amount of sand into the pocket, place a nail or a gagger into the pocket, and then throw sand by the handful to fill the pocket). This was generally all the compacting required. Using this idea, they put boards into the headstock of a lathe, placed the mold beneath the lathe, and fed sand to the rotating headstock. The centrifugal force of the rotating headstock threw sand into the flask with enough force to be solidly compacted. The headstock had to be covered to direct the sand stream downward. This was the beginning of the well-known sandslinger.

The sandslinger found widespread success and is still being used in many foundries, especially large jobbing casting plants. The sandslinger is the first high-pressure molding device. Mold hardness can be readily varied, depending on the amount of sand fed into the head and the speed with which the slinger moves over the work. Sandslingers have been automated and hydraulically controlled to remove much of the manual effort required in their operation.

From 1896 to approximately 1955, air-operated molding machines improved continually. Larger squeezers, higher-capacity rollovers, and bigger jolt cylinders resulted in the molding of larger flasks and in higher production. A distinct improvement occurred when a squeeze was added to the jolt rollovers. Previously, jolt rollovers were topped off with an air rammer compacting the remaining sand, thus slowing production. More information on modern molding machines is available in the section "Green Sand Molding Equipment and Processing" in the article "Sand Processing" in this Volume.

Synthetic Sands. Since the beginnings of sand molding, the art of making metal using green sand depended on the skill of the molders. Molds were made strong and hard on the outside (near the flask edge) but soft in the middle, especially the drag surface. The art of venting a mold aided the production of good castings. Naturally bonded sands contained too many clay fines and water; thus, ramming had to be held to a minimum to produce reasonably accurate

castings. Synthetic sands (washed and dried silica sand to which binders such as fireclay and/or bentonite are added) appeared in the late 1920s. The use of these synthetic sands permitted molds to be produced in the green state (without being baked and dried). In the early days of using synthetic sands, the molds were still made to be hard on the outsides and quite soft in the middle. This difference in density imposed limitations on molding machines and a challenge to molding machine manufacturers.

The demand for more accurate castings led to the need for molds of uniform and higher density. Mold wall movement became a known defect of sand molds (and castings) in the 1940s and 1950s. Sand formulations continued to improve, and higher densities and mold hardnesses were available. Uniform mold hardness became a necessity for close, accurate two-pattern size castings. Because of the success of core blowers in the high production of cores, several attempts were made in 1940 to blow green sand molds, but the results were unsatisfactory. Later developments, which combined sand blowing with a hydraulic squeeze, achieved good results. More information on sand molding and foundry sands is available in the articles "Sand Molding" and "Aggregate Molding Materials" in this Volume.

Advances in Casting Alloys

At the turn of the 19th century, both in Europe and the Americas, foundry practice and foundry methods had vastly improved, yet the 19th century brought about dramatic improvements in metals, equipment, and processes. The full possibilities of iron became far better understood during this century, and gray iron was found to be the most versatile and diverse of all cast metals. As a result, the use of iron for castings was vastly increased, even though malleable iron, chilled iron, and finely cast steel were also tremendously advanced during this period.

The world was approaching the highly mechanized state in which we now find it, and the iron family and its older nonferrous relatives were destined to play vital roles in that mechanization. No modern luxuries and few modern essentials would be available today were it not for the foundry industry and the cast metals that the artisans, engineers, and inventors of the 19th century made usable and practicable.

Cupola Iron

The true birth of gray iron (a product of the cupola) and close chemical and metallurgical control were both 19th century developments. Gray iron is a true illustration of the chemistry of metals as applied to the science of casting and is described in detail in the article "Gray Iron" in this Volume. The developments that took place between 1810 and 1815 in the field of cast iron reveal this relationship. In 1810, French chemist Louis J. Broust, after extensive investigations, described cast iron as a solution of carbide of iron in iron. To modern metallurgists, this must seem extremely elemental, but when it is realized that few scientific data were available at this time, the work of the early chemists assumes its proper proportions. Also in 1810, Johns Jakob Berzelius, a Swedish chemist, produced ferrosilicon by melting silica, carbon, and iron fillings in a sealed crucible. In that same year, German physicist Wilhelm Stromeyer produced several grades of ferrosilicon in more exact experiments and proved that it was silicon and not silica in the metal.

In 1814, Karl Karsten, a German scientist and metallurgist, published the results of experiments proving that oxygen does not exist as an essential ingredient of cast iron, but that the different types of cast iron are due to the different forms of the carbon content. He then described two compounds of iron and carbon--one rich in carbon and poor in iron (graphite) and the other poor in carbon and rich in iron (white iron). Karsten was also one of the first to observe the effects of sulfur. His experiments showed that 0.05 to 0.25% S in iron made the metal hot short, while as little as 0.05% **P** made iron cold short. Although these researchers opened new vistas for foundrymen and metallurgists, in the final analysis it was the practical foundrymen who used this newly found information, which existed solely as pure research without practical application. Perhaps the greatest single step in this direction was the development of the cupola.

The Wilkinson cupola, which originated in England in 1794, was a great step forward, but mechanically it still fell far short of the efficient and economical melting units available to iron founders today. Records show that the early cupola had a stationary bottom with a front draw built on a stone foundation. The charge was carried up a flight of steps to the top or was thrown and shoveled from one landing or platform to another until it could be charged from the top. The shell of the cupola was generally made from castings, with an opening in front of sufficient size to permit the slag to be raked out with a hook. This cupola melted very slowly, and iron dripped out continuously into a reservoir in front, from which ladles were filled. To an experienced foundryman, this indicates the troubles the early melters encountered, yet they made quality castings.

In the United States, the cupola was introduced around 1815. In Baltimore, two of these early cupolas were still in operation in 1902. This melting unit, existing on scrap and pig iron, so widened the gap between smelting and melting that the foundry and reduction blast furnaces soon became completely separate. Merchant pig iron producers, relieved of the duties of casting metals, went on the achieve the highly specialized skill that today is theirs. Foundrymen, on the other hand, provided with a ready and reliable supply of scrap of pig iron, were able to control with greater certainty many of the variables that had proved uncontrollable.

In 1850, another important improvement was made in the cupola--the drop bottom--without which not efficient cupola could operate today. This innovation, so familiar to modern iron foundrymen, seems to have marked the beginning of modern cupola design; further developments occurred in rapid succession (see the article "Melting Furnaces: Cupolas" in this Volume). The stack was made smaller than the crucible and was built higher to aid draft. The blast was introduced from tuyeres on opposite sides of the cupola, and a melt could now be poured in about 10 h. Some 10 years after the introduction of the drop bottom, the one-piece cupola appeared, constructed of boiler plate casing in both crucible and stack. Then came the introduction of air by means of air chambers and blast tubes. Next the cupola designers eliminated the taper to provide the same diameter from top to bottom (Fig. 6).

Fig. 6 Straight-sided lined cupola introduced after the middle of the 19th century.

The first commercial cupola in the United States was the Colliau cupola, which was introduced in 1874. This cupola was prefabricated insofar as possible and was built primarily as a commercial product. It was highly successful, being a fast and economical melting unit. When first introduced, it presented a number of improvements, such as a hot blast, and double rows of tuyeres. After the Colliau cupola, the Whiting cupola was developed. It is still sold by the company bearing the name of its inventor, John H. Whiting. In the 1880s, Whiting developed a cupola that employed two rows of tuyeres, with the lower row arranged to form an annular air inlet that distributed the blast around the entire circumference of the furnace. The tuyeres could also be adjusted vertically for changes in classes of work, type of fuel, and cupola diameter. This cupola permitted the use of either coal or coke as a fuel and was equipped with a safety alarm and blast meter. The Whiting cupola, with its standardized construction, soon proved a boon to foundrymen and was widely accepted.

Connellsville Coke

The story of the cupola and cast iron in this period would not be complete without reference to the development of Connellsville coke. Coke was in general use in Europe in 1750, but because of the heavy timber resources of the United States, it was not produced here until 1817. From that time until 1860, American foundrymen generally made coke for their own use; after 1860, coke became a commercial product. Connellsville coke was first produced in 1841 at Connellsville, Pennsylvania, in beehive ovens. The product proved so popular that the demand for Connellsville coke remained high until 1914, when by product coke came into greater demand.

The use of coke and bituminous coal was made possible by the introduction of the hot-blast furnace in 1828 by James B. Neilson of Scotland. At first, the blast pipes ran through the furnace. The pipes were later run through a charcoal oven, and finally they were placed on top of the furnace itself. This device increased melting output from 10 to 40% so that by 1869 the production of coke and bituminous pig iron exceeded that of charcoal pig iron, and by 1875 the use of coke pig iron alone surpassed that of anthracite pig iron.

Chilled Iron

Another American development of the mid-19th century involved the introduction of chilled-iron railroad car wheels. Asa Whitney of Philadelphia obtained a basic patent in 1847 on a process for annealing chilled-iron car wheels cast with chilled tread and flange. They were satisfactory as long as cold-blast charcoal iron was used. However, trouble developed when melting practice changed from the use of anthracite coal to the hot blast.

In 1880, an attempt was made to introduce manganese for the production of chilled iron, but the resulting product did not possess adequate wear properties. Finally, a small amount of ferromanganese was introduced directly into the ladle with good results. Thus originated one of the basic products of the foundry industry--chilled car wheel iron. The excellent performance of this foundry product, as well as its wear resistance and economical properties, made possible the long-haul, heavier railroad freight loads of today.

Malleable Iron

No discussion of iron would be complete without mention of American blackheart malleable iron, as contrasted with European whiteheart malleable iron. Although credit for the progress and growth of the American malleable iron industry belongs to many, its origin lies with Seth Boyden of Newark, New Jersey.

Boyden's experiments, beginning in 1820, were primarily based on an attempt to duplicate the whiteheart European product developed by French scientist R.A.F. Réaumur. Boyden was endeavoring to lower the cost of harness hardware and wanted a strong iron that could be easily machined. Because of a larger percentage of silicon than was available in the Réaumur process, Boyden was able to produce the strength, but not the white color, of the European product. However, Boyden (either by design or accident) had shortened the annealing time to 6 or 10 days. This left free temper carbon graphitization as opposed to Réaumur's decarburization. Boyden first used a crucible and then an air furnace with a capacity of about 450 kg (1000 lb). His annealing furnace was a beehive unit into which pots loaded with castings were lowered through the top. The beehive was eventually replace with a continuous annealing furnace having a sloping floor. This unit was known as a shoving furnace because the pots and castings were shoved in from one end and out the other.

Boyden's work was important, but the most significant advances in the malleable iron field were made by the men who developed the malleable industry to its level of prominence in the foundry picture. More information on the manufacture and properties of malleable iron is available in the article "Malleable Iron" in this Volume.

Cast Steel

Next in the chronological sequence of casting developments is steel. For centuries, the goal of manufacturing steel castings in large quantities was pursued, but inadequate equipment was the limiting factor. In addition, steel was well known centuries earlier as the Damascus and Toledo sword blades of legendary fame, but this steel was forged from the pasty masses of iron produced in the Catalan forge. The first reliable record of steelmaking was the work of Huntsman in England in 1750. Huntsman's developments in crucible refractories (the crucible process) first produced steel that could be poured as a liquid.

Steel castings are also said to have been discovered by Jacob Mayer, Technical Director of the Bochumer Verein, Bochum, Germany, sometime before 1851. Records of the Bochumer Verein Company, which is still engaged in producing steel castings, indicate that cast steel church bells were produced in 1851. Some of these bells weighed as much as 15 Mg (17 tons). Cast steel guns were also made at the Krupp Works in Germany in 1847. In all probability, much smaller steel castings were made before the bells were cast, because it is difficult to believe that such large castings would be attempted without considerable previous experience. The steel church bell castings were displayed at various expositions throughout Europe and created quite a sensation because of their fine, clear tones and the fact that their selling price was about half that of the bronze bells formerly in general use. In a park outside of Bochum, one of the early steel church bells is enshrined as a marker of steel casting history. This bell even escaped the desperate need for scrap steel in Germany during World War II.

Steel produced by the crucible process remained expensive, and it was not until the converter, the open hearth furnace, and finally the electric arc furnace were introduced that steel was produced commercially in quantities that were economically feasible. The steel for these early castings, in addition to being made in crucible furnaces, was poured in loam molds. It was not until 1845 that steel castings (steel cast to final shape) appeared on the scene. On July 14 of that year, Swiss metallurgist Johann Conrad Fischer exhibited various small castings produced from crucible steel. On July 23, 1845, Fischer applied to the British Patent Office for priority rights to a new method of making horseshoes that consisted of casting steel in sand molds.

In the United States, cast steel was produced by the crucible process in 1818 at the Valley Forge Foundry, but difficulties resulting from the lack of adequate materials--principally refractories for crucibles--caused the experiment to be abandoned. In 1831-1832, high-quality clay from Cumberland, West Virginia, enabled William Garrard of Cincinnati, Ohio, to establish the first commercial crucible steel operation in this country. It is interesting to note that the first commercial steel castings from the Garrard plant sold for 18 to 25 cents per pound and were first used as blades and guards for the McCormick reaper.

The history of steel castings in the United States begins with the Buffalo Steel Company of Buffalo, New York (later known as the Pratt and Letchworth Company). The foundry was built in 1860, and in 1861 it produced the first crucible steel made in the district. Records indicate that these first crucible steel castings were for railroad applications. Some of the first commercial steel castings produced in the United States are believed to have been made by the William Butcher Steel Works (later the Midvale Company) near Philadelphia in July of 1867. These castings are said to have been crucible steel crossing frogs car wheels, probably for the Philadelphia and Reading Railway.

In 1870, William Hainsworth of Pittsburg began the manufacture of cast steel cutting parts for agricultural implements using a two-pot coke-fired crucible furnace. In 1871, Hainsworth founded the Pittsburg Steel Casting Company, which is reputed to have been the first company in the country devoted exclusively to the manufacture of steel castings. Some of the early steel foundries established in this country before 1890 are listed in Table 1.

Table 1 Partial listing of early steel foundries in the United States

Original	Location	Date of incorporation	Now known as
Buffalo Steel Co.	Buffalo, NY	1861	Discontinued operations

Wm. Butcher Steel Works	Nicetown, PA	July 1866	Discontinued operations
Pittsburgh Steel Casting Co.	Pittsburgh, PA	March 1871	Discontinued operations
Chester Steel Casting Co.	Chester, PA	1872	Discontinued operations
Otis Iron and Steel Co.	Cleveland, OH	*Circa* 1874	Discontinued operations
Isaac G. Johnson and Co.	Spuyten Duyvil, NY	*Circa* 1850[a]	Discontinued operations
Eureka Steel Castings Co.	Chester, PA	1877	Discontinued operations
Hainsworth Steel Co.	Pittsburgh, PA	*Circa* 1880	Discontinued operations
Old Fort Pitt Foundry	Pittsburgh, PA	*Circa* 1881	MacIntish-Hemphill Div., E.W. Bliss Co.
Solid Steel Casting Co.	Alliance, OH	August 1882	American Steel Foundries Alliance Works
Standard Steel Castings Co.	Thurlow, PA	*Circa* 1882	Discontinued operations
Johnson Steel Street Ry. Co.	Johnstown, PA	March 1883	Johnstown Corp.
Pacific Rolling Mills Co.	San Francisco, CA	1884	Discontinued operations
S.G. Flagg and Co.	Philadelphia, PA	1882-1885	Discontinued operations
Cowing Steel Castings Co.	Cleveland, OH	1882-1885	Discontinued operations
Sharon Steel Casting Co.	Sharon, PA	February 1887	Discontinued operations

(a) Began making steel castings in 1880

William Kelly, whose invention of the converter clearly anticipated the work of Sir Henry Bessemer (although the latter gave his name to the unit), first operated his converter in 1851, a full 5 years before Bessemer's patent was obtained. Neither man realized that his efforts were being paralleled by the other, but it has been well established that Kelly was the first to use the converter.

Kelly developed his idea out of experiments on the refining of pig iron as a result of his inability to obtain high-quality ore at his works in Eddyville, Kentucky. His theory was that the iron in ore is not metallic but a chemical compound of oxygen and iron. He came to the conclusion that, after the metal was melted, additional fuel would not be required but that the heat generated by the union of the oxygen in air with the carbon in the metal would be sufficient to decarburize the iron. Kelly's associates, fearing for his sanity, sent him to a doctor for treatment, with the result that the doctor agreed to back Kelly in his venture. In 1851, he was able to produce a rather soft steel, but had difficulty with high carbon. In the meantime, in England, Sir Henry Bessemer was working along almost identical lines. However, he had metallurgical

assistance. Robert Mushet of England developed an alloy of iron, carbon, and manganese that purified the metal and ensured the presence of enough carbon to make steel. Although Bessemer obtained American patents, Kelly proved his patent priority in 1857, and in 1866 Kelly and Bessemer joined forces.

A Kelly converter was first used in 1857-1858 at the Cambria Works at Johnstown, Pennsylvania. Later, Kelly obtained the rights to use Mushet's patent. Bessemer's first converter in the United States was installed at Troy, New York, in 1865. This converter was introduced into foundries and was further improved in 1891 by the Tropenas converter (Fig. 7), which blew over the surface of the metal rather than through it. The lower-pressure blast and resultant deeper metal bath produced better results.

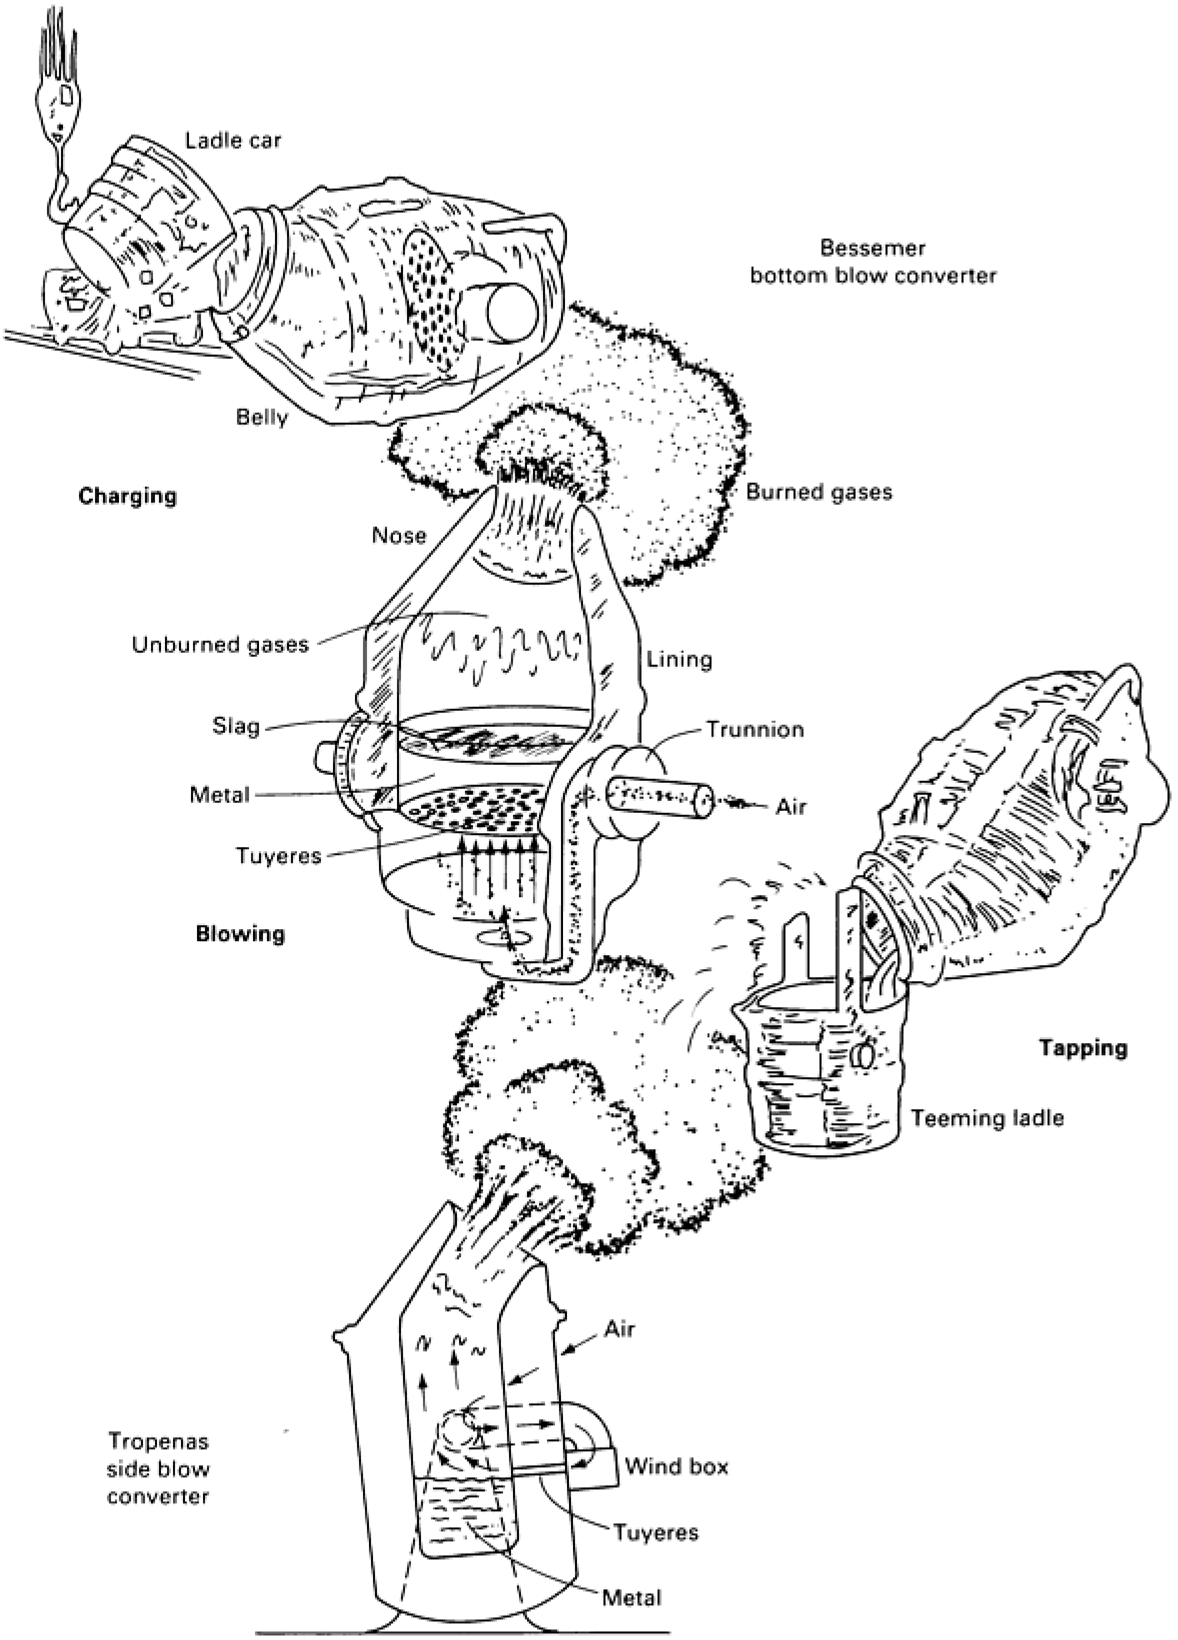

Fig. 7 The Bessemer and Tropenas converters.

The converter had scarcely gained acceptance when another furnace came into use and gave the steel industry the capacity it required. This was the Siemens-Martin open hearth, a development dating back to 1845, plus the succeeding experiments of J.M. Heath. However, this unit did not become successful until the great heat of the open hearth

regenerative furnace could be supplied to it. This became possible in 1857 as a result of the invention of the gas producer, which was patented that year.

Because of its high initial cost, the first open hearth furnace was not installed in the United States until 1870. However, with its tremendous capacity, it soon surpassed the converter in tonnage until it was in turn challenged by the electric are furnace.

The electric arc furnace (Fig. 8) was invented by Sir William Siemens, who developed an electric arc in 1878. However, it was little used until improved by Girod, Heroult, Keller, and others in 1895. An electric arc furnace was first installed in the United States in 1906 at the Holcomb Steel Company (later the Crucible Steel Company) at Syracuse, New York.

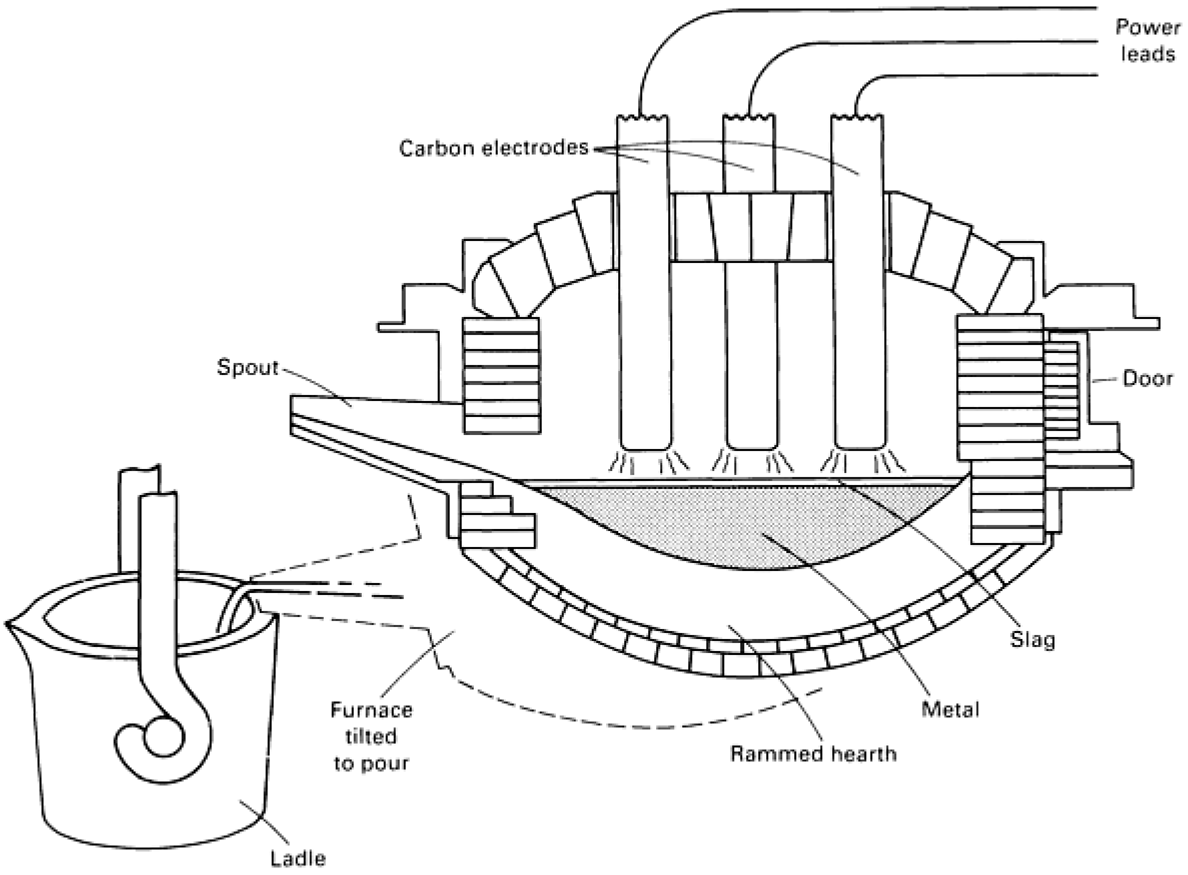

Fig. 8 Cross section of an electric arc furnace.

Induction electric furnaces were not introduced from Sweden until 1930, and many of the American developments of this furnace were made by Dr. E.F. Northrup and Dr. G.H. Clamer of the Ajax Metal Company, Philadelphia, Pennsylvania. Information on electric arc and induction furnaces is available in the articles "Melting Furnaces: Electric Arc Furnaces" and "Melting Furnaces: Induction Furnaces" in this Volume.

Cast Alloy Steels. In 1888, the first manganese cast steel was made in the United States at the Taylor-Wharton Iron & Steel Company in High Bridge, New Jersey, under license from Robert Hadfield of England. This was also the first cast alloy steel to be produced in America, and it was used for railway crossings and switch frogs. In 1903, A.L. Marsh, an American, made an alloy of 80% Ni and 20% Cr. He was studying alloys for use as thermocouples, and he observed that this alloy had high electrical resistance and could sustain operation for extended periods at high temperature without excessive oxidation--an ideal combination for electric heating elements. This and similar high nickel-chromium alloys later became the standard for electrically heated equipment and appliances.

Before World War I, E. Maurer and B. Strauss in Germany and H. Brearley in England were considering the alloys of iron with chromium and nickel for use as pyrometer tubes and gun barrels. They noted resistance to etchants by certain

compositions and realized the potential utility of such steels as stainless or rust-free in corrosive environments. By 1912, the German firm of Krupp had obtained patents on a martensitic, hardenable 14% Cr alloy and on an austenitic, nonhardenable 20Cr-7Ni alloy, which they called VM and VA, respectively. By 1916, Brearley had received patents in the United States and Great Britain on cutlery made from hardenable steels containing 9 to 16% Cr with 0.70% max C. Thus, the major classes of heat-resistant and corrosion-resistant alloys were all discovered and patented from 1905 to 1915.

The use of these materials in castings for industrial applications awaited the next decade. During World War I, urgent demands for expanded production from the infant automobile and aviation industries created the need for improved heat-treating procedures. In 1916, a patent was issued on the use of high nickel-chromium-iron electrical resistance alloys in cast carburizing boxes. These were supplied at first by foundries set up by the producers of the electrical resistance wire, and later by independent foundries formed to specialize in heat-resistant castings. At the same time, the increased output of the munitions and synthetic dye industries was making the corrosion resistance of the iron-chromium alloys attractive for handling strong oxidizers, such as nitric acid. As a result, the foundries that were making pumps and valves in carbon steel were asked to make these parts in rustless iron and stainless steel. With the end of the war and the industrial expansion that followed, the demand for both heat- and corrosion-resistant castings increased substantially.

The growth of high-alloy casting consumption has been stimulated by the continuing research objective of providing users with the materials and data needed to solve process design problems. Since 1930, there has been considerable development of new alloys and refinement of old ones as detailed in the articles found in the sections on ferrous casting alloys and nonferrous casting alloys in this volume.

Foundry Mechanization

With gray iron, malleable iron, and steel added to the foundrymen's metals for casting to shape, it follows that equipment and methods for the rapidly growing castings industry were also being given increasing attention. Molding, coremaking, sand preparation and conditioning, and metals and materials handling methods also progressed during the 1800s.

To complete the story of the development of the art and science of casting, it is only logical to trace the early progress of the tremendous mechanization of the industry. Actually, sand casting is a relatively recent development (in terms of the antiquity of casting technology), and it occupies an indispensible place in the industry. As with the development of the molding machine, foundrymen soon realized that a mixed molding material was essential. With the use of loam, the early machines for the treatment and preparation of sands aimed at compounding or grinding rather than mixing and mulling. Early in the 1870s, machines began to appear that were essentially paddle mixers. In the 1890s and early 1900s, manufacturers began to adapt equipment used by the ceramic industry. In 1912, the first muller, with individually mounted revolving mullers of varying weights, was placed on the market. Since that time, mullers that effectively coat the sand grains have been successfully used in the preparation of sand for both cores and molds.

This same period saw the first steps taken toward the development of sand screening machinery, which eventually resulted in the riddle, the magnetic separator, and the complete sand preparation plant. Mold-conveying methods, introduced about 1890, originally involved a continuous series of moving cars that looped at a steady speed from molder to pouring station and then to cool and shakeout.

Core manufacture was also standardized and equipment made available for mass production in American foundries. Long rooms filled with workers producing cores could be seen as early as 1888. All cores were racked and dried in kilns and then placed on racks to be carried to the foundry. The importance of core production soon sparked the development of baking ovens specially adapted for foundry use so that cores of different types could be baked for longer or shorter times as required. An early developer of the foundry core oven was Eli Millett in 1887. Today, coremaking, like sand molding and conveying, is a complex and highly specialized division of every foundry (see the article "Coremaking" in this Volume).

Early credit for the tumbling mill must be given to the W.W. Sly Company of Cleveland, Ohio. The Sly cleaning machine was a boon to foundrymen because it enabled them to offer their customers a finished product. In addition to tumbling mills for small castings, the sand blast was developed for larger work by R.E. Tilghman of Philadelphia, Pennsylvania, in 1870 (see the article "Blast Cleaning of Castings" in this Volume). The use of such equipment did not begin to broaden, however, until about 1900, when it was installed at the Logan Manufacturing Company at Phoenixville, Pennsylvania. Of the rapid improvements made since then by equipment firms, mention should be made of the American Foundry Equipment Company (now the Wheelabrator-Frye Company of Mishawaka, Indiana, and the Pangborn Corporation of

Hagerstown, Maryland), whose constant innovations and engineering technology, have added much to the ease and efficiency with which foundries handle many cleaning room operation.

In the 19th century, it was common for the pouring ladle to be hoisted by a jib crane located beside the furnace. The molds, arranged in a semicircle, were poured by swinging the crane from mold to mold. Modern overhead cranes have revolutionized the handling of the molten steel. Geared safety ladles (Fig. 5) were designed and built by James Nasmythe in 1867. Prior to this, bull ladles were tipped by a number of men applying leverage on large horizontal arms. Hand-shanked ladles made their appearance about the same time as the geared tilt ladles.

In the final quarter of the 19th century, industrial growth in the United States exceeded all previous experience. The mass production of machines, the new consumerism, the proliferation of steel-framed buildings, and the spread of electric power and telegraph networks all created an appetite for metals and in turn placed increasing demands on the casting industry.

The 20th Century

The 20th century began without any indication of the dramatic changes that computers and automation would bring about by the 1960s. The changes in equipment and methods would be quite obvious. As the 20th century began, the average U.S. foundry poured more tonnage than was cast throughout the world when the Nation was born. Despite so striking a transformation in the industry, man was called upon to expend far less energy. With minimal physical effort, workers produced increasingly sophisticated shapes in less time for increasingly intricate machines. As automation took over, production rates climbed until one automated foundry in the automotive field in 1967 was able to established a consistent production figure of 6 man-hours per ton of castings. Machines replaced the labor of man and horse, and with the sudden impetus given metal manufacturing in World War I, machinery became a necessity. Without cast metal parts, the machine age could never have existed.

The metal casting industry adopted automation and did so rapidly. Characteristically, the first fully automated plant in the United States (one of the first in the world) was a Rockford, Illinois, foundry that cast hand grenades for the U.S. Army in 1918.

The history of metal casting shows that the foundryman is as eager as any manufacturer to take full advantage of inventions and even to inspire them. America's first commercial metal caster, Joseph Jenks, was awarded the first patent in America. Thomas Edison called Seth Boyden one of America's greatest inventors, for Boyden established two basic industries in America--patent leather and malleable iron. In 1851, James Bogardus's factory in Chicago, which was constructed with cast iron supports, opened the way for what many art historians considered to be America's only original contribution to the arts of the world--the skyscraper.

By 1960, less than 1% of the foundries in operation were a century old. The trend continued as huge conglomerates entered the picture. American metal casting was big business. After a walking tour, Walt Whitman described the Nation: "Colossal foundry, flaming fires, melted metal, pounding trip hammers, surging crowds of workmen shifting from point to point, waste and extravagance of material, mighty castings; such is a symbol of America."

In the first year of the new century, foundries in the United States poured more open hearth steel than those in the United Kingdom--almost as much as the rest of the world combined. As far back as 1864, the military foundry at Old Fort Pitt (Pittsburgh) had cast a 510 mm (20 in.) smooth-bore Rodman cannon weighing 52 Mg (115,000 lb). This was a hundred times bigger than the famed Urban Gun of Muhammad II that was used to fell the walls of Constantinople in 1453. Three years later, the Krupp plant in Essen, Germany, poured a 45 Mg (50 ton) cast steel cannon, and the fate of the French army in the War of 1870 was sealed.

Casting Markets. The largest consumer of metal castings, however, was not the military but the automobile industry, which in 10 years provided a greater incentive to metal casting than cannons, bells, and the steam engine had in a century and a half. Approximately 25% of all castings produced in this century have been component parts for automobiles, trucks, and tractors.

In 1924, Henry Ford made 1 million automobiles in 132 working days. Casting knowledge and the world's first mass production concept were vital to this phenomenal production increase. Automobile output in the first 10 years of the 20th century increased 3500%, with a corresponding increase in demand for castings. The mass production of trucks, tractors,

and other mechanized farm and industrial equipment also heightened the demand for castings. This was followed in rapid succession by parts for such mushrooming industries as refrigeration (1930s); aviation (1940s); air conditioning (1950s); and data processing, electronics, and aerospace technology (1960s). Cast metals played a vital role in each. Major markets for castings are reviewed in the following article "Casting Advantages, Applications, and Market Size" in this Volume.

Foundry Organizations. Metallurgy began to achieve prominence in 1889 when nickel was alloyed to make a stronger steel. Although the science of metallurgy is now recognized as the basis of sound metal casting technology, in the beginning it was welcomed only by the more advanced foundry owners interested in the continuing benefits to be achieved by accepting a new technology. A group of these enterprising foundry owners arranged to form a number of industry-sponsored organizations dedicated to metal science and research and development, which, its leading members realized, could be turned to commercial advantage.

The American Foundrymen's Association (since 1948, the American Foundrymen's Society) was formed in 1896 out of the Foundrymen's Association of Philadelphia, itself only 3 years old. The New England Foundrymen's Association was formed that same year, and 1 year later the American Malleable Casting Association (changed 30 years later to the Malleable Iron Research Institute and in 1934 to the Malleable Founder's Society) was formed. In 1900, the Carnegie Research Scholarships of the Iron and Steel Institute were founded, followed by the Steel Founders' Society of America in 1902. The Foundry Equipment Manufacturers' Association (now the Casting Industry Supplier's Association) was founded in 1918, and the Gray Iron Institute was founded in 1928. Other casting associations included the American Die Casting Institute (1929), the Alloy Casting Institute (1940), the Nonferrous Founders' Society (1943), and the Foundry Educational Foundation and National Castings Council (1947). The Investment Casting Institute was founded in 1953, the Society of Die Casting Engineers in 1954, and the Ductile Iron Society in 1959. The goal of worldwide cooperation in metal casting prompted the formation in 1923 of the International Committee of Foundry Technical Associations (ICFTA, Zurich, Switzerland), which strives through 24 nations and an annual International Foundry Congress to exchange technical data.

Permanent Mold Processes. Developments in molding logically included the use of permanent molds, although the permanent mold preceded the loam mold and the sand mold by centuries. Subsequent types of permanent molds gradually appeared, but for many years they were limited in application by the metal available. Permanent molding can be defined simply as the pouring of liquid metal into a preheated metallic mold. As described in the article "Classification of Processes and Flow Charts of Foundry Operations" in this Volume, currently used permanent mold casting methods include die casting (high-pressure, low-pressure, and gravity), centrifugal casting (vertical and horizontal), and hybrid processes such as squeeze casting and semisolid metal casting.

The centrifugal casting process, which involves the pouring of molten metal into a rapidly rotating metallic mold, was developed by A.G. Eckhardt of Soho, England, in 1809. The method was soon adopted by the pipe foundries and was first used in Baltimore, Maryland, in 1848. Sir Henry Bessemer, famed for his converter, used centrifugal casting to remove gases and was the first to pour two or more metals into a single rotating mold. The centrifugal casting of steel was first attempted in 1898 at the plant of the American Steel Foundries in St. Louis, Missouri. Railroad car wheels were spun cast in 1901 at a rotation speed of 620 rpm.

Slush Casting. Following the early development of the centrifugal method, a permanent mold method known as slush casting was introduced. Slush casting is a process in which molten metal is poured into a split metal mold (generally made of bronze) until the mold is filled; then, immediately, the mold is inverted and the metal that is still liquid is allowed to run out. The time required for this casting operation is sufficient to freeze a metal shell in the mold, corresponding to the shape of the cavity wall. The thickness of the wall of the casting depends on the time interval between the filling and the inverting of the mold, as well as on the chemical and physical properties of the alloy and the temperature and composition of the mold. Usually lead and zinc alloy castings are produced by slush casting. The process is limited to the production of hollow castings (lamp bases are the principal product). More detailed information on slush casting can be found in Volume 5 of the 8th Edition of *Metals Handbook.*

Aluminum, the most abundant metal in the earth's crust, was a development of this century. Isolated in 1825, it derives its name from the Latin *alumen,* meaning bitterness. Aluminum was first exhibited in 1855, but for many years was so difficult to obtain that it was more costly than gold. In 1888, the Pittsburgh Reduction Company offered the metal in half-ton lots for $2 a pound and had difficulty attracting buyers and users until one manufacturer discovered it made good, inexpensive tea kettles. Within 5 years, the price decreased to 62 cents a pound, and by 1900 it was down to 32 cents per pound. In 1890, only 28,000 kg (62,000 lb) of aluminum was produced in the United States. Production was low until World War II, but by 1963, $635,934,000 worth of aluminum castings were shipped in the United States. In 1963, this industry, undreamed of in 1900, employed 35,970 people in 951 plants with a payroll of $221,567,000. In the first 7

months of 1968 alone, more than 412,000 Mg (450 tons) of aluminum were cast in the United States. The article "Aluminum and Aluminum Alloys" in this Volume contains more information on the processing and applications of aluminum alloys.

Magnesium. The development of magnesium as a casting metal parallels the history of aluminum (see the article "Magnesium and Magnesium Alloys" in this Volume). During World War I, magnesium sold in the United States for $5 a pound, and by 1935 only 170 Mg (375,000 lb) had been cast. By 1944, however, the industry was producing more than 39,000 Mg (43 tons) a year, a good portion of which was cast.

Die Casting. Manually operated casting machines were patented as early as 1849 (Sturgiss) and 1852 (Barr) in an effort to satisfy the insatiable demands of a growing reading public by way of rapidly cast lead type. These early inventions led to Ottmar Mergenthaler's Linotype, an automatic casting machine in which molten lead is forced by piston stroke into a metal mold. The first die casting machine bearing the Linotype name was patented in 1905 by H.H. Doehler. Two years later came E.B. Wagner's casting machine, a prototype of the now familiar hot chamber die casting machine. It was first used on a large scale during World War I for binocular and gas mask parts. Zinc alloys were used for die casting as early as 1907, but were not competitive until Price & Anderson developed the Zamak die casting alloy in 1929. Additional information on die casting machines can be found in the article "Die Casting" in this Volume.

Investment (lost wax) casting, one of the oldest casting techniques, was rediscovered in 1897 by B.F. Philbrook of Iowa, who used it to cast dental inlays. Industry paid little attention to this sophisticated process until the urgent military demands of World War I overtaxed the machine tool industry. Shortcuts were then needed to provide finished tools and precision parts, avoiding time-consuming machining, welding, and assembly.

Molding Sands and Equipment. The 20th century saw the refinement of processes and materials used in the foundry for over 400 years. Until the 1920s, sand testing consisted of squeezing a handful of sand to judge its ability to compact and stick together. Early in that period, a sand research committee of the American Foundrymen's Society began to develop sand test methods. By 1924, standards were established that covered the various properties of molding sands. A better understanding of molding sand technology has resulted in sands of a higher degree of uniformity being prepared for the repetitive green sand (clay-bonded) molding sand. This high degree of achievement could only be possible with the great advances in sand testing produced by the foremost researchers and developers of sand testing instrumentation. The current understanding of the fundamentals of clay mineralogy, sand preparation, sand compaction, and the physical properties of molding and core sands all contribute to the success of the modern foundry industry.

Ductile Irons and Austempered Ductile Irons. Continuing technological advances that seek to fulfill the need for materials capable of providing greater thermal, chemical, and mechanical properties have brought forth the development of new alloys and properties never believed possible. During World War II, the inoculation of gray iron became common practice, because high-quality cast irons replaced the scarcer steel in many castings. Shortly after the war, a new type of iron, variously known as spheroidal graphite cast iron, nodular iron, and (more universally) ductile iron, was patented and announced by the International Nickel Company. It was a major breakthrough in metallurgy because its high strength and ductility allow it to compete with malleable iron and, in certain applications, with steel.

If ductile iron is austenitized and quenched into a salt bath or a hot oil transformation bath at a temperature in the range of 320 to 550 °C (610 to 1020 °F) and held at that temperature, transformation to a structure containing mainly bainite with a minor proportion of austenite takes place. Irons so transformed are referred to as austempered ductile irons (ADI). Austempering generates a range of structures depending on the time of transformation and the temperature of the transformation bath. The properties are characterized by very high strength, with some ductility and toughness, and often an ability to work harden, giving appreciably higher wear resistance than that of other ductile irons. See the article "Ductile Irons" in this Volume for an extensive review of the properties of ductile irons and ADI.

Organic Binders. Since World War II, experimentation has been accelerated in organic and chemical sand binders for the thermosetting of molds and cores (see the article "Resin Binder Processes" in this Volume). Beginning with the Croning process (shell process), phenolics led the way to urea and the dielectric process and then to furans and urea-free resins. The continued development of binders for the production of chemically bonded cores and molds in being directed toward increasing productivity as well as achieving the dimensional repeatability necessary to meet the new challenges of net shape and near-net shape casting requirements (Table 2). Many patterns were made of epoxy resins and polyurethane and other expendables such as polystyrene.

Table 2 Development of core and mold processes

Process	**Approximate time of introduction**
Core oil	1950
Shell: liquid and flake	1950
Silicate/carbon dioxide	1952
Airset oils	1953
Phenolic acid-catalyzed no-bake	1958
Furan acid-catalyzed no-bake	1958
Furan hot box	1960
Phenolic hot box	1962
Oil urethane no-bake	1965
Phenolic/urethane/amine cold box	1968
Silicate ester-catalyzed no-bake	1970
Phenolic urethane no-bake	1974
Alumina phosphate no-bake	1977
Furan sulfur dioxide	1978
Polyol urethane no-bake	1978
Warm box	1982
Free radical cure sulfur dioxide	1983
Phenolic ester no-bake	1984
Phenolic ester cold box	1985

Automation. By the late 1950s, it was obvious that a second industrial revolution had begun, consisting of machines manufacturing, repairing, and operating other machines through the control of elaborate electronic brains. The most dangerous and tedious jobs were relegated to robots programmed to lift, carry, and pour. Cupolas could now be charged and discharged not only mechanically but also automatically. These and other developments are outlined in the article "Foundry Automation" in this Volume.

Advancements During the Past Decade. The last decade has seen technological developments unfold at a rate never before experienced by this industry. In many cases, new technologies have been thrust upon the industry by a changing marketplace, a marketplace that is now demanding higher-quality and more cost-effective castings. Added to these demands is foreign competition, a force that is driving U.S. foundries toward new technology as a means of survival. All of these elements have changed the metal casting marketplace so drastically and at such a rapid rate that U.S. producers of cast components are diligently sifting through the many new technologies available in an attempt to find the ones that will provide the quality and productivity levels needed to compete in the world market.

Casting processes such as evaporative (lost) foam casting and semisolid casting, a scientific approach to the gating and risering of castings using computer simulation of solidification, the computer-aided design and manufacture of castings, integrated foundry systems (Fig. 9), the melting of metals using the plasma arc cupola, cast metal-matrix composites, and argon-oxygen decarburization for steel refining will all contribute to the continued advancement of metal casting. All of the aforementioned subjects are described in this Volume.

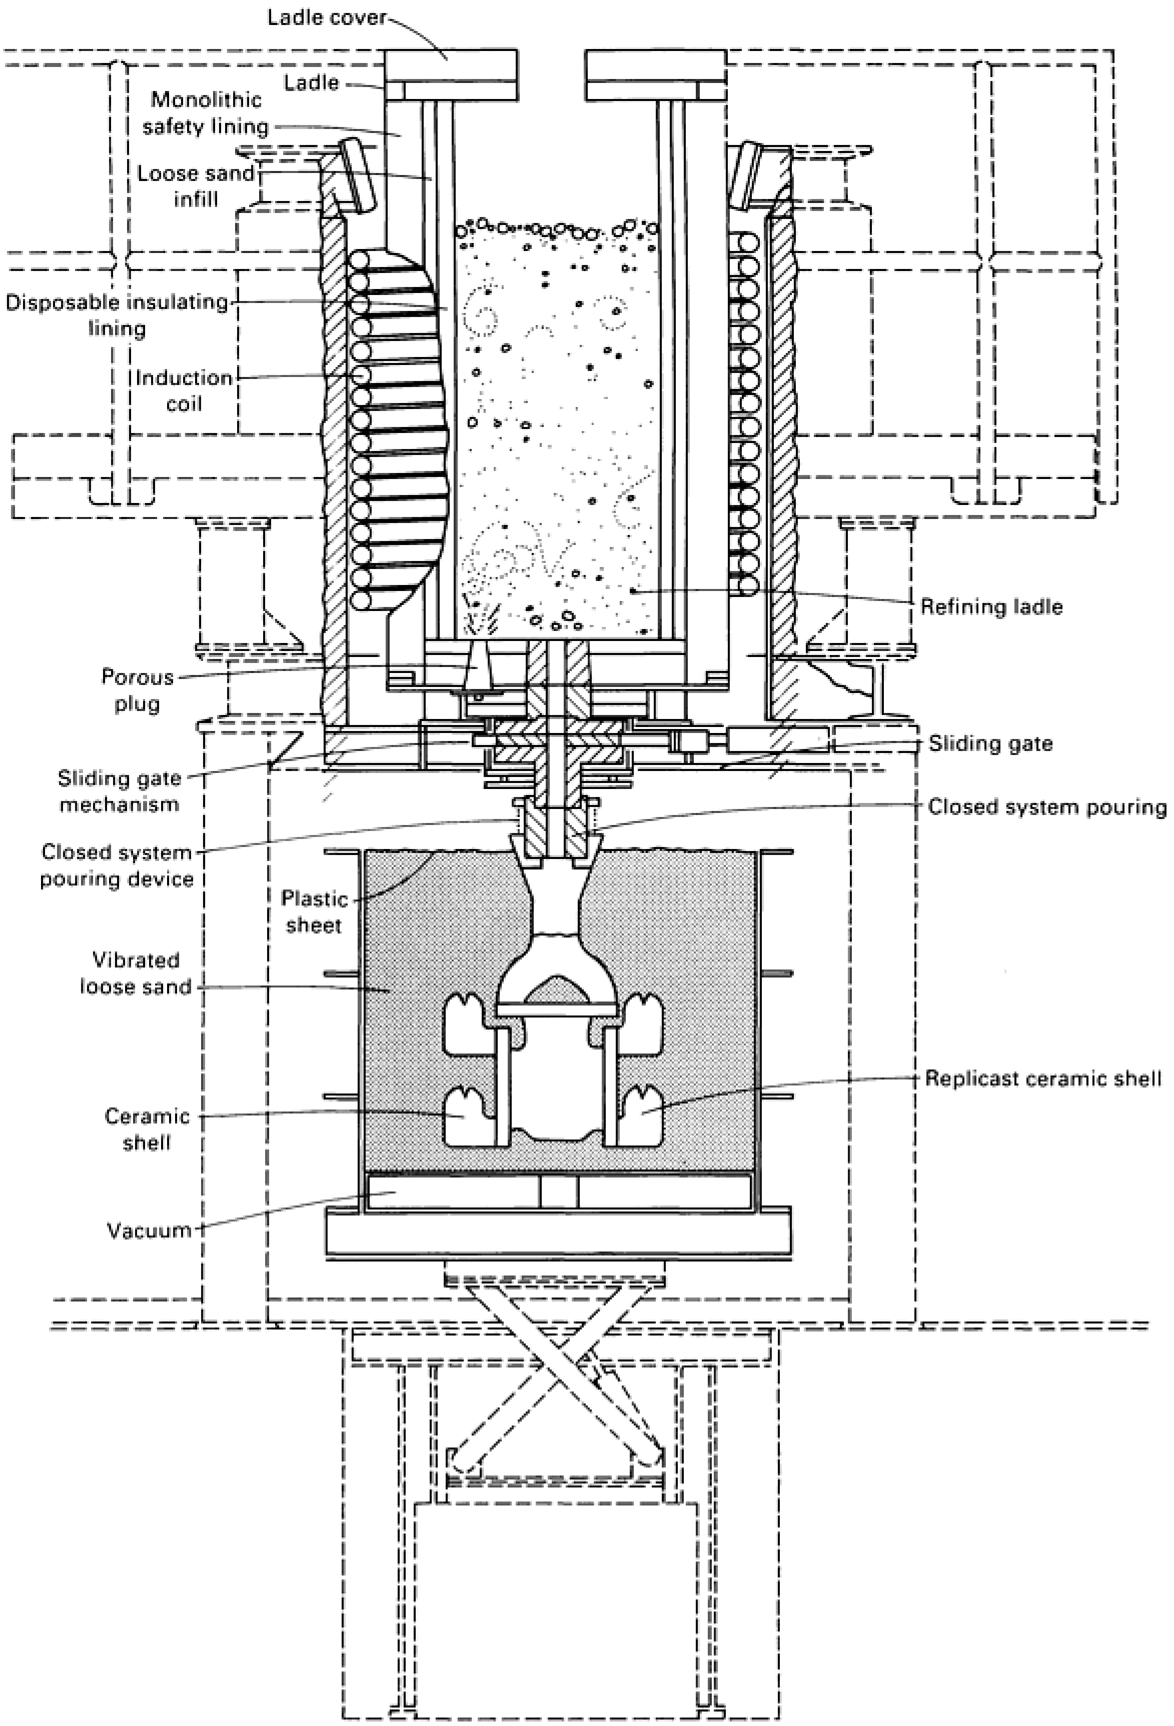

Fig. 9 Schematic showing the essential elements of an integrated Replicast casting system. See the articles "Foundry Automation" and "Replicast Process" in this Volume for additional information on integrated foundries and the ceramic shell Replicast process, respectively.

Looking ahead to the year 2000, the metal casting industry will continue to explore new technologies in the interests of achieving higher-quality castings that can meet the critical performance standards being imposed. This is demonstrated by the history of metal casting and by the striking fact that the industry has advanced further in the last 50 years than it has in the preceding 3000.

Casting Advantages, Applications, and Market Size

David P. Kanicki, American Foundrymen's Society

Introduction

METAL CASTING is unique among metal forming processes for a variety of reasons. Perhaps the most obvious is the array of molding and casting processes available that are capable of producing complex components in any metal, ranging in weight from less than an ounce to single parts weighing several hundred tons (Fig. 1). Foundry processes are available and in use that are economically viable for producing a single prototype part, while others achieve their economies in creating millions of the same part (Fig. 2). Virtually any metal that can be melted can and is being cast.

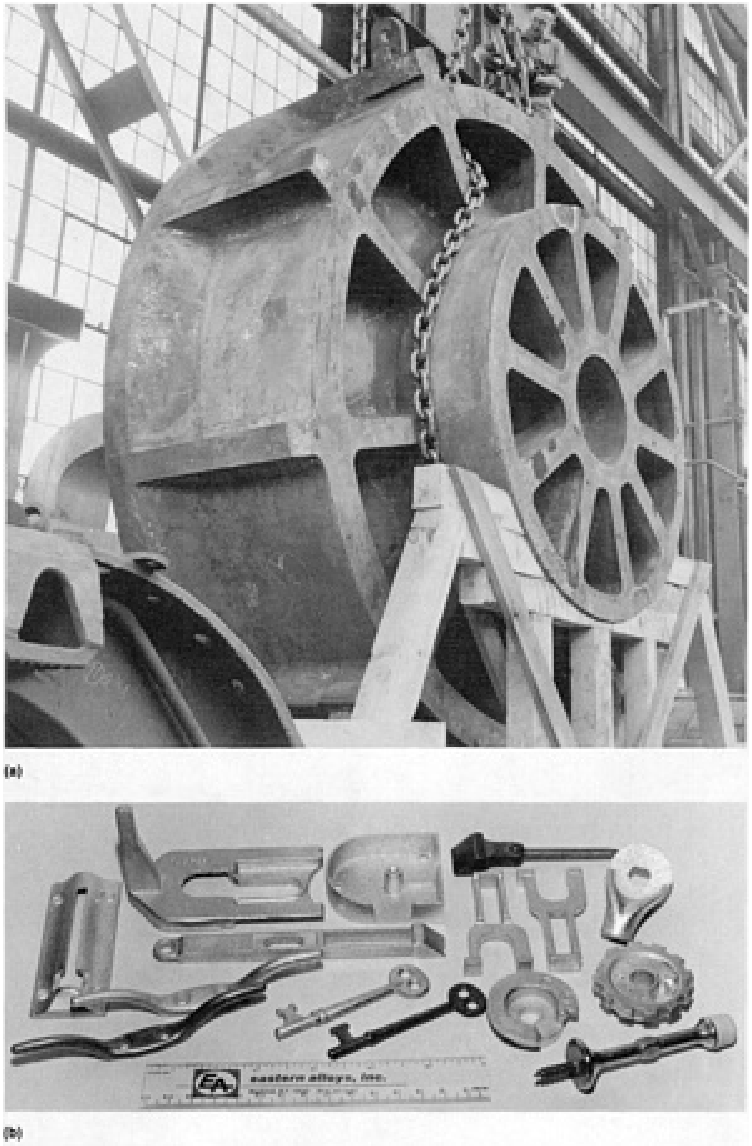

Fig. 1 The versatility of the metal casting process. (a) A 61,500 kg (135,600 lb) hot-forming die used for producing nuclear reactor pressure heads. (b) A variety of small hardware parts weighing only ounces each

Fig. 2 Cast iron automobile engine blocks being produced by the millions

In terms of value and volume, metal casting ranks second only to steel rolling in the metal producing industry. According to U.S. Department of Commerce statistics, metal casting remains one of the ten largest industries when rated on a value-added basis. Annually, more than 3000 U.S. foundries produce 12 to 14 million tons of castings in a variety of ferrous and nonferrous metals. The annual value of foundry products is estimated to be approaching $20 billion. This article will examine the advantages of the metal casting process, the major applications of cast components, and the technical and market trends that are shaping the foundry industry and the products it produces.

The Versatility of Metal Casting

It is estimated that castings are used in 90% or more of all manufactured goods and in all capital goods machinery used in manufacturing (Ref 1). The diversity in the end use of metal castings is a direct result of the many functional advantages and economic benefits that castings offer compared to other metal forming methods. The beneficial characteristics of a cast component are directly attributable to the inherent versatility of the casting process.

A review of Ref 2 illustrates the multifaceted nature of casting technology. Reference 2 describes in detail 38 methods for manufacturing a metal casting. These techniques are grouped into five categories. These categories, together with some of the individual processes within each group, include:

- Conventional molding processes (green sand, shell, flaskless molding)
- Precision molding and casting processes (investment casting, permanent mold, die casting)
- Special molding and casting processes (vacuum molding, evaporative pattern casting, centrifugal casting)
- Chemically bonded self-setting sand molding (no-bake, sodium silicate)
- Innovative molding and casting processes (rheocasting, squeeze casting, electroslag casting)

Most of these processes are described in detail in the Section "Molding and Casting Processes" in this Volume.

This brief sampling of casting processes illustrates the versatility currently available in the foundry industry. This diversity, in most cases, represents the continual refinements that have characterized the basic sand, ceramic, and metal

mold casting methods, but others represent new approaches to producing cast metal components. Probably the most prominent example of innovative casting technology, which is receiving much attention from both producers and users, is evaporative pattern casting, often referred to as lost foam casting (Fig. 3). Lost foam processing is discussed in the article "Sand Molding" in this Volume (see the section "Unbonded Sand Molds").

Fig. 3 Expandable polystyrene pattern and finished casting produced by lost foam casting

It is interesting to note the number of significant developments in both molding and casting that have occurred during the past 10 years, as documented in this Volume and in Ref 2. Some of these developments are reviewed below.

Molding developments. Two recent developments that have proved practical and are in current use in foundries are impact molding and the Replicast process.

Impact molding can be described as a high-density green sand process. It operates on the principle of compaction by acceleration (Ref 3). By using a mixture of natural gas and/or compressed air, a controlled explosion takes place that hurls the sand grains against the pattern. The wave of energy created produces a uniformly hard yet permeable mold. Because there is a little variation in mold hardness, the process is reportedly capable of producing near-net shape castings with the economies of green sand molding.

The Replicast process was developed by the Steel Castings Research and Trade Association of Sheffield, England. This process can be best characterized as a hybrid of the investment casting process (lost wax process) and evaporative pattern casting. In investment casting, a wax or plastic pattern is used to shape a ceramic shell mold, but the Replicast process utilizes an expanded polystyrene (EPS) pattern that is coated in a refractory slurry and then invested in a ceramic slurry to produce the ceramic shell (see the article "Replicast Process" in this Volume).

Although investment casting has long been recognized for its ability to produce castings with very smooth and detailed surface finishes with excellent dimensional tolerances, used of the EPS pattern is said to reduce costs by replacing the wax normally used in investment casting. One U.S. foundry that has adopted Replicast reports two major benefits (Ref 4):

- Test-design and prototype patterns can be fabricated from solid EPS to avoid die tooling costs
- For high-production die injection, expanded polystyrene has far lower material cost than wax; this is particularly important when producing larger parts

The same foundry also reports three major applications for Replicast in their operation:

- Testing casting designs and making prototypes

- Producing existing parts in an alternative alloy where the available tooling would not be suitable for the new alloy
- Making short-run replacement parts, such as replacing outdated equipment when new patterns cannot be justified

Impact molding and the Replicast process serve as good examples of the continually evolving technology of metal casting. Other processes are under development. Each is aimed at meeting customer needs, offering economical alternatives to other metal forming techniques, and expanding the already wide variety of metal casting technologies.

Process Developments. Significant developments are also occurring in the area of casting operations. Two relatively new processes demonstrate the advances being made in producing clean, thin-wall ferrous and non-ferrous castings. One such technique for producing aluminum castings is called the Cosworth process. The other, developed for iron and steel casting is the FM process.

The Cosworth process was developed to meet the need for highly specialized components for the Formula One racing car engines manufactured by Cosworth Engineering, Ltd., in England (Ref 5). Zircon sand molds with a furan binder system are filled from the bottom of the mold by using an electromagnetic pump. A vertical launder is located in the middle of a holding furnace, and it moves the metal at a controlled rate into the rigid sand mold. Locating the filling tube in the middle of the furnace helps ensure that only the cleanest metal enters the mold, thus reducing the possibility of slag or dross entering the mold cavity.

With a blanket of inert gas covering the molten metal in the furnace, the molten aluminum is protected from oxygen and other gases that may lead to porosity in the casting. In addition, because the mold fill rate is closely controlled, turbulence is minimized, and this also prevents the pickup of oxygen and other gases that may lead to porosity.

Major advantages claimed for the process include yields of 85% or better, castings that are typically 10 to 12% lighter than those produced by other methods, excellent mechanical and physical properties, and the ability to specify machining allowances in the range of 1.5 to 2 mm (0.06 to 0.08 in.). Several American foundries are in the process of adopting or seriously investigating the Cosworth process for their aluminum casting operations.

The FM process has been specifically developed to produce thin-wall iron and steel casting (Ref 6). The name FM comes from *fonte mince,* meaning thin iron. Developed and used by the French firm Pont-a-Mousson, the FM process is a mold filling technique (versus mold pouring) that utilizes a controlled differential pressure to fill molds with high-melting metals, including superalloys.

Like the Cosworth process, the FM process utilizes a bottom filling technique that is controlled and yet allows for rapid filling of the mold. Any type of mold (green sand, metal, shell, and so on) can be used with the FM process. The rapid fill rates are achieved by exerting a low pressure on the liquid metal and a negative pressure on the mold and, in certain cases, on the furnace itself. Evacuation of gases from the mold is also achieved during mold filling.

Casting wall thicknesses of 2.5 to 3.0 mm (0.10 to 0.12 in.) have been obtained in gray, ductile, and alloyed cast irons and in low-carbon steels. The properties of nickel-base superalloys and high-chromium steels are also improved with this process.

Materials Developments. Research into casting materials in recent years has also produced some significant results. Among these are austempered ductile iron and aluminum-lithium investment castings.

Austempered ductile iron, with properties that fall between those of through-hardened steels and case-carburized steels, has already begun to create new markets for cast irons because it is increasingly becoming an economical alternative to steel weldments, forgings, stampings, and other metal products (Ref 7). Some of the current applications for austempered ductile iron include gears, crankshafts, chain sprockets, stamping dies, railroad wheels, and other structural and load-bearing components (see the article "Ductile Iron" in this Volume for additional information).

Aluminum-Lithium Alloys. Research into aluminum-lithium as an investment casting material also holds promise in opening new markets to metal casting, particularly in the aircraft industry. The primary benefit of aluminum-lithium alloys is a reduction in material density, which is the major property in reducing structural weight in aircraft (Ref 8). In

some application, aluminum-lithium alloys, due to the effect of lithium on the elastic modulus of a part, exhibit an increase in stiffness of 10 to 15% and a decrease in the crack growth rate during fatigue. Research on these alloys for casting is in its early stages, but if initial findings can be confirmed and demonstrated, aluminum-lithium could lead to new aircraft markets for castings by replacing wrought aluminum-lithium products, such as forgings, extrusions, sheet, and plate.

These process and materials developments and other developments, such as the filtration of molten metals to remove oxides and other nonmetallics that can be deleterious to the final casting, represent only some of the advances currently taking place in metal casting and illustrate the versatility of the casting process. They also demonstrate the trend in the industry toward higher quality, lower costs, and new markets.

Functional Advantages

Beyond the rapidly emerging technologies that are keeping metal casting in the forefront in the metal forming industry, castings possess many inherent advantages that have long been accepted by the design engineer and metal parts user. In terms of component design, casting offers the greatest amount of flexibility of any metal forming process. The casting process is ideal because it permits the formation of streamlined, intricate, integral parts of strength and rigidity obtainable by no other method of fabrication. The shape and size of the part are primary considerations in design, and in this category, the possibilities of metal castings are unsurpassed. The flexibility of cast metal design gives the engineer wide scope in converting his ideas into an engineered part (Ref 9).

The freedom of design offered through the metal casting process allows the designer to accomplish several tasks simultaneously. These include the following (Ref 10):

- Design both internal and external contours independently to almost any requirement
- Place metal in exact locations where it is needed for rigidity, wear, corrosion, or maximum endurance under dynamic stress
- Produce a complex part as a single, dependable unit
- Readily achieve an attractive appearance

The following list of functional advantages of castings and the metal casting process was compiled from Ref 9 and 10. These advantages illustrate why castings have been and continue to be the choice of design engineers and materials specifiers.

Rapid Transition to Finished Product. The casting process involves pouring molten metal into a cavity that is close to the final dimensions of the finished component; therefore, it is the most direct and simplest metal forming method available.

Suiting Shape and Size to Function. Metal castings weighing from less than an ounce to hundreds of tons, in almost any shape or degree of complexity, can be produced. If a pattern can be made for the part, it can be cast. The flexibility of metal casting, particularly sand molding, is so wide that it permits the use of difficult design techniques, such as undercuts and curved, reflex contours, that are not possible with other high-production processes. Tapered sections with thickened areas for bosses and generous fillets are routine.

Placement of Metal for Maximum Effectiveness. With the casting process, the optimum amount of metal can be placed in the best location for maximum strength, wear resistance, or the enhancement of other properties of the finished part. This, together with the ability to core out unstressed sections, can result in appreciable weight savings.

Optimal Appearance. Because shape is not restricted to the assembly of preformed pieces, as in welding processes, or governed by the limitations of forging or stamping, the casting process encourages the development of attractive, more readily marketable designs. The smooth, graduated contours and streamlining that are essential to good design appearance usually coincide with the conditions for easiest molten metal flow during casting. They also prevent stress concentrations upon solidification and minimized residual stress in the final casting.

Because of the variety of casting processes available, any number of surface finishes on a part are possible. The normal cast surface of sand-molded casting often provides a desired rugged appearance, while smoother surfaces, when required, can be obtained through shell molding, investment casting, or other casting methods.

Complex Parts as an Integral Unit. The inherent design freedom of metal casting allows the designer to combine what would otherwise be several parts of a fabrication into a single, intricate casting. This is significant when exact alignment must be held, as in high-speed machinery, machine tool parts, or engine end plates and housings that carry shafts. Combined construction reduces the number of joints and the possibility of oil or water leakage. Figure 4 shows a part that was converted from a multiple-component weldment into a two-part cast component.

Fig. 4 Compressor case for a jet engine that was converted from a multiple-component weldment into a two-part cast component by a major jet engine manufacturer. The company converted all of its formerly welched cases to castings; this reduced by 27,000 the number of parts in one of its newest engines.

Improved Dependability. The use of good casting design principles, together with periodic determination of mechanical properties of test bars cast from the molten metal, ensures a high degree of reproducibility and dependability in metal castings that is not as practical with other production methods. The functional advantages that metal castings offer and that are required by the designer must be balanced with the economic benefits that the customer demands. The growth of metal casting and its current stability are largely the result of the ability of the foundry industry to maintain this balancing act. The design and production advantages described above bring with them a variety of cost savings that other metal working processes cannot offer. These savings stem from four areas (Ref 10):

- The capability to combine a number of individual parts into a single integral casting, reducing overall fabrication costs
- The design freedom of casting minimizes machining costs and excess metal
- Patterns used in casting lower in cost compared to other types of tooling
- Castings require a comparatively short lead time for production

For these and because it remains the most direct way to produce a required metal shape, metal casting will continue to be a vitally important metal forming technology. The diversity in end use in castings is also evidence of the flexibility and versatility of the metal casting process. Major casting end uses and market trends are discussed below.

Casting Market Trends and End Uses

The use of metal castings is pervasive throughout the economies of all developed countries, both as components in finished manufactured goods and as finished durable goods (Ref 1). As indicated earlier, castings are used in 90% of all manufactured goods and in all capital goods machinery used in manufacturing. They are also extensively used in transportation, building construction, municipal water and sewer systems, oil and gas pipelines, and a wide variety of other applications (Ref 11).

Industry Structure. In the broadest sense, foundries are categorized into two general groups: ferrous foundries (those that produce the various alloys of cast iron and cast steel) and nonferrous foundries (those that produce aluminum-base, copper-base, zinc-base, magnesium, and other nonferrous castings). The wide variety of ferrous and nonferrous casting alloys is extensively reviewed in the Sections "Ferrous Casting Alloys" and "Nonferrous Casting Alloys" in this Volume.

For marketing purposes, foundries are also categorized according to the nature of their operations as being either captive (producing castings for their own use) or jobbing (producing castings for sale). The market is sometimes further broken down by major casting processes when they can be readily identified or are particularly significant. This is done more often in the case of nonferrous castings; in this case, the product is usually categorized as being produced in sand, permanent mold, or die cast. Because 90% or more of all iron and steel castings are produced in some form of sand medium, distinguishing the process used is not quite as significant. The U.S. Department of Commerce procedure statistics for steel investment castings.

Ferrous castings shipments are usually classified by market category. For example, iron castings are generally categorized as engineered (designed for specific, differentiated customers) and nonengineered (produced in large volumes of interchangeable units, usually consisting of ingot molds, pressure and soil pipe).

The diversity among the various foundries makes it difficult to determine the exact structure of the industry. For example, it is not unusual for a single operating foundry to produce a variety of metals and alloys, both ferrous and nonferrous, in the same plant. Some also use a variety of processes in their operations. Many aluminum foundries, for instance, use both sand and permanent mold processes, and some event produce die castings in the same facility.

In addition, the foundry industry consists of a variety of large and small facilities. In terms of numbers of workers, it is estimated that nearly 80% of casting plants in the United States and Canada employ fewer than 100 persons (Ref 12). Table 1 gives a breakdown of the industry by major metal cast and employment range. Total employment in the industry is approximately 180,000.

Table 1 Breakdown of foundries by employment and primary metal cast in 1986

Includes U.S. and Canadian plants

Employment	Gray and ductile iron	Malleable iron	Steel	Nonferrous	Total
>1000	13	1	3	6	23
500-999	23	2	17	19	61
250-499	55	2	29	60	146
100-249	200	13	95	205	513
50-99	234	8	95	282	619
20-49	304	3	115	560	982
<20	234	1	101	1326	1662
Total	**1063**	**30**	**455**	**2458**	**4006**

Casting Shipments. The U.S. Department of Commerce Bureau of Census maintains the only generally available statistics on casting shipments. Statistics on most metals are available from 1943 to the present. In recent years, the accuracy of the information on gathering and reporting methodology of the Department of Commerce for casting shipments has been called into question. Part of the problem lies in the use of a standard industry code (SIC) system for gathering and reporting data.

In the many cases, shipments of castings by captive foundries are reported under SIC codes other than those for foundries, because the parent company of a foundry may be categorized under a different SIC code (for example, motor vehicles--SIC 3711; agricultural equipment--SIC 3522). The SIC classifications used to report casting shipments generally include SIC 3321 (gray and ductile iron), 3322 (malleable iron), 3325 (steel foundries), and 3361-9 (nonferrous foundries and die casting plants).

For this reason, many industry observers believe that casting shipments are understated. Nonetheless, the Bureau of Census statistics are generally recognized as the best available information on the subject, and despite their shortcomings, they offer insight into the generally production and shipment trends of the industry.

Ferrous castings easily make up the largest production sector of the foundry industry in terms of volume, with gray iron outdistancing the other major metals constituting this group. During the last four decades (1947 to 1986), iron and steel foundries shipped an average of 15.5 million tons of castings annually. The periods from 1947 to 1956 and 1957 to 1966 were remarkably stable; annual shipments averaged 15.0 and 15.3 tons per year for the 20-year period. The following decade (1967 to 1976) saw a significant upturn as the average annual shipments of iron and steel castings rose to slightly more than 17.5 million tons. Iron casting shipments have averaged about 14 million tons per year during the last four decades.

The last 10 years (1977 to 1986) were trying times for American foundries. Ferrous casting shipments rose to more than 17 million tons in 1978 before falling about 9.5 million tons by 1982. Between 1983 and 1985, shipments hovered between 10 and 12 million tons. Shipments dropped again in 1986, slipping to about 8.6 million tons that year. During the decade in question, ferrous casting shipments averaged about 13 million tons per year, with iron castings accounting for nearly 12 million. Figure 5 shows ferrous casting shipments from 1978 to 1987.

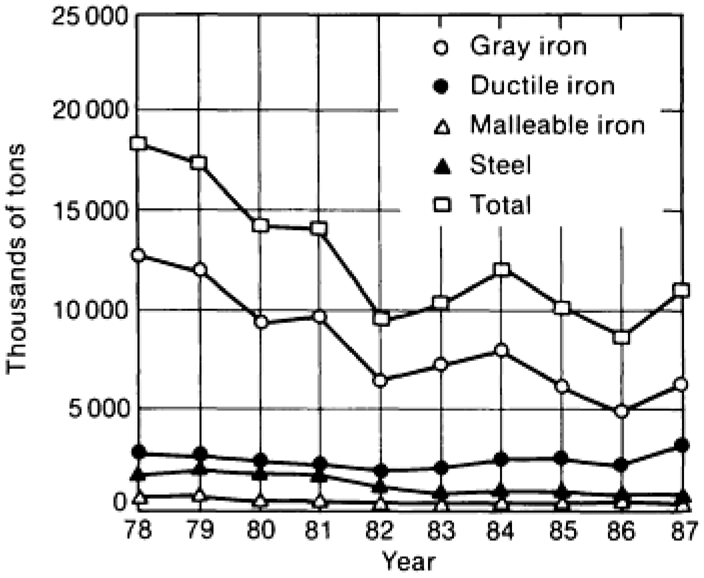

Fig. 5 U.S. ferrous casting shipments from 1978 to 1987

Nonferrous castings shipments have followed a similar path since 1947. Copper-base casting shipments averaged nearly 500,000 tons per year between 1947 and 1956, but between 1977 and 1986, they slipped to about an average of 300,000 tons annually. Aluminum casting shipments, on the other hand, have showed slow, steady growth since the early 1950s. Between 1947 and 1956, an average of 290,000 tons of aluminum castings were shipped per year. During the last decade, this has risen dramatically to an annual average of more than 950,000 tons per year.

In general, total nonferrous casting shipments (aluminum, copper-base and zinc) averaged 1.05 million tons annually between 1947 and 1956; 1.32 million tons per year from 1957 to 1966; 1.83 million tons annually from 1967 to 1976; and 1.44 million tons during the last decade. Figure 6 illustrates nonferrous casting shipments between 1977 and 1986.

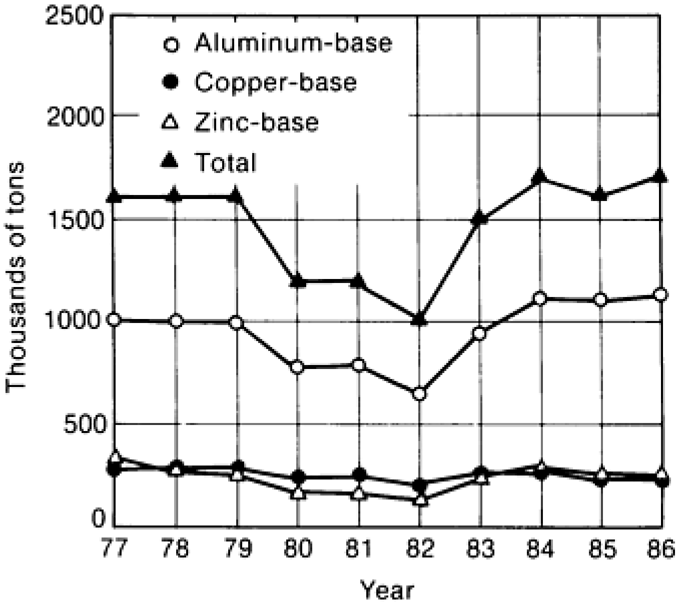

Fig. 6 U.S. nonferrous casting shipments from 1977 to 1986

Most recently, ferrous castings have shown good improvement, increasing from 8.6 million tons shipped in 1986 to 10.9 million in 1987. Nonferrous shipments remained relatively stable, with 1.3 million tons shipped through ten months of 1987, about par for the same period in 1986.

Metal Casting Worldwide. In the case of production of both ferrous and nonferrous castings, U.S. producers are considered the world leader (excluding the Soviet Union) (Ref 1). World production of metal castings exceeded 51 million short tons in 1982, with the United States accounting for 10.5 million tons, or about 20%. This was down from the 27% share the United States enjoyed in 1979. At the same time, Japan increased its share of the world casting market from 11 to 15%. West Germany and Italy each increased their market shares between 1979 and 1982 by 1%, to 8.4 and 4.5%, respectively.

Since the end of the 1970s, casting production around the world has shown a significant decline, generally reflecting the state of manufacturing. World production of ferrous and nonferrous castings declined from 69.8 million short tons in 1979 to 51.6 million tons in 1982, a drop of about 26%. Ferrous castings fell some 27%, from 64.6 million tons in 1979 to 47.3 million tons in 1982. Nonferrous castings fared slightly better during this period, slipping about 18%, from 5.2 to 4.3 million tons. Table 2 lists the casting production trends of nine major casting producing countries between 1982 and 1986, the 5-year period after the U.S. Trade Commission conducted its study (Ref 1).

Table 2 Ferrous casting production from 1982 to 1986

Figures given in thousands of metric tons

Country	Year				
	1982	1983	1984	1985	1986
United States	8,651,455	9,313,866	10,856,200	9,991,393	8,564,725
Japan	5,735,001	5,515,999	5,128,896	5,240,261	4,860,591
West Germany	3,501,299	3,311,600	3,387,300	3,499,900	3,452,000

France	2,230,264	2,014,387	1,855,634	1,902,608	1,797,960
United Kingdom	1,621,700	1,549,100	1,490,500	. . .	1,222,000
Brazil	1,207,700	986,142	. . .	1,407,324	1,543,147
Canada[a]	671,913	781,722	981,730	856,077	865,777
Korea	639,000	762,000	805,000	848,000	934,000
Taiwan	401,990	492,150	599,122	637,660	778,930

(a) Canada's tonnage is estimated to be 75% of actual.

Casting End Uses. Metal castings have a great variety of end uses and are therefore largely taken for granted by the consuming public. Castings are often the hidden components of the machines and other equipment used on a daily basis, such as automobiles, lawn mowers, refrigerators, stoves, typewriters, and computers. Only in rare cases does a consumer make a conscious decision to buy a cast product unless it is readily identifiable, as in the case of cast iron or aluminum cookware, cast iron bathtubs, or ornamental products such as cast bronze sculptures.

Designers of industrial equipment and machinery, on the other hand, have long recognized the performance qualities of castings and regularly specify their use. These functional and economic advantages were described earlier. The major markets for cast products are listed in Table 3.

Table 3 Major markets for metal castings

Ranked in order of tonnage shipped. In some cases, the total of "Other major markets" is larger as a whole than the individual markets listed.

Ferrous castings

Gray iron

Ingot molds
Construction castings
Motor vehicles
Farm equipment
Engines
Refrigeration and heating
Construction machinery
Valves
Soil pipe
Pumps and compressors
Pressure pipe
Other major markets include machine tools, mechanical power transmission equipment, hardware, home appliances, and mining machinery, oil and natural gas pumping and processing equipment

Malleable iron

Motor vehicles
Valves and fittings

Construction machinery
Railroad equipment
Engines
Mining equipment
Hardware
Other major markets include heating and refrigeration, motors and generators, fasteners, ordnance, chains, machine tools, general industrial machinery

Ductile iron

Pressure pipe
Motor vehicles
Farm machinery
Engines
Pumps and compressors
Valves and fittings
Metalworking machinery
Construction machinery
Other major markets include textile machinery, wood working and paper machinery, mechanical power and transmission equipment, motors and generators, refrigeration and heating equipment, air conditioning

Steel

Railroad equipment
Construction equipment
Mining machinery
Valves and fittings
General and special industrial machinery
Motor vehicles
Metalworking machinery
Other major markets include steel manufacturing, spring goods, heating and air conditioning, recreation equipment, industrial material handling equipment, ships and boats, aircraft and aerospace

Nonferrous castings

Aluminum

Auto and light truck
Aircraft and aerospace
Other transportation
Engines
Household appliances
Office machinery
Power tools
Refrigeration, heating, and air conditioning
Other major markets include machine tools, construction equipment, mining equipment, farm machinery, electronic and communication equipment, power systems, motors and generators

Magnesium

Power tools
Sporting goods
Anodes
Automotive
Other major markets include office machinery, health care, aircraft and aerospace

Copper-base

Valves and fittings
Plumbing brass goods
Electrical equipment
Pumps and compressors
Power transmission equipment
General machinery
Transportation equipment
Other major markets include chemical processing, utilities, desalination, petroleum refining

Zinc

Automotive
Building hardware
Electrical components
Machinery
Household appliances
Other major markets include scientific instruments, medical equipment, radio and television equipment, audio components, toys, sporting goods

Casting Market Trends. The production of castings, as well as the markets for metal castings, has been affected by a number of factors during the last decade. Because castings are usually produced as components for machinery and equipment, shipments and the relative health of the foundry industry are closely aligned with the level of business of its major customer markets. The condition of U.S. foundries is indicated in Fig. 7, which shows the trends of seven important casting markets between 1972 and 1987.

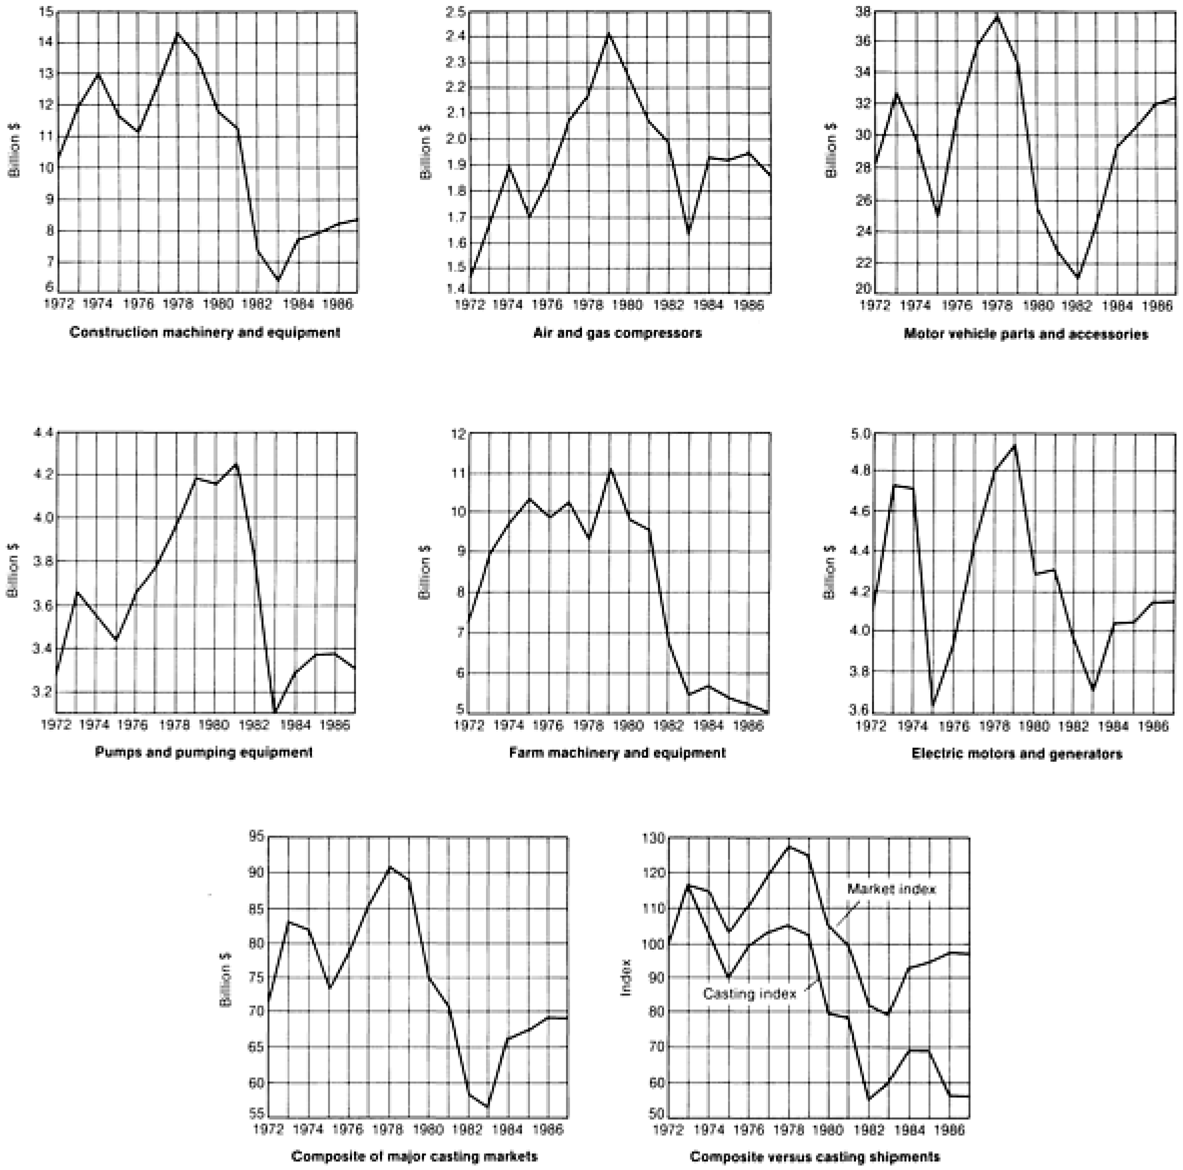

Fig. 7 Market trends of seven major casting end users from 1972 to 1987. Dollar amounts given in constant dollars. The composite market represents 15 major segments and includes the markets shown in this figure as well as such markets as valves, internal combustion engines, and heating equipment. Source: American Cast Metals Association

Among the major factors that have affected the production of castings is the new and rapidly evolving technology in both processes and materials. Cast iron ingot molds, for example, which traditionally represented one of the largest tonnage markets for gray iron, are being steadily reduced to low tonnages because of the use of the efficient continuous casting process in steelmaking. On the positive side, the increasing demand for near-net shape components is stimulating the use of investment casting, permanent molding, and other precision casting methods because of their inherent capability to reduce or minimize secondary operations, such as machining. Continued developments in directional solidification and single-crystal technology, squeeze casting, and semisolid metal casting could also contribute to increased casting production (see the articles "Directional and Monocrystal Solidification," "Squeeze Casting," and "Semisolid Metal Casting and Forging" in this Volume).

New materials developments are also affecting casting markets. One example is the use of plastic pipe and plumbing parts where gray iron and copper-base castings were once dominant. Other, more recent advances in engineered materials, such as polymers, resin- and metal-matrix composites, and ceramics, also hold long-term prospects for challenging the traditional metal casting and other metal forming markets. It should be noted, however, that some metal-matrix components are produced by casting processes (see the article "Cast Metal-Matrix Composites" in this Volume).

Economic and political trends have also played a role in the production of castings, as well as in all of manufacturing. The decision by the U.S. Congress in the late 1970s to set gas mileage requirements for domestically produced automobiles involved ramifications that are still being dealt with. This legislation led to a decade of the downsizing of U.S. cars. To attain the 27.5 miles/gal, (~12 km/L) goal set by Congress, U.S. automakers worked to reduce the weight of their cars. This led to lower total poundage of iron and steel, including castings. Engine blocks, heads, and other power train components--all important castings applications--were reduced in size and weight; in some cases, parts were designed out of newer automobiles. Aluminum castings were sometimes used in place of ferrous alloys.

The influx of imported castings and products that use castings has affected domestic foundries. This trend is considered to be long-term because many overseas casting operations have become firmly entrenched in U.S. markets.

Although U.S. producers of metal castings are confronted with declines in several important markets, prospects for growth are also visible. Both declining and growing markets for metal castings, as well as some of the factors affecting growth and decline, are given in Table 4.

Table 4 General trends in major metal casting markets

Declining markets	
Gray iron motor vehicle	
Trend	Decline from 3.4 mill on tons in 1979 to 2 million by 2000
Factors	Demands for less fuels consumption has meant smaller cars, smaller engines, lighter parts, near-net shape parts. Gray iron per car to decline from 600 to 300 lb
Other possible trends	Intake manifold to aluminum and possibly a polymer or magnesium. Transmission case to aluminum. Head and block partially to aluminum. Camshaft partially to powderd metals and/or steel. Exhaust manifold to ductile iron and possibly fabricated stainless steel.
Trend	Offshore producers now supply 30% of U.S. demand. We have become offshore dependent. A domestic supply shortage could be a reality by 1989, a 9 million domestic car year.
Trend	Major captive foundries will probably concentrate on blocks and heads.
Ingot molds	
Trend	Decline from 3.5 million tons in 1979 to 500,000 tons in 1995
Factors	Continuous casting of steel eliminates the ingot. Offshore competition for steel has reduced the raw steel production in U.S. from 136 million tons to 90 million tons. Ingot mold consumption of 52 lb/ton of raw steel production is reduced to 14 lb.
Iron municipal castings	
Trend	Decline from 1 million tons to 500,000 tons per year
Factors	Offshore competition, now 30% of demands, has been major factor. Price reductions have caused foundry closings.

Malleable iron	
Trend	Decline from 700,000 tons in 1979 to 50,000 tons annually
Factors	Lost markets to ductile iron, aluminum and plastics. Only major usage will probably be for small electrical parts and pipe fittings.
Steel railroad	
Trend	Decline from 1 million tons of steel casting shipments annually to 500,000 tons; had dropped to near 200,000 tons in 1983
Factors	Freight car production declined from 90,000 in 1979 to 6000 in 1983; return to 50,000 cars is forecast
Growth markets	
Ductile iron	
Trend	Growth from 0 in 1948 to 3.1 million tons in 1979; forecast growth to over 4 million tons by 2000
Factors	Replacing malleable iron in most market segments and some major steel casting products. Increased usage of austempered ductile iron as a replacement for carburized steel. Slight loss in passenger car utilization from 200 to 190 lb per car due to loss of differential carrier and case to front-end drive and light engines. An increase in export of pressures pipe to third world countries is expected.
Aluminum castings	
Trend	Growth from 1.1 million tons in 1979 to 1.85 million tons in 2000
Factors	Replacing iron castings in passenger cars and light trucks--now 90 lb per car, forecast to be 140 lb per car. Die castings, permanent mold castings, and sand cast aluminum are all expected to show growth. Evaporative pattern casting will show greatest growth, primarily in intake manifold and engine head.
Investment castings	
Trend	Growth from 110,000 tons in 1985 to 250,000 tons annually in 2000
Factors	Automotive application will spur growth because of near-net shape capabilities. Commercial growth will come in valve and pump application, but automation will be required.
Magnesium die castings	
Trend	Growth from 10,000 tons to 110,000 tons per year

Factors	New automotive usage is provide gain if price of magnesium is competitive. Its strength-to-weight ratio is a major advantage.
Corrosion-resistant steels	
Trend	Growth from 40,000 tons in 1985 to 90,000 tons in the year 2000
Factors	Key factor is recovery in the processing industries--food, desalination, petrochemical.
Machined castings	
Trend	Shipments of fully machined cast part from noncaptive foundries are forecast to grow to 500,000 tons per year in aluminum, iron, and steel.
Factors	Drive by casting consumers to reduce fixed costs and break even

Source: International Metalcasters' Council

The many factors that have influenced casting production in the United States have also affected the number of operating foundries in this country. In 1955, some 6000 foundries were operating. Today, that number stands at about 3400. A continued shakeout of marginal foundry operations is anticipated through the end of the century. However, although the base of operating foundries has decreased, American foundries have become bigger and more productive. In 1955, U.S. foundries shipped an average of 3000 tons per year; average shipments have since risen to nearly 5600 tons per foundry annually.

The last decade has been particularly tumultuous for the metal casting industry. Many of the changes that have taken place have created permanent structural shifts in foundry markets and the metal casting industry itself. These changes have caused foundries to respond with higher-quality products and innovative materials and technologies, as revealed in this article and throughout this Volume.

Introduction to Principles of Liquid Metal Processing

Seymour Katz, General Motors Research Laboratories

Introduction

THIS SECTION is intended to provide fundamental information on presolidification phenomena. Because much of the information is in the realm of physical chemistry, the first article provides a theoretical introduction to the subject. The next two articles provide pertinent thermochemical data for ferrous and nonferrous (aluminum and copper) casting alloys. The last three articles deal with important presolidification phenomena, composition control (alloy addition and impurity removal), and casting defects with origins in the liquid state (gas defects and inclusions).

Nomenclature

In order to assist the reader, Table 1 summarizes the nomenclature used in the various articles in this Section. Additional nomenclature used throughout this Volume can be found in the Abbreviations and Symbols.

Table 1 Nomenclature used in this Section

a_i	Activity of component *i* relative to pure material standard state
a_i^o	Activity of component *i* in the pure material standard state
A	Interfacial surface area
A_0	Surface area of an alloy particle
C_i	Concentration of component *i*
C_P	Heat capacity
C_S	Sulfide capacity
CE	Carbon equivalent
d_p	Particle diameter
D	Diffusion coefficient
DR	Desulfurization ratio
e_i^j	Interaction coefficient for 1 wt% standard state
E	Cell potential

f_i	Activity coefficient for 1 wt% standard state
F^*	Integral free energy of solution
F	Faraday's constant
G_i	Gibbs free energy of component *i*
ΔG	Integral molar free energy
$\Delta \overline{G}_i$	Partial molar free energy of component *i*
$\Delta \overline{G}_i^o$	Molar free energy of component *i*
$\Delta \overline{G}^{xs}$	Excess partial molar free energy of component *i*
$\Delta \hat{G}_i^o$	Free energy of component *i* in solution at the 1 wt% standard state
ΔG_i^o (% *i*)	Free energy of solution from pure material to 1 wt% standard state
G_i^o (X_i)	Free energy of solution from the pure material to the hypothetical pure material standard state
h	Convective heat transfer coefficient
h_i	Activity of component *i* relative to the 1 wt% standard state
H_i	Molar enthalpy of component *i*
ΔH_i^o	Standard enthalpy of formation
ΔH_i	Partial molar enthalpy of component *i*
$\Delta \overline{H}_i^{xs}$	Excess partial molar enthalpy of component *i*
J	Mass flux
k, k', k_B	Rate constants

k_A	Constant related to the absorption of an element on a surface
k_H	Constant related to hydrogen solubility in iron
k_m	Mass transfer coefficient
K_{mN}	Liquid-phase mass transfer coefficient
K	Equilibrium constant
m,m'	Solubility factors giving change in carbon solubility in Fe-C-*X* from unit mass addition of a third element
M_i	Molecular weight of component *i*
n_i	Moles of component *i*
N_i	Mole fraction of component *i*
p_i	Pressure of component *i* in the gas phase
p_i^o	Pressure of component *i* in its standard state
P	Constant pressure conditions
P^S,P^M	Partition coefficient. Ratio alloy element concentration between liquid and solid phases in equilibrium. The superscripts S and M refer to stable and metastable products of Fe-C solidification, respectively.
Q	Heat Flux
$\dot{Q}$	Gas flow rate
r,r_0	Radius of a rod
R	Universal gas constant
S	Ratio of surface area to volume
S_c	Ratio carbon concentration: iron alloy melt to eutectic
S_r	Rectified saturation degree, that is, weight fraction Fe-C eutectic formed on solidification of hypoeutectic iron

$\Delta\overline{S}_i$	Partial molar entropy of component *i*
$\Delta\overline{S}_i^{xs}$	Excess partial molar entropy of component *i*
$\Delta\overline{S}_i^{o}$	Molar entropy of component *i* in the pure material standard state
t	Time
t	Celsius temperature
t_m	Melting time
T	Kelvin temperature
V	Gas flow rate
V'	Gas volume per tonne of metal
V_0	Volume of an alloy particle
w	Mass fraction: desulfurization to iron
W	Weight of melt
X_i	Mole fraction of component *i*
Greek symbols	
α	Phase designation
α_{ij}	Alpha activity coefficient function for Darken's quadratic formalism
γ_i	Activity coefficient of component *i* relative to pure material standard state
g_i^o	Henry's law constant
δ	Boundary layer thickness
e_i^j	Interaction coefficient; pure material standard state

θ	Fraction of surface sites covered by surface-active atoms
κ	Empirical constant indicating iron compositions that have the same microstructure at a given cooling rate
λ	Particle shape factor
ν_i	Stoichiometric coefficient for component *i* in a reaction
ρ	Density
Superscripts	
B	Bulk property
e, equil	Equilibrium condition
f	Final condition
l	Liquidus concentration
[scripts]	Solidus concentration
S	Surface condition
*	Interface condition

Principles of Physical Chemistry

Seymour Katz, General Motors Research Laboratories

Introduction

TWO SUBJECTS that underlie all foundry processes, from melting to heat treatment, are chemical thermodynamics and chemical kinetics. Relationships derived from the disciplines are extremely useful in providing a quantitative framework for explaining and predicting chemical behavior. This includes all the chemical processes involved in preparing liquid metal for casting (going back to the winning of ores, if desired), the chemical processes involved in making molds and cores, the casting and solidification processes, the microstructural development of alloys, and the phase changes that occur after casting (for example, by heat treatment).

Thermodynamics defines the most stable chemical system (equilibrium system) that can be produced, given a set of starting conditions (compositions, temperature, pressure, and so on). An examples is the phase diagram. It gives the stable phases that coexist at equilibrium, given the composition, temperature, and pressure.

While chemical thermodynamics is only concerned with the initial and final states of a system, chemical kinetics is concerned with how and at what rate the system is transformed from the initial to the final state. The practical importance of chemical kinetics implies that systems often fail to reach the most stable condition and that the path taken plays a major role in determining the speed of the reaction. In general, kinetics assumes its greatest importance when atomic movement is restricted, such as at low temperatures or in solids. Thermodynamics most often applies when atoms have high mobility, as in gases and liquids and at high temperatures. Another factor that determines the relative applicability of thermodynamics and kinetics is time. The less time available for a process, the more likely that kinetic processes will govern the chemical state of the system.

Chemical Thermodynamics

There are three thermodynamic laws that provide the basis for the relationships that describe chemical systems. These laws hold that perpetual motion and absolute zero temperature can never be achieved. The relationship between the thermodynamic laws and, for example, phase diagrams is not immediately apparent. However, the connection exists and is testimony to a great deal of brilliant theoretical work carried out over the last 100 years.

For metallurgical systems, the most important thermodynamic variables are enthalpy and Gibbs free energy. The former governs the disposition of heat, and the latter governs chemical equilibrium.

Enthalpy and Heat Capacity

The heat content of a material is termed its enthalpy *H.* Because the value of the enthalpy is proportional to the amount of material present, *H* is usually tabulated as enthalpy per unit mass. Common units of *H* are joules/mole, calories/gram, or Btu/pound. Thus, the total enthalpy of n_i moles of material *i* is:

$$(H_i)_{\text{total}} = n_i H_i \qquad \textbf{(Eq 1)}$$

For a mixture of materials, the total enthalpy is the sum of the individual enthalpies:

$$H_{total} = \sum_i n_i H_i \qquad \textbf{(Eq 2)}$$

The heat capacity C_P, given in joules/mole · K, and so on, is a measure of how *H* varies with temperature and is defined as:

$$Cp = \left(\frac{\partial H}{\partial T} \right)_P \qquad \textbf{(Eq 3)}$$

where the subscript *P* indicates that the values refer to constant pressure conditions.

Enthalpy and heat capacity govern the thermal state of a system and the heat generated or absorbed by chemical reactions. These variables are particularly important for establishing the energy requirements for processes, for determining rates of solidification, and for heat treatment processes. Enthalpy and heat capacity data are tabulated in Ref 1.

Gibbs Free Energy

Conditions for Equilibrium. Chemical equilibrium is a condition in which the chemical components of a system have no tendency to change. In mechanical systems, equilibrium is understood as the condition in which the potential energy is at a minimum. For chemical systems at constant temperature and pressure, and analogous statement for chemical equilibrium is that the Gibbs free energy is at a minimum, or equivalently from calculus:

$$dG(P,T,n_i \ldots) = 0 \qquad \textbf{(Eq 4)}$$

For systems in which chemical change can occur, *dG* can be expressed in partial differential form:

$$dG = \left(\frac{\partial G}{\partial T}\right)_{P,n_i....} dT + \left(\frac{\partial G}{\partial T}\right)_{T,n_i....} + dP + \left(\frac{\partial G}{\partial T}\right)_{P,T,n_i....} d_{n_i} + ... \qquad \textbf{(Eq 5)}$$

where n_i stands for moles of component *i*. The term $(\partial G/ \partial n_i)_{P,T,n_i....}$, . . . is called the partial molar free energy G_i, or the chemical potential.

It is clear from Eq 4 and 5 that, at equilibrium and at constant temperature and pressure, the following relationship exists:

$$0 = \overline{G}_i\, dn_i + \overline{G}_j\, dn_j + \ldots \qquad \textbf{(Eq 6)}$$

When the change in composition is dictated by a chemical reaction, stoichiometry provides a relationship between dn_i, dn_j, and so on, and Eq 6 can suitably be transformed to:

$$0 = v_i\, \overline{G}_i + v_j\, \overline{G}_j + \ldots \qquad \textbf{(Eq 7)}$$

where v_i, v_j, and so on, are the stoichiometric coefficients in the chemical reaction equation. For products and reactants, the stoichiometric coefficients are positive and negative numbers, respectively. As an example, for the chemical reaction:

$$4Al + 3O_2 = 2Al_2O_3 \qquad \textbf{(Eq 8)}$$

Equation 7 becomes:

$$0 = 2\, \overline{G}\, Al_2O_3 - 4\, \overline{G}_{Al} - 3\, \overline{G}\, \ddot{O}_2 \qquad \textbf{(Eq 9)}$$

Tabulation of Thermodynamic Data. To make thermodynamic calculations convenient, a system was developed for tabulating thermochemical data so that relatively small amounts of data could describe a wide range of chemical conditions. This was done by defining special conditions called standard states. Thus, for a chemical compound *i* that is an ideal gas at pressure p_i, $\overline{G}_i$ is now written:

$$\overline{G}_i = G_i^\circ + RT\left(\frac{p_i}{p_i^\circ}\right) \qquad \textbf{(Eq 10)}$$

where G_i^o is the free energy per mole of *i* in its standard state and p_i^o is the pressure of *i* in its standard state. The second term on the right-hand side of Eq 10 is the free energy change to take a mole of *i* from its standard state p_i^o to p_i. For gases, the usual standard state is p_i^o = 1 atm. Thus, p_i^o is usually omitted in writing Eq 10.

Both $\overline{G}_i$ and G_i^o are absolute values that cannot be measured. Changes in these variables can be measured from an arbitrary baseline. By convention, the baseline is taken as the elements in their standard states for which $(G_i^o)_{elements} = 0$ is defined at all temperatures. To indicate that the values are relative to a baseline, Eq 6, 7, and 10 are rewritten by replacing $\overline{G}_i$ and G_i^o with $\Delta G_i\ _i$ and ΔG_i^o, respectively. Values of ΔG_i^o for many compounds (called the standard free energy of formation) and phase changes have been tabulated (Ref 2, 3). Because ΔG_i^o is a function of temperature, the most common tabulations are based on another thermodynamic definition of ΔG_i^o, that is:

$$\Delta G_i^o = \Delta H_i^o - T\, \Delta S_i^o \qquad \textbf{(Eq 11)}$$

where ΔH_i^o and ΔS_i^o are the standard enthalphy and the entropy of formation, respectively. The tabulations provide ΔH_i^o and ΔS_i^o data. The value of ΔG_i^o is calculated for any temperature using Eq 11.

Equilibrium Constant. Substituting Eq 10 into Eq 7 gives the most important relationship governing reaction equilibrium:

$$\sum_i v_i.\Delta G_i^\circ = -RT\sum_i \ln p_i^{vi} \qquad \textbf{(Eq 12)}$$

Here, the thermodynamic data on the left are related to actual pressures (concentrations) on the right. Equation 12 is ordinarily written in abbreviated form as:

$$\Delta G^o = -RT \cdot \ln K \qquad \textbf{(Eq 13)}$$

where K is the equilibrium constant.

The form of K is illustrated in the following. Given the gas phase chemical reaction:

$$2H_2 + O_2 = 2H_2O \qquad \textbf{(Eq 14)}$$

the equilibrium constant is:

$$k_{14} = \frac{p_{H_2O}^2}{p_{H_2P_{O_2}}^2} \qquad \textbf{(Eq 15)}$$

Activity and Condensed Phase Equilibrium. Metallurgical applications are primarily concerned with condensed phases (solids and liquids), which do not behave in the manner of an ideal gas. That is, for a condensed material, ΔG_i^o does not vary with the logarithm of the concentration as might be inferred from Eq 12, where for an ideal gas, ΔG_i^o varies directly with ln p_i. To preserve the useful equilibrium constant expression for nonideal, condensed phases, Eq 10 and 12 are retained in form but rewritten to enable the use of data expressing nonideality. Thus:

$$\Delta\overline{G}_i = \Delta G_i^\circ + RT.\ln\left(\frac{a_i}{a_i^\circ}\right) \qquad \textbf{(Eq 16)}$$

$$\sum_{\mathrm{i}} vi\ \Delta G_i^\circ = -RT\sum_i \ln a_i^{vi} \qquad \textbf{(Eq 17)}$$

The difference between Eq 16 and 10 and Eq 17 and 12 is that a term a_i, called activity, replaces the pressure term. The activity is a function of concentration but usually not a simple function of concentration. Analogous to the case with gases, the activity in the standard state a_i° is taken as unity. The equilibrium constant is now defined in terms of activity.

$$\ln k = \sum_i \ln a_i^{vi} \qquad \textbf{(Eq 18)}$$

Activity Coefficients--Departure From Ideality. Common expressions for activity are:

$$a_i = \gamma_i X_i \qquad \textbf{(Eq 19)}$$

$$h_i = f_i\ (\%i) \qquad \textbf{(Eq 20)}$$

where the concentration terms X_i and (%i) are the mole fraction and weight percent, respectively, of the solute i, and γ_i and f_i are the activity coefficients that measure departure from ideality, that is, generally γ_i and $f_i \neq 1$. The terms a_i and h_i

are often called the Raoultian activity and the Henrian activity, respectively, to distinguish the standard state being used. The Raoultian activity is usually used in conjunction with the pure material standard state, while the Henrian activity is used with the 1 wt% standard state (to be explained). The latter standard state and Eq 20 are used to describe dilute solutions and have been extensively applied to ferrous systems, especially steel. The pure material standard state and Eq 20 are used in most other cases.

The two standard states, their activities, and their activity coefficients are illustrated with Fig. 1, which gives the activity composition relationships for the liquid iron-nickel system. The point A represents the pure material standard state for nickel (pure nickel in its most stable form (liquid) at the temperature of concern, 1873 K). Activity, given on the ordinate, is based on Eq 19. The ideal solution line (Raoult's law line), where $a_{Ni} = X_{Ni}$, is labeled. The change in the partial molar free energy of nickel in transferring nickel to solution is given by Eq 21, which was obtained by substituting Eq 19 into Eq 16:

$$\Delta\overline{G}_{Ni} = \Delta G^{\circ}_{Ni} + RT \cdot \ln X_{Ni} + RT \cdot \ln \gamma_{Ni} \qquad \textbf{(Eq 21)}$$

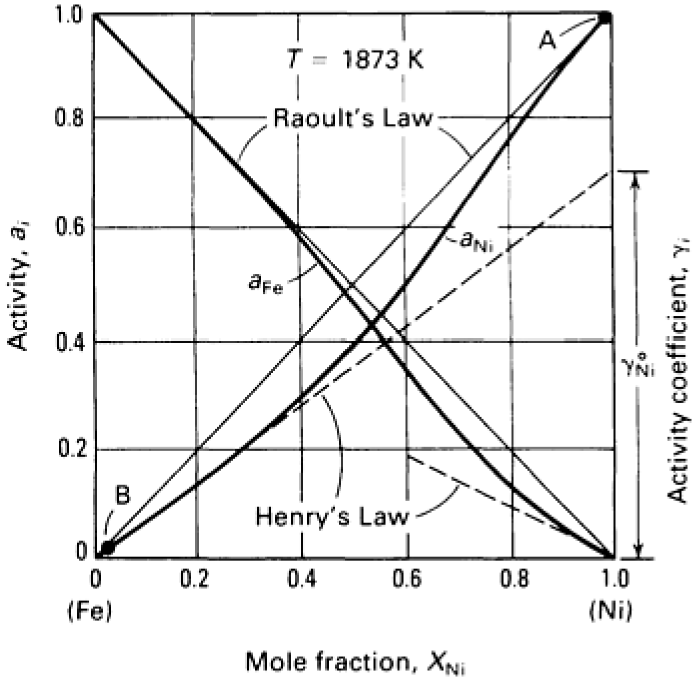

Fig. 1 Activities of iron and nickel in their binary solutions at 1873 K. Source: Ref 4, 5.

In this case, $\Delta G^{\circ}_{i} = 0$ because the standard state and the baseline conditions are identical. The term $RT \cdot \ln X_{Ni}$ is the change in $\Delta\overline{G}_{Ni}$ for an ideal solution $\Delta\overline{G}^{ideal}_{Ni}$. The term $RT \cdot \ln \gamma_{Ni}$ provides the correction for the real system. As seen, $\gamma_{Ni} < 1$. Thus, $\Delta\overline{G}_{Ni}$ is more negative than $\Delta\overline{G}^{ideal}_{Ni}$. Larger negative free energy values indicate greater stability. Thus, real solutions of nickel in iron are more stable than ideal solutions of nickel in iron.

A common characteristic of the activity of a component in solution is the relatively linear portion of the curve as $X_i \to 0$. This limiting slope, designated g^0_i (Fig. 1), is known as the Henry's law constant.

The 1 wt% solution standard state is marked point B in Fig. 1. It falls within or near the range in which the activity coefficient is a constant (g^0_i). By defining the standard state at point B, $f_i = 1$ in the linear region and conveniently h_i = (%*i*). The expression that corresponds to Eq 21 for the 1 wt% standard state is:

$$\Delta\overline{G}_{Ni} = \Delta \hat{G}^{o}_{Ni} + RT \cdot \ln (\%Ni) + RT \cdot \ln (f_{Ni}) \qquad \textbf{(Eq 22)}$$

In Eq 22, ΔG°_{Ni} is designated $\Delta \hat{G}^{o}_{Ni}$ to indicate that it refers to the 1 wt% standard state. Clearly, for any iron-nickel composition, $\Delta\overline{G}_{\text{Ni}}$ is the same whether it is calculated by Eq 21 or 22. Therefore, the choice is one of convenience. In this case, $\Delta \hat{G}^{o}_{Ni} \neq 0$. It is the change in free energy in taking pure liquid nickel to point B on the Henry's law line.

The difference in ΔG°_{i} between standard states A and B is

$$\Delta \hat{G}^{o}_{i} = \Delta G^{o}_{i} + RT.\ln\left(\frac{a_B}{a_A}\right) = \Delta G^{o}_{i} + RT.\ln\left(\frac{M_s g^{o}_{i}}{M_s + 99M_i}\right) \quad \textbf{(Eq 23)}$$

where the activities for composition *A* and *B* are Raoultian and M_s and M_i are the molecular weights, respectively, of solvent and solute. The equilibrium constant expressions (Eq 17) for the pure material and 1 wt% standard states are:

$$\sum_i v_i \Delta G^{o}_{i} = -RT \sum \ln(g_i X_i)^{v_i} \quad \textbf{(Eq 24)}$$

$$\sum_i v_i \Delta \hat{G}^{o}_{i} = -RT \sum \ln[f_i(\%i)]^{v_i} \quad \textbf{(Eq 25)}$$

Very often $\Delta\overline{G}^{o}_{i}$ for components in the equilibrium constant are expressed in different standard states. There is no problem with this as long as appropriate values ΔG°_{i} or $\Delta \hat{G}^{o}_{i}$ are used.

Tabulations of Activity Coefficient Data. Tabulations of ΔG°_{i} data were already discussed. From Eq 23, 24, and 25, it is seen that data for g^{0}_{i}, γ_i, and f_i are also needed. Tabulations of g^{0}_{i} and $\Delta \hat{G}^{o}_{Ni}$ for elements in solution in liquid iron, cobalt, and copper are given in Ref 3. Similar data for aluminum are included in the article "Thermodynamic Properties of Aluminum-Base and Copper-Base Alloys" in this Section. Data for γ_i and f_i for iron, copper, and aluminum multicomponent alloys are available in Ref 6, 7, and 8. These data are based on a formalism (Ref 9) that is discussed in the article "Thermodynamic Properties of Aluminum-Base and Copper-Base Alloys" in this Section. Another formalism (Ref 10, 11) is used to describe the activities of carbon and silicon in multicomponent ferrous alloys in the article "Thermodynamic Properties of Iron-Base Alloys" in this Section. Most of the tabulated values were obtained from studies in dilute solution (Henry's law region). From Fig. 1 it can be seen that the shapes of the activity curves are complex. Therefore, data for the Henry's law region has only limited applicability outside the region.

To describe $\Delta\overline{G}_i$ over the entire composition range, tables giving $\Delta\overline{G}_i$ as a function of composition are used. These data are usually available only for binary alloy systems. Tables for important aluminum and copper binary systems are given in the article "Thermodynamic Properties of Aluminum-Base and Copper-Base Alloys" in this Section. Comparable data for iron are available in Ref 12. Because $\Delta\overline{G}_i$ is temperature dependent, the data are commonly given as $\Delta\overline{H}_i$ and $\Delta\overline{S}_i$, where $\Delta\overline{G}_i$ is obtained by:

$$\Delta\overline{G}_i = \Delta\overline{H}_i - T \cdot \Delta\overline{S}_i \quad \textbf{(Eq 26)}$$

Examples of the use of Eq 1 to 26 are found in other articles in this Section.

Phase Diagrams

Phase diagrams describe the phases that coexist at equilibrium. Because chemical equilibrium is involved, phase diagrams have a thermodynamic basis. The complexity and variety of relationships demonstrated by phase diagrams place a

detailed description beyond the scope of this article. A qualitative demonstration of the interrelationship between phase diagrams and thermodynamics will be given.

For a multiphase system, a condition of equilibrium is that the partial molar free energy or chemical potential of each component must be the same in all phases (α, β, . . .):

$$\Delta\overline{G}_i^a = \Delta\overline{G}_i^b \qquad \textbf{(Eq 27)}$$

Thus, for example, the chemical potential of carbon in carbon-saturated iron is the same as graphite, despite less than 5 wt% C in saturated iron. A similar situation exists with respect to silicon/aluminum-silicon alloy equilibrium, where the chemical potential of pure silicon is matched by less than 15 wt% Si in solution.

Phase diagrams describe stability relationships for compounds and solutions (solid and liquid). To understand the relationships based on thermodynamics, it is necessary to compare the phase diagram (temperature-composition plot) with the equivalent free energy-composition plot. To construct the free energy-composition plot, it must be recognized that for a binary solution the integral molar free energy is:

$$\Delta G = X_1 \cdot \Delta\overline{G}_1 + X_2 \cdot \Delta\overline{G}_2 \qquad \textbf{(Eq 28)}$$

Substituting Eq 16 into Eq 28 and assuming ideal solutions ($\alpha_i = X_i$) yields F^*, the free energy change in forming 1 mol of an ideal, binary solution from components in the pure standard state (taken as the pure liquid in this case):

$$F^* = \Delta G - (X_1 \cdot \Delta G_1^\circ + X_2 \cdot \Delta G_2^\circ) = RT\,(X_1 \cdot \ln X_1 + X_2 \cdot \ln X_2) \qquad \textbf{(Eq 29)}$$

A plot of F^* as a function of X_2 is given in Fig. 2. Clearly, $F^* < 0$ with a minimum at $X_2 = 0.5$. For nonideal solutions ($\gamma_i \neq 1$), the curve can be higher or lower than the ideal line, and it can be asymmetrical. It can be shown that the intercepts of a tangent line drawn at any point on the curve will give ($\Delta\overline{G}_1 - \Delta G_1^\circ$) and ($\Delta\overline{G}_2 - \Delta G_2^\circ$) (Ref 13). These are the partial molar free energies of solution from the liquid standard state. For metallic solutions, $\Delta G_i^\circ = 0$; therefore, $\Delta\overline{G}_i$ is obtained directly from this plot.

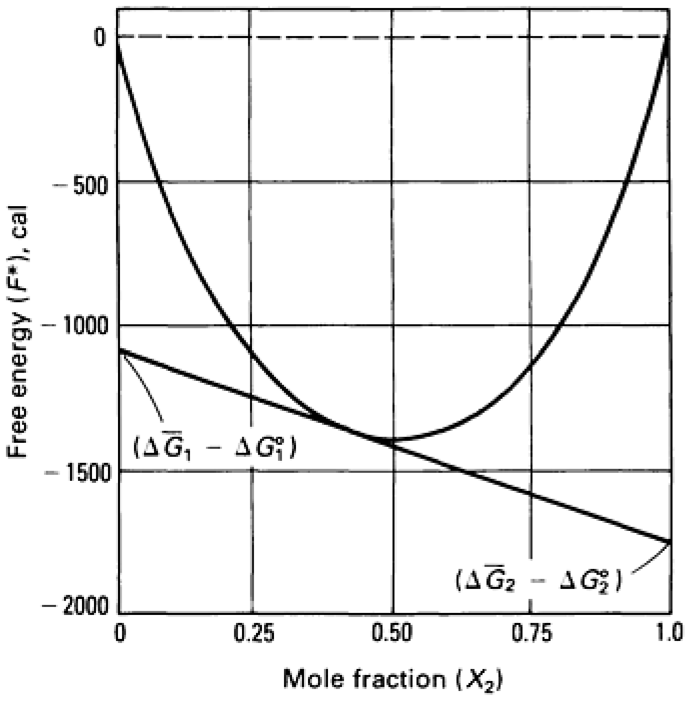

Fig. 2 Free energy of formation of an ideal solution from liquid components in the pure material standard state. Also illustrated is the graphic method of tangents to determine the partial molar free energies of solution.

The free energy of a phase of definite composition is represented as a point on the free energy-composition diagram. Clearly, if such a phase were in equilibrium with a solution, the equilibrium solution and the compound would have to lie along the same tangent line in order for Eq 27 to hold. This condition is illustrated in Fig. 3(a). Figure 3(b) shows the phase diagram that results from the thermodynamic constraints. In Fig. 3(a), $F^* < 0$ for pure solid phase 1 because the liquid was chosen as the standard state, and at the temperature chosen, the liquid is less stable than the solid.

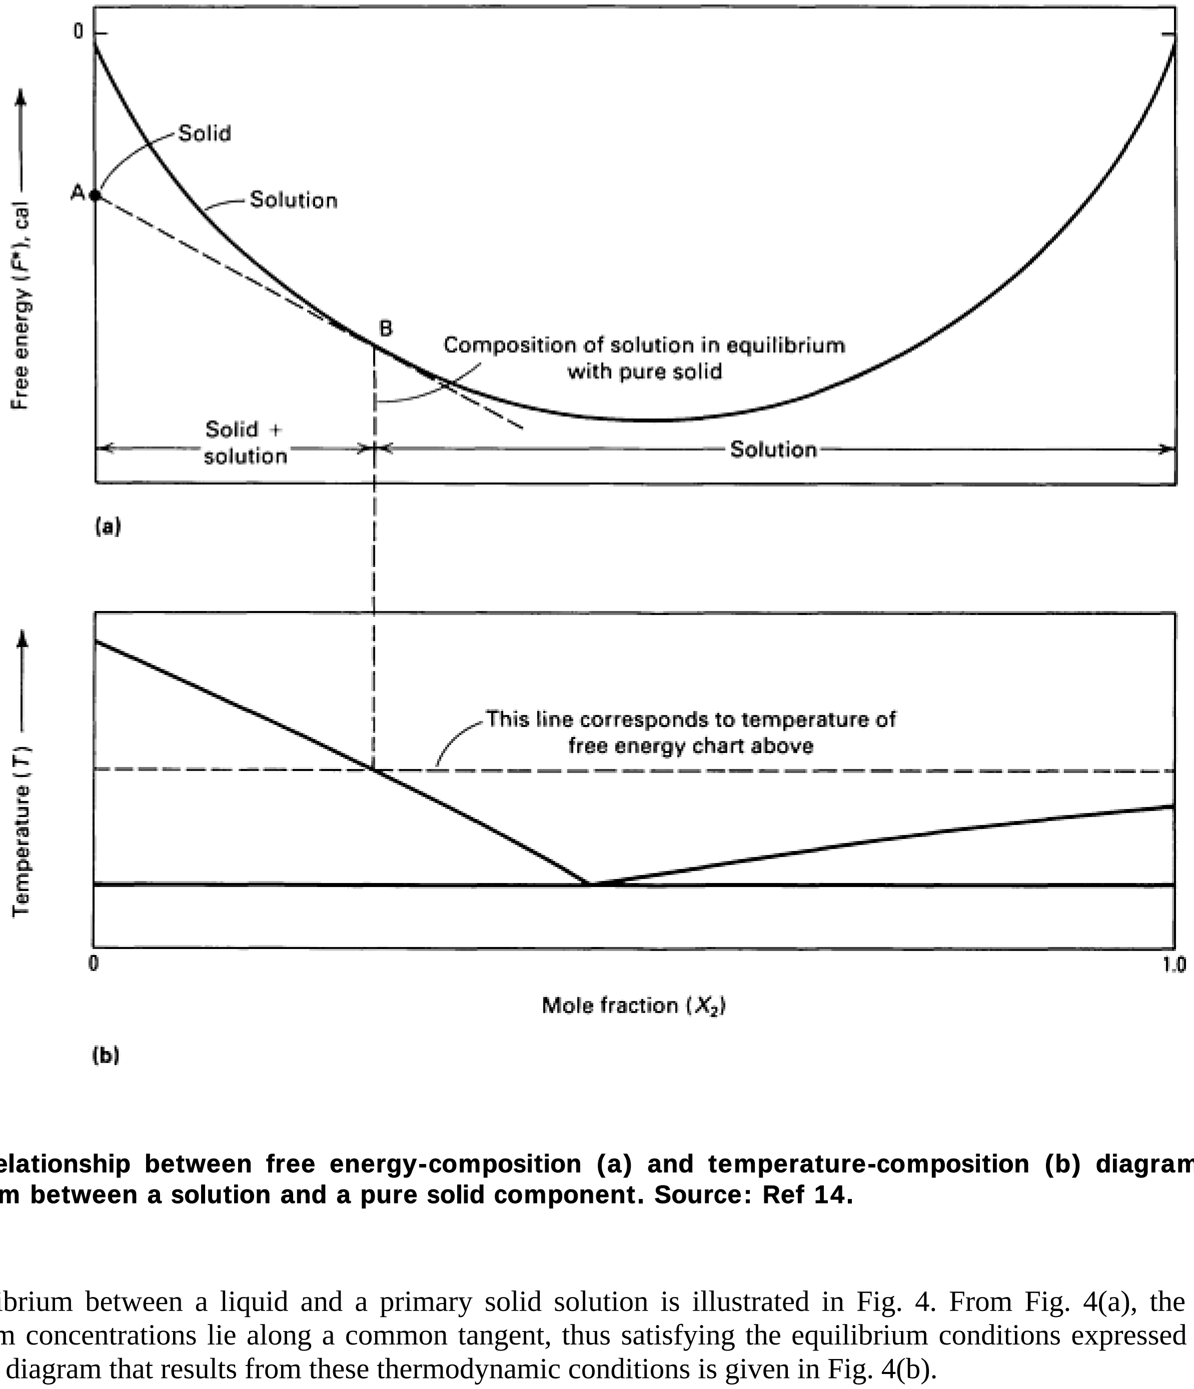

Fig. 3 Relationship between free energy-composition (a) and temperature-composition (b) diagrams for the equilibrium between a solution and a pure solid component. Source: Ref 14.

The equilibrium between a liquid and a primary solid solution is illustrated in Fig. 4. From Fig. 4(a), the respective equilibrium concentrations lie along a common tangent, thus satisfying the equilibrium conditions expressed by Eq 27. The phase diagram that results from these thermodynamic conditions is given in Fig. 4(b).

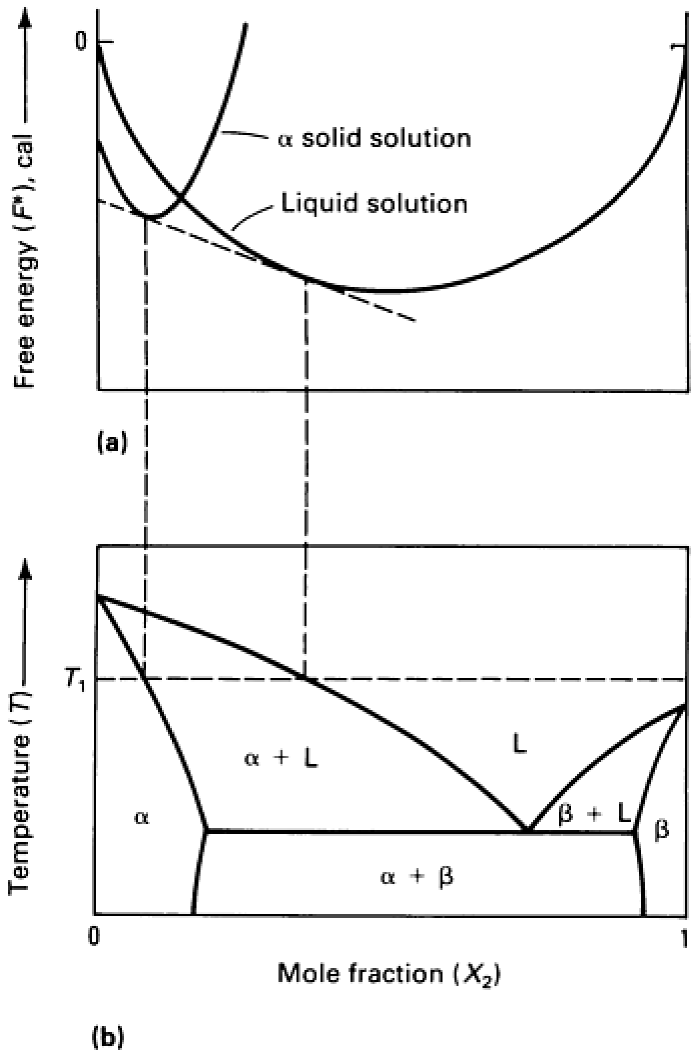

Fig. 4 Relationship between free energy-composition (a) and temperature-composition (b) diagrams for the equilibrium between a liquid and a primary solid solution. Source: Ref 15.

For small values of X_2, either solution can theoretically exist. The solid phase is expected to be present, however, because it is more stable (lower F^*). If, by virtue of such factors as rapid cooling, the liquid phase is retained in a region where the solid is more stable, a metastable condition would exist. This is not uncommon is systems of metallurgical interest. Common examples are cementite (Fe_3C), which is metastable with respect to iron and graphite, and the glass (supercooled liquid) condition of slags, which is metastable with respect to crystalline compounds.

Chemical Kinetics

The rates of chemical processes depend so much on local conditions that it is difficult to describe the processes in the universal terms used in thermodynamics. The rates of chemical change in solid cast metals are usually governed by solid diffusion. This subject will be examined in the Section "Principles of Solidification" in this Volume. For processes involving fluids at high temperatures, the rates of chemical reactions are inherently rapid and usually not rate limiting. The processes that generally limit the rate are nucleation of the product phase and interphase mass transport (moving material between immiscible phases).

Nucleation

The problem of nucleation is universal to the kinetics of solidification, and the subject will be treated more extensively in the article "Nucleation Kinetics" in this Volume. However, a few general comments are in order.

Nucleation of a phase in an inclusion-free metal requires supersaturation with respect to the material being precipitated. For this condition, the chemical potential of the material in the melt exceeds that in the precipitate, which is the requirement for spontaneous reaction. Initially, the diameter of the precipitated phase is in the atomic range. Thermodynamics dictates that the activity of particles increases with decreasing radius of curvature. Therefore, the activity of atomic-size particles is very high. This in turn requires very high melt supersaturation to meet the requirement for spontaneous nucleation. This barrier to the generation of nuclei from a homogeneous melt, imposed by thermodynamics, makes it unlikely that appreciable nucleation occurs by this mechanism. Instead, nucleation is initiated on particles purposely introduced to the melt before solidification. For example, TiB_2 particles are in use to nucleate aluminum melts (Ref 16), and complex oxysulfide particles nucleate graphite in gray and ductile iron (Ref 17, 18).

Interphase Mass Transport

Because high-temperature reactions are rapid, the rate-limiting step in many cases of heterogenous reaction is the diffusion of reactants to and from the reaction interface. This is particularly the case when the reactants are dilute. Because the reaction rate in these cases is rapid relative to rates of diffusion, the concentration of a reacting species at the reaction interface is either above or below the bulk concentration. The condition that exists depends on whether the activity of the reactive species in the second phase is higher or lower than the activity in the bulk.

The model, frequently used in quantifying mass transfer limited kinetics, assumes that there is a thin stagnant film at the interface across which a concentration gradient exists. The model is schematically represented in Fig. 5. Transport across

the boundary layer is assumed to occur only by diffusion. Applying Fick's first law of diffusion, the flux of species *i* across the boundary layer is:

$$J = \frac{D}{d}(C_i^* - C_i^B) = k_m(C_i^* - C_i^B) \qquad \textbf{(Eq 30)}$$

where *D* is the diffusion coefficient, δ is the boundary layer thickness, and C^*_i and C_i^B are concentrations of the diffusion species, respectively at the interface and in the bulk. The term *D*/δ is seldom used; instead, the mass transfer coefficient k_m is used to represent *D*/δ. When phase 2 is a fluid, δ decreases with increasing fluid velocity along the interface (that is, increased convection). Thus, k_m is a function of the fluid dynamic condition.

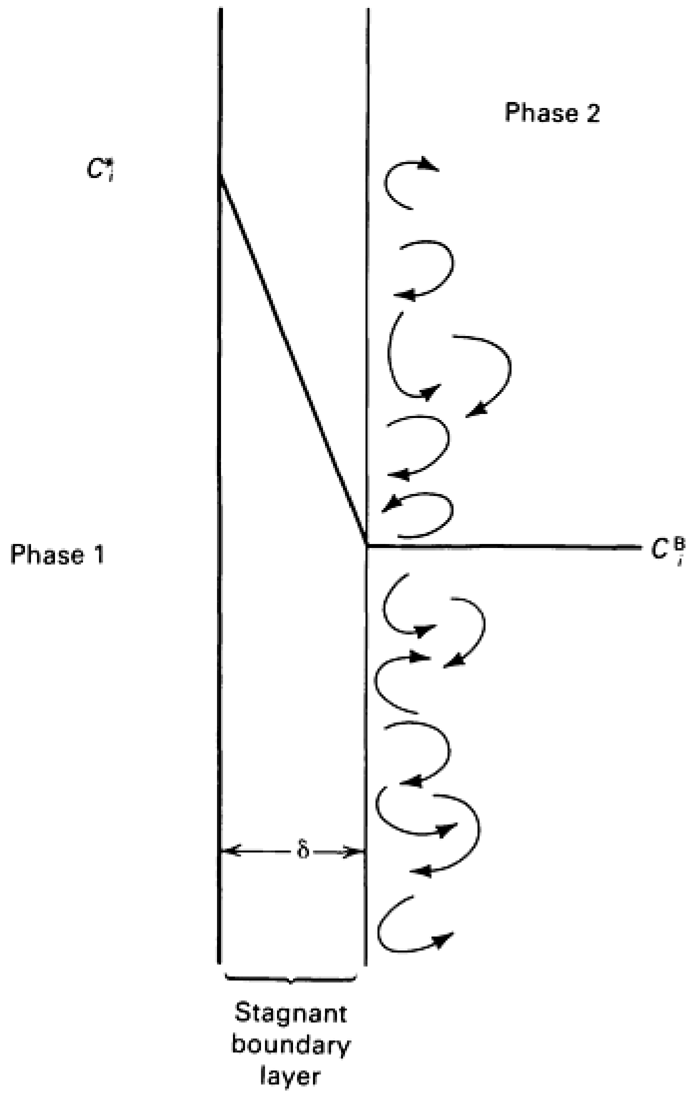

Fig. 5 Boundary layer model used for mass transfer limited kinetics.

To determine the rate of reaction, that is, *J*, it is necessary to know C^*_i. This is difficult to determine experimentally. To circumvent the problem, one of two assumptions is commonly made. For extremely fast reactions in which the equilibrium constant is very large, C^*_i can be assumed to be 0. Thus, Eq 30 reduces to:

$$J = -k_m C_i^B \qquad \textbf{(Eq 31)}$$

This assumption has been used to describe the high-temperature gasification of coke (Ref 19). The second assumption is that equilibrium between the two phases is established at the reaction interface. In this case, Eq 30 is written as:

$$J = k_{\mathrm{m}} \left(C_i^{*equil} - C_i^B \right) \qquad \textbf{(Eq 32)}$$

The value of C_i^{*equil} is determined from the equilibrium constant expression, knowing the activities of all the reactants and products except C_i^{*equil}. A number of examples of this treatment will be found in succeeding articles in this Section.

There are cases in which the reaction rate (rate constant k) at the interface, unimpeded by diffusion, is of the same order as the mass transfer limited rate. In this case, the observed rate and the rate constant k' are affected by both processes. This relationship is illustrated below.

Because diffusion of *i* through the boundary layer and the reaction of *i* at the interface occur sequentially, the rates of both processes must be the same at steady state. Thus:

$$J = k_{\mathrm{m}}(C^*_i - C_i^B) = -k(C^*_i - C_i^{*equil}) \qquad \textbf{(Eq 33)}$$

where the last term gives the first-order rate of reaction occurring at the interface. Eliminating C^*_i in the last two terms in Eq 33 yields:

$$J = k' \left(C_i^{*equil} - C_i^B \right) \qquad \textbf{(Eq 34)}$$

where

$$\frac{1}{k'} = \left(\frac{1}{k_m} + \frac{1}{k} \right) \qquad \textbf{(Eq 35)}$$

It is clear from Eq 34 and 35 that for the condition k **?** k_{m}, Eq 34 reduces to Eq 32. Applications in which mixed control is important are nitrogen absorption in iron alloy melts (Ref 20) and coke gasification at intermediate temperature (Ref 19).

Thermodynamic Properties of Aluminum-Base and Copper-Base Alloys

Basant L. Tiwari, General Motors Research Laboratories

Introduction

THIS ARTICLE will provide accessible information on the thermodynamic properties of liquid aluminum-base and copper-base alloys. Three alternative means have been used to report the thermodynamic data:

- Activities and activity coefficients
- Partial and integral molar thermal properties
- Interaction coefficients

In addition, the utility of phase diagrams will be briefly discussed. Knowledge of activities and activity coefficients is necessary in describing solution behavior and in solving problems that involve chemical equilibria. The thermal properties are useful in understanding the liquid state and in correlating data on solution behavior. The interaction coefficients provide a simple means of calculating activity coefficients in dilute solutions and are also used to correlate experimental data on dilute solutions.

Activities and Thermal Properties

The activity *a* of constituent *i* in a solution is given by the relationship:

$$\Delta \overline{G}_i = \Delta \overline{H}_i - T\Delta \overline{S}_i = RT \ln a_i \qquad \textbf{(Eq 1)}$$

where $\Delta \overline{G}_i$, $\Delta \overline{H}_i$, and $\Delta \overline{S}_i$ are the partial molar free energy, enthalpy, and entropy, respectively, of constituent *i* in solution relative to the pure constituent *i* at the solution temperature as the standard state; *T* is the temperature (in degrees kelvin), and *R* is the universal gas constant. Thus, from the knowledge of $\Delta \overline{H}_i$ and $\Delta \overline{S}_i$ as functions of temperature and solution composition, one may calculate $\Delta \overline{G}_i$, a_i, and γ_i (activity coefficient of component *i* relative to pure material standard state) for all conditions of solution. It is important to realize, however, that thermal property values vary with solution composition, unlike the properties of pure substances.

Replacing a_i in Eq 1 with $X_i\gamma i$ yields:

$$\Delta \overline{G}_i = RT \ln X_i + RT \ln \gamma_i \qquad \textbf{(Eq 2)}$$

where X_i is the mole fraction of component *i.* In Eq 2, the term $RT \ln \gamma_i$ is called partial molar excess free energy and is expressed by the symbol $\Delta\overline{G}_i^{XS}$. It represents the contribution to $\Delta \overline{G}_i$ resulting from the departure of solution from ideal behavior. Thus, one may write:

$$\Delta\overline{G}_i^{XS} = RT \ln \gamma_i \qquad \textbf{(Eq 3)}$$

Corresponding to Eq 1, $\Delta\overline{G}_i^{XS}$ can also be expressed as:

$$\Delta\overline{G}_i^{XS} = \Delta\overline{H}_i^{XS} - T\,\Delta\overline{S}_i^{XS} = RT \ln \gamma_i \qquad \textbf{(Eq 4)}$$

However, because $\Delta \overline{H}_i$ for the ideal solution is 0 by definition, $\Delta\overline{H}_i^{XS}$ and $\Delta \overline{H}_i$ are identical. Therefore, Eq 4 can be rewritten as:

$$\Delta\overline{G}_i^{XS} = \Delta \overline{H}_i - T\,\Delta\overline{S}_i^{XS} = RT \ln \gamma_i \qquad \textbf{(Eq 5)}$$

Equations 1 and 5 are commonly used to calculate activities and activity coefficients from the thermal properties of the solution.

Although the partial molar thermal properties of individual constituents in a solution are most useful in solving chemical process problems, the integral properties are valuable in the discussion of the nature of solutions and also serve in some cases as the source of data on the partial properties. The integral molar free energy is related to the partial molar free energy by the following relationship:

$$\Delta G_i = X_i \Delta \overline{G}_i + \overline{X}_j \Delta \overline{G}_j + \ldots . X_n \Delta \overline{G}_n \qquad \textbf{(Eq 6)}$$

Similar equations can also be written to express other integral thermal properties.

In Tables 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, and 14, thermodynamic data in the form of activities, activity coefficients, partial molar thermal properties, and integral molar properties have been compiled for selected aluminum-base and copper-base alloys. The alloy systems have been chosen based on their commercial importance and on the concentration of the major alloying elements. In general, the concentrations of the alloying elements in the commercial alloys are below 10 at.%, and under this condition the interaction coefficient method described below provides a convenient means of calculating the activities of the constituents in solution. When the concentrations are close to or greater than 10 at.%, the interaction coefficient method does not yield accurate values. With this factor in mind, thermodynamic data have been selected for the following alloy systems: Al-Mg, Al-Si, Cu-Al, Cu-Ni, Cu-Sn, and Cu-Zn.

Interaction Coefficients

The use of interaction coefficients, first suggested by Wagner (Ref 3), provides a convenient means of organizing thermodynamic data on dilute solutions. Wagner proposed a Taylor series expansion for the excess partial molar free energy in order to express the logarithm of the activity coefficient of a dilute constituent in a multicomponent solution. The values of the activity coefficients calculated from this method are as accurate as the original data from which the interaction coefficients are determined, provided it is applied to solutions that are quite dilute ($X_i < 0.1$).

Consider a dilute solution of *i, j,* and *k* dissolved in a common solvent, s. If all but the first-order terms of the Taylor series expansion are neglected, the activity coefficient of solute *i* is expressed by the relationship:

$$\ln g_i = \ln g_i^o = X_i\left(\frac{\partial \ln g_i}{\partial X_i}\right) + X_j\left(\frac{\partial \ln g_i}{\partial X_j}\right) + X_k\left(\frac{\partial \ln g_i}{\partial X_k}\right) \quad \textbf{(Eq 7)}$$

In Eq 7, the partial derivatives are called interaction coefficients and are expressed by the symbol e_i^j, where the superscript denotes the constituent that affects the activity coefficient of the subscript constituent. Thus:

$$\epsilon_i^i = \left(\frac{\partial \ln \gamma_i}{\partial X_i}\right)_{X_j} X_k = 0; X_i \rightarrow 0$$

$$\epsilon_i^j = \left(\frac{\partial \ln \gamma_i}{\partial X_j}\right)_{X_k} = 0; X_i, X_j \rightarrow 0 \qquad \textbf{(Eq 8)}$$

$$\ln \gamma_i = \ln \gamma_i^o + X_i \epsilon_i^i + X_j \epsilon_i^j + X_k \epsilon_i^k$$

In Eq 8, g_i^o is the limiting value of γ_i at infinite dilution:

$$g_i^o = \lim_{X_i \rightarrow 0} \gamma_i \qquad \textbf{(Eq 9)}$$

If the solution of *i* in s obeys Henry's law over a small range of concentration, then γ_i is a constant over this range, and $e_i^i = 0$.

It can be shown by using the Gibbs-Duhem equation that:

$$e_i^j = e_j^i \qquad \textbf{(Eq 10)}$$

and this reciprocal relation is most useful in determining values of ε from activity data.

Values of e_i^i are determined from experimental data on the binary system ***i***-s, and values of e_i^j are determined from experimental data on the ternary system ***i-j***-s. Values of γ^o and ε for aluminum-base and copper-base alloys are given in Tables 15, 16, 17, 18, and 19.

The standard state for ε and γ^o described above is the pure material at the temperature of the solution, and the concentration is expressed in mole fraction. In dealing with dilute solutions, however, it is common to use a hypothetical 1 wt% solution as the standard state. Under this condition, the Taylor series expansion corresponding to Eq 8 is:

$$\log f_i = e_i^i\ (\%i) + e_i^j\ (\%j) - e_i^k\ (\%k) \qquad \textbf{(Eq 11)}$$

where f_i, which is the activity coefficient for 1 wt% standard state, equals $a_i/\%i$ and:

$$e_i^j = \left(\frac{\partial \log f_i}{\partial \% j} \right)_{\%k=0;\%i\%j\to 0} \qquad \textbf{(Eq 12)}$$

In Eq 11, f_i is the activity coefficient, and the zeroeth-order term, log f_i^o, disappears because the activity coefficient at infinite dilution f_i^o is equal to 1.

The reciprocal relationship, corresponding to Eq 10, is:

$$e_i^j = \frac{M_i}{M_j} e_j^i \qquad \textbf{(Eq 13)}$$

where M_i is the atomic weight of *i*. The relationship between the two types of the interaction coefficients is:

$$e_i^j = \frac{M_s}{(2.303)(100)M_j} e_i^j \qquad \textbf{(Eq 14)}$$

where M_s is the atomic weight of the solvent (Al, Cu).

Thermal Properties for Hypothetical Standard State

It is a common practice in solving problems on chemical equilibria to use the hypothetical pure component (X_i) or hypothetical weight percent (%*i*) as the standard state. For this purpose, thermodynamic properties for the hypothetical standard states are needed. The values of γ^o can be used to determine Gibbs free energies of mixing for elements in liquid base metal, using Eq 15 and 16:

$$\Delta G_i^o\ (X_i) = RT \ln\ g_i^o \qquad \textbf{(Eq 15)}$$

and

$$\Delta G_i^o(\%i) = RT \ln \frac{g_i^o M_s}{100 M_i} \qquad \textbf{(Eq 16)}$$

The values of ΔG_i^o (X_i) and ΔG_i^o (%*i*) thus calculated for aluminum-base and copper-base alloys are also given in Tables 15 and 17. The principal advantage of using the hypothetical standard states is that at low concentrations the activity of *i* can be set equal to its atom fraction or weight percent, depending on the composition scale used to express the standard state.

Phase Diagrams

A phase diagram is essentially a map that shows the relative stabilities of various phases present at equilibrium under the varying conditions of temperature and composition. Therefore, for a given composition of an alloy, a phase diagram can be used to determine the phases, which will be present at equilibrium as the melt solidifies. In addition, a phase diagram can also be used to estimate the activity of the components in liquid solution and to understand the behavior of the liquid solution (Ref 8). For example, if the diagram is for a simple eutectic system, it is likely that no strong intermetallic compound exists. If, however, a strong compound in the solid state appears in the diagram, then association of dissimilar atoms is probably occurring in the liquid. Therefore, one can predict whether a liquid solution will exhibit strong negative or positive deviations from the ideal behavior from the shapes of the liquids and azeotropes.

The phase diagrams of the Al-Si and Cu-Zn systems, which are chosen based on their commercial importance, are shown in Fig. 1 and 2. The aluminum-silicon diagram (Fig. 1) represents a simple eutectic system, and the alloys containing 8.5 to 13% Si are widely used to produce automotive parts. Generally, the higher the silicon content, up to the eutectic composition (12.6% Si), the greater the fluidity and, consequently, the easier an alloy is to cast. The copper-zinc diagram (Fig. 2) however, shows a high solubility of zinc in solid copper-zinc solution and the formation of several other phases over a wide range of zinc concentrations. Copper alloys containing up to 35% Zn and significant amounts of other alloying elements are quite common. The copper-zinc phase diagram is used to adjust the compositions in order to produce alloys with the desired properties.

Thermodynamic Properties of Iron-Base Alloys

D.M. Stefanescu, University of Alabama

Introduction

BECAUSE the structures of steel and cast iron directly influence their mechanical properties, one of the most important tasks of a metallurgist is to control the solidification structure in castings. To accomplish this, it is necessary to understand and control the thermodynamics of the liquid and solid phases and the kinetics of solidification (nucleation and growth of various phases). The information linked to the practical interests that thermodynamics can provide when considering iron-base alloys encompasses a rather wide range.

Only two issues will be addressed in this article. The first is the calculation of solubility lines, relevant to the construction of phase diagrams, and the second is the calculation of the activity of various components, which allows for the determination of probability of formation and relative stability of various phases. Alloying elements will then be discussed in terms of their influence on the activity of carbon, which provides information on the stability of the main carbon-rich phases of iron-carbon alloys, that is, graphite and cementite.

Thermodynamics of Binary Fe-*X* Systems

Only the Fe-C and Fe-Si systems will be discussed in this article. Information on the Fe-O system is available in the article "Inclusion-Forming Reactions" in this Volume.

The Fe-C System. The phase diagram of the binary Fe-C system includes the stable (Fe-graphite) and metastable (Fe-Fe_3C) equilibria. The most recent diagram is shown in Fig. 1. The solubility of carbon in iron is described in Eq 1, 2, 3, 4, 5, 6, and 7 (Ref 2, 3).

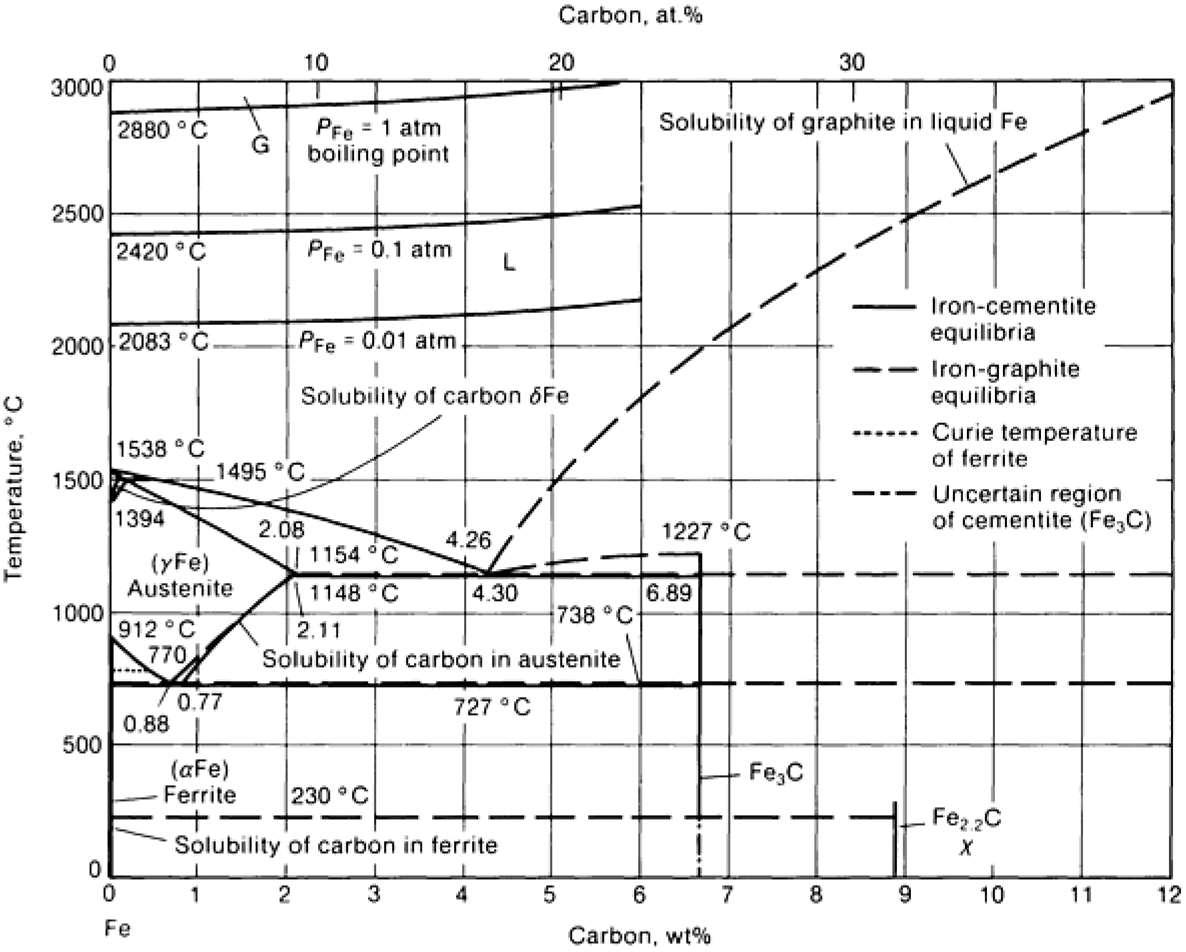

Fig. 1 Phase diagram for the binary Fe-C system. Source: Ref 1.

For the stable system, that is, with graphite as the equilibrium high-carbon phase, Eq 1, 2, and 3 are used. For the liquid:

$$\text{wt\%C}_{max} = 1.3 + 2.57 \times 10^{-3}\, t \qquad \textbf{(Eq 1)}$$

in the interval 1152 to 2000 °C (2106 to 3632 °F), with *t* being the temperature in degrees Celsius. Using thermodynamic quantities, Eq 1 can be written as:

$$\log X_{C\max} = -\frac{12.728}{T} + 0.727 \log T - 3.049 \qquad \textbf{(Eq 2)}$$

where XC_{max} is the maximum solubility of graphite in liquid iron in mole fraction and *T* is the temperature in degrees Kelvin. Equation 2 is valid for the interval 1425 to 2300 K. For the austenite:

$$\text{wt\%C}_{max} = -0.435 + 0.355 \times 10^{-3}\, t + 1.61 \times 10^{-6}\, t^2 \qquad \textbf{(Eq 3)}$$

For the ferrite:

$$wt\%C_{\max} = 2.46\ x\ 10^3 \exp\left(-\frac{11460}{T}\right) \qquad \textbf{(Eq 4)}$$

For the metastable system, that is, with Fe_3C as the equilibrium high-carbon phase, Eq 5, 6, and 7 apply. For the liquid:

$$wt\%C_{\max} = 4.34 + 0.1874(t - 1150) - 200 \ln \frac{t}{1150} \qquad \textbf{(Eq 5)}$$

For the austenite:

$$\text{wt\%C}_{\max} = -0.628 + 1.222 \times 10^{-3}\, t + 1.045 \times 10^{-6}\, t^2 \qquad \textbf{(Eq 6)}$$

For the ferrite:

$$wt\%C_{\max} = 1.8\ x\ 10^3 \exp\left(-\frac{10908}{T}\right) \qquad \textbf{(Eq 7)}$$

Equations 1, 2, 3, 4, 5, 6, and 7 can be used to calculate the maximum solubility of carbon in various phases (liquid, austenite, ferrite) as a function of temperature. For example, to calculate the carbon content of the stable eutectic, Eq 1 is used with t = 1152 °C (2106 °F) to obtain $\%C_{max}$ = 4.26%.

Prediction of phase stability relies heavily on knowledge of the activity of various elements. In the specific case of iron-carbon alloys, an increase in the activity of carbon in the liquid parallels a greater ability of carbon to separate as graphite; that is, the activity of carbon is a measure of an increased tendency of the alloy to solidify as the stable system. On the other hand, a decreased activity of carbon reflects the carbide-promoting behavior of the system, that is, the metastable solidification tendency.

The general equation used to describe the activity of a component 2 in a component 1 according to the Darken formalism (Ref 4) is:

$$\log \frac{g_2}{g_2^o} = a_{12}(X_2^2 - 2X_2) \qquad \textbf{(Eq 8)}$$

where γ_2 is the activity coefficient of component 2 = a_2/X_2 (a_2 being the activity of component 2 and X_2 the mole fraction of component 2); g_2^o is the activity coefficient of component 2 in the range of infinitely dilute solutions, that is, when % component 2 $\cong 0$; it is only a function of temperature ($\gamma_2 \rightarrow g_2^o$ as $X_2 \rightarrow 0$); and α_{12} is the function of temperature, usually of the shape A/T + B, where A, B are constant.

For the activity of C in an iron melt, Eq 8 is valid for component 1 (Fe) and component 2 (C) with (Ref 5):

$$a_{Fe-C} = -\left(\frac{1270}{T} + 0.74\right) \qquad \textbf{(Eq 9)}$$

$$\log g_C^o = \frac{1180}{T} - 0.87 \qquad \textbf{(Eq 10)}$$

Using the natural logarithm (base e) instead of the common logarithm (base 10), Eq 8 can be written as follows for the Fe-C systems:

$$\ln g c = \frac{2714}{T} - 2 + \left(\frac{2920}{T} + 4.01\right)\left(2X_c - X_C^2\right) \qquad \textbf{(Eq 11)}$$

Equation 11 is in good agreement with experimental data, as shown in Fig. 2.

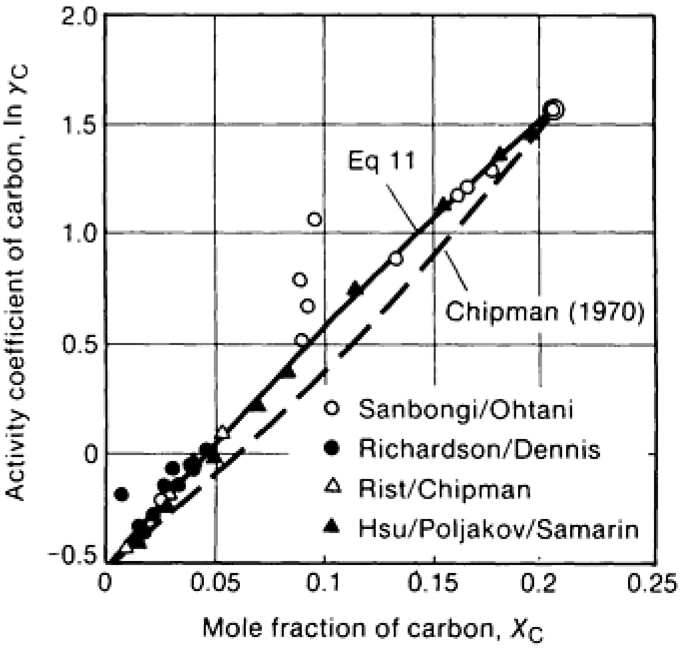

Fig. 2 Dependence of the activity coefficient of carbon on the mole fraction of carbon in liquid iron at 1550 °C (2820 °F). Source: Ref 5.

The Fe-Si System. Equation 8 can be used to calculate the activity of silicon in the Fe-Si system, with the following remarks (Ref 5): $X_{Si} \leq 0.2$; component 1 is iron; component 2 is silicon:

$$a_{Fe-Si} = -\left(\frac{153}{T} + 3.02\right) \quad \textbf{(Eq 12)}$$

$$\log g_{Si}^{o} = 0.914 - \frac{6863}{T} \quad \textbf{(Eq 13)}$$

As shown in Fig. 3, calculations with Eq 12 and 13 are in good agreement with experimental data (note that the equation in Fig. 3 results from introducing Eq 12 and 13 into Eq 8 and using a natural logarithm rather than a common logarithm).

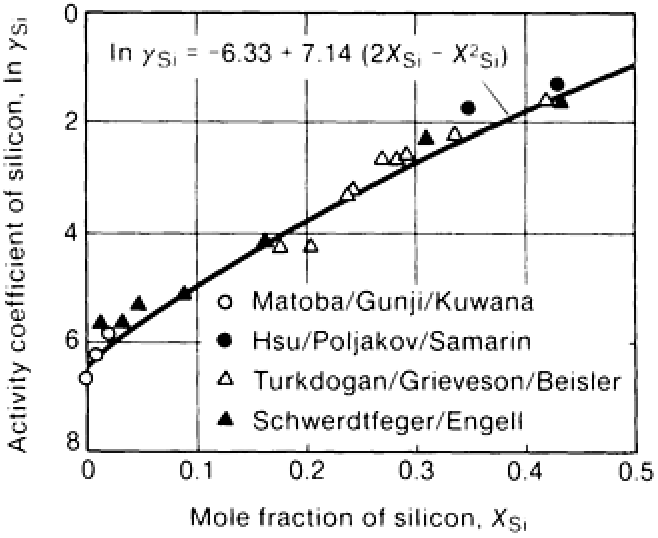

Fig. 3 Dependence of the activity coefficient of silicon on the mole fraction of silicon in liquid iron at 1600 °C (2910 °F). Source: Ref 5.

Thermodynamics of Ternary Iron-Base Alloys

Using a Taylor series expansion for the excess partial molar free energy, one researcher derived an expression for the activity coefficient of component 2 in a multi-component solution, which for dilute solutions can be written as (Ref 6):

$$\ln f_2 = \ln \frac{\gamma_2}{\gamma_2^o} X_2 \epsilon_{22} + X_3 \epsilon_{23} + X_4 \epsilon_{24}, \ldots \quad \textbf{(Eq 14)}$$

where γ_2 is the activity coefficient of component 2 dissolved in the three-component system, g_2^o is the activity coefficient of component 2 in the range of infinitely dilute solution, and ε_{22}, ε_{23}, ε_{24}, . . . are coefficients defined as:

$$\epsilon_{22} = X_1 \xrightarrow{\text{limit}} 1 \frac{\partial \ln f_2}{\partial X_2}$$

$$\epsilon_{23} = X_1 \xrightarrow{\text{limit}} 1 \frac{\partial \ln f_2}{\partial X_3} \quad \textbf{(Eq 15)}$$

For infinitely dilute solutions, that is, $X_2 \rightarrow 0$, $X_3 \rightarrow 0$:

$$\varepsilon_{23} = \varepsilon_{32}$$

Simplification of the Darken formalism for infinite dilutions gives the interrelationship between ε and α, as follows (Ref 7):

$$\frac{e_{22}}{2.303} = -2a_{12}$$
$$\frac{e_{33}}{2.303} = -2a_{13} \qquad \textbf{(Eq 16)}$$
$$\frac{e_{23}}{2.303} = \frac{e_{32}}{2.303} = -a_{23} - a_{12} - a_{13}$$

The solute concentration is often given in weight percent. For a ternary system, Eq 14 is written:

$$\log f_i = e_{ii}\,[\%i] + e_{ij}\,[\%j] \qquad \textbf{(Eq 17)}$$

where the interaction coefficient e is related to ε by:

$$\varepsilon_{ii} = 230\,(M_i/M_1)\,e_{ii} + [(M_1 - M_i)/M_1]$$
$$\varepsilon_{ij} = 230\,(M_j/M_1)\,e_{ij} + [(M_1 - M_j)/M_1] \qquad \textbf{(Eq 18)}$$

Data on interaction coefficients in liquid iron for carbon, hydrogen, nitrogen, oxygen, and sulfur are given in Table 1. For metallurgical reactions involving dilute solutions, it is often necessary to change the standard state from pure component to that of 1 wt% in solution. The free energy change is given by:

$$\Delta G_S = RT \ln \frac{0.5585 g_i^o}{M_i} \qquad \textbf{(Eq 19)}$$

Free energies of solution ΔG_s of selected elements in liquid iron are given in Table 2.

Thermodynamics of Ternary Fe-C-X Systems

Detailed equilibrium diagrams of the Fe-C-B, Fe-C-Cr, Fe-C-Cu, Fe-C-Mn, Fe-C-Mo, Fe-C-N, Fe-C-Ni, Fe-C-Si, and Fe-C-W systems are available in Ref 10. Only the Fe-C-Si, Fe-C-P, and Fe-C-Mn systems will be discussed in this article.

The Fe-C-Si System. The addition of silicon to a binary iron-carbon alloy decreases the stability of Fe_3C, which is already metastable, and increases the stability of ferrite (the α field is enlarged, and the γ field is constricted). The equilibrium diagrams in Fig. 4 show that as the silicon content in the Fe-C-Si system increases, the carbon contents of the eutectic and eutectoid decrease ($\%C_{max}$ decreases), while the eutectic and eutectoid temperatures increase (Ref 11). The activity coefficient, γ_2, of component 2, dissolved in a three-component system as a function of the concentration X_2 and X_3 of dissolved components 2 and 3, is described by Eq 20 (Ref 7):

$$\log \frac{g_2}{g_2^o} = -2a_{12}X_2 + (a_{23} - a_{12} - a_{13})X_3 + a_{12}X_2^2 + a_{13}X_3^2 + (a_{12} + a_{13} + a_{23})X_2X_3 \qquad \textbf{(Eq 20)}$$

where α_{12}, α_{13} are the modified interaction parameters of the two-component systems, α_{23} is the modified interaction parameter that describes the activity of both dissolved components, and g_2^o is the activity coefficient of component 2 in the range of infinitely dilute solution.

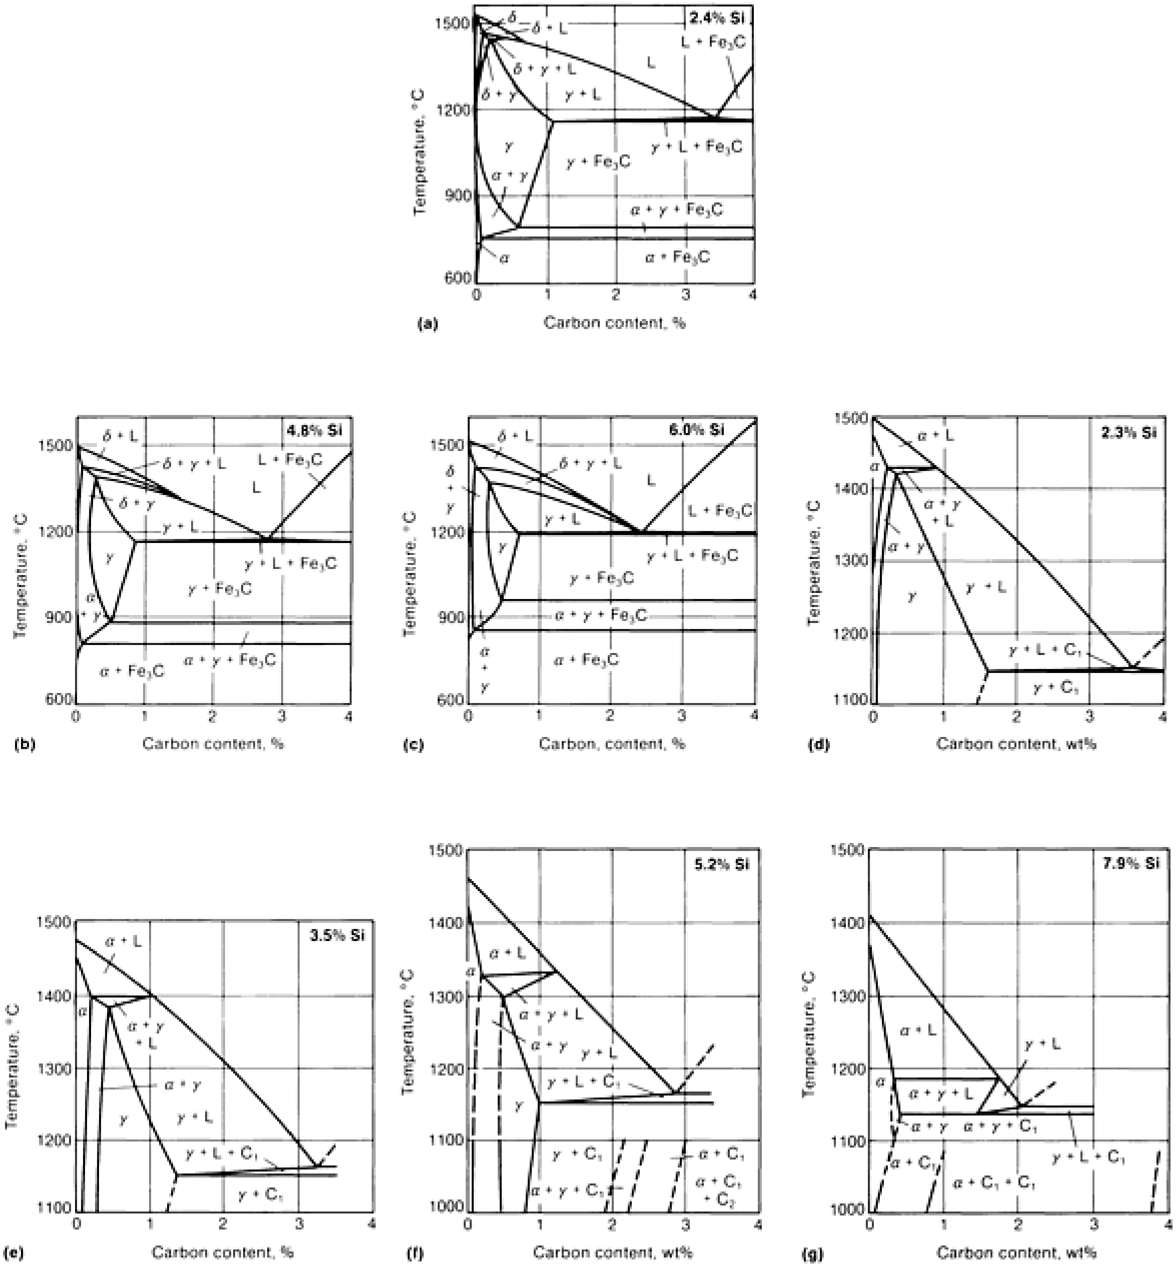

Fig. 4 Influence of silicon content on the solubility lines and equilibrium temperatures of the Fe-C system. (a) to (c) Source: Ref 11, (d) to (g) Source: Ref 10.

Starting from Eq 20, the activity of carbon and silicon in an Fe-C-Si melt can be calculated as a function of temperature and concentration with the following relationships (Ref 5):

$$\begin{aligned}\log a_C = {} & (1180/T) - 0.87 + [(2540/T) + 3.48]\, X_C \\ & - [(1270/T) + 1.74]\, X_C^2 + \log X_C \\ & + [(1423/T) + 4.75]\, X_{Si} - [(153/T) + 3.02]\, X_{Si}^2 \\ & - [(1423/T) + 4.76]\, X_C X_{Si}\end{aligned} \quad \text{(Eq 21)}$$

$$\begin{aligned}\log a_{Si} = {} & -(6863/T) + 0.914 + [(306/T) + 6.04]\, X_{Si} \\ & - [(153/T) + 3.02]\, X_{Si}^2 + \log X_{Si} \\ & + [(1423/T) + 4.76]\, X_C\end{aligned} \quad \text{(Eq 22)}$$

$$- [(1270/T) + 1.74]\ X_C^2$$
$$- [(1423/T) + 4.76]\ X_C X_{Si}$$

The Fe-C-P System. Because the partition coefficient of phosphorus between solid and liquid iron is low, phosphorus segregates into the liquid during solidification, and the melt becomes supersaturated in phosphorus, which results in the formation of Fe_3P. Therefore, the four possible solid phases of the stable and metastable systems are austenite (γ), Fe_3P, Fe_3C, and graphite. The calculated liquidus surfaces for the four phases and the eutectic lines formed by their interactions are shown in Fig. 5, which is a superimposition of the γ-Fe_3P-Fe_3C and the γ-Fe_3P-graphite (Gr) diagrams. Two ternary eutectic points are shown in Fig. 5. To the left is L $\rightarrow \gamma + Fe_3P + G_r$ at 954 °C (1749 °F) and $y_C = 0.099$, $y_P = 0.123$. To the right is L $\rightarrow \gamma + Fe_3P + Fe_3C$ at 948 °C (1738 °F) and $y_C = 0.106$, $y_P = 0.123$. Here, $y_P = X_P/(1 - X_C)$, and $y_C = X_C/(1 - X_C)$, where X_P is the weigh fraction of phosphorus and X_C is the weigh fraction of carbon. In general, it is agreed that phosphorus does not have a strong graphite- or carbide-stabilizing influence.

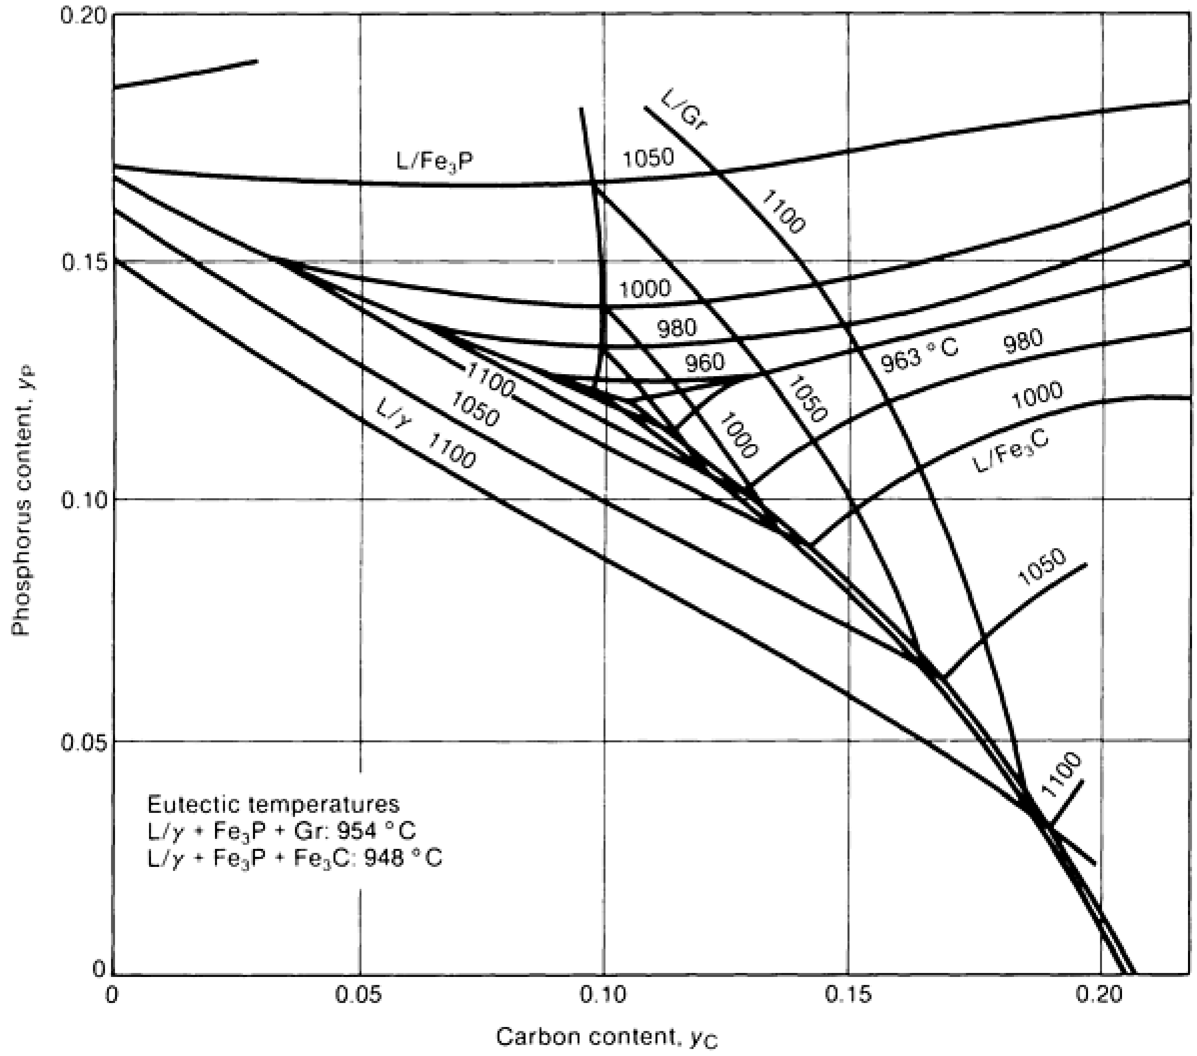

Fig. 5 calculated liquidus surfaces in the Fe-C-F phase diagram. Source: Ref 12.

The Fe-C-Mn System. The influence of increasing manganese contents in the Fe-C-Mn system over the equilibrium phase diagram is shown in Fig. 6. It is evident that manganese:

- Decreases the eutectoid temperature
- Increases the eutectoid interval, that is, the range of temperature and carbon contents over which α, γ, and carbide can coexist

- Decreases the carbon content in the eutectoid and in the eutectic
- Increases the eutectic temperature (by about 3 °C, or 5 °F, for each 1% Mn)

The carbide M_3C, which is $(FeMn)_3C$, is stable over a wide range of manganese and iron contents, extending at 1000 °C (1832 °F) from Mn_3C to nearly pure Fe_3C. At high manganese contents (for example, above 40% Mn), other manganese carbides such as M_5C_2, M_7C_3, $M_{23}C_6$, and $M_4C_{1+x}(\varepsilon)$ can form (Ref 10).

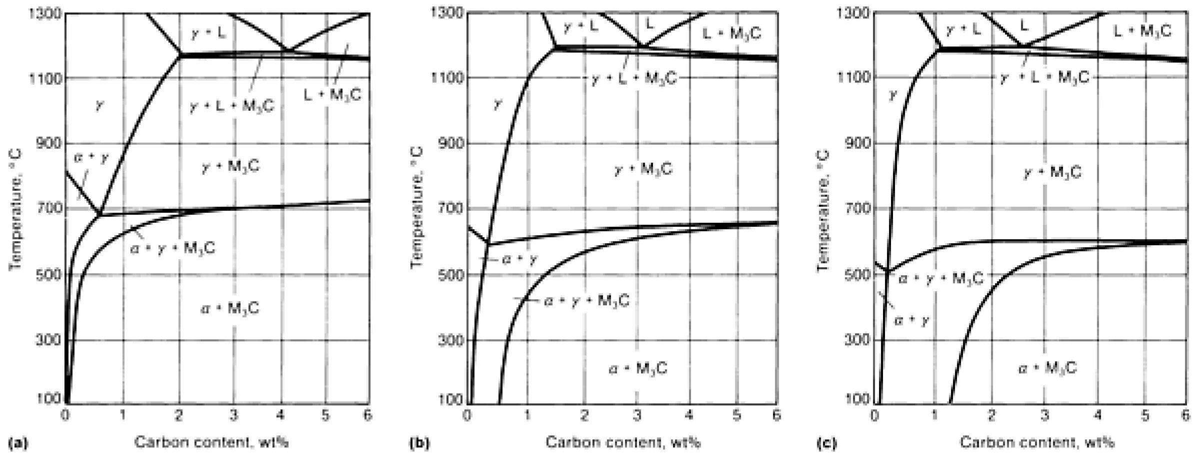

Fig. 6 Vertical sections through the Fe-C-Mn ternary phase diagram at 4.92 (a), 12.8(b), and 19.7 (c) wt% Mn.

Influence of a Third Element on the Equilibrium Temperatures. Various elements, dissolving in liquid and solid iron phases, change the equilibrium temperatures on the Fe-C diagram, as indicated in Table 3. This results in increased or decreased α and γ fields.

Table 3 Influence of a third element on the temperature change of critical points on the Fe-C diagram

+, increase; -, decrease

(a) Calculated results.

Of particular interest for the case of cast iron is the influence of third elements on the stable-metastable eutectic interval (T_{st} - T_{met}). In general, elements that increase the T_{st} - T_{met} interval promote graphite formation, while those that decrease the interval promote carbide formation. Based on their specific influence on the T_{st} - T_{met} interval, third elements can be classified into the following four groups(Fig. 7):

- Strong graphitizers that increase T_{st} and decrease T_{met}, such as silicon, aluminum, nickel, and copper (Fig. 7a)
- Weak graphitizers that decrease both T_{st} and T_{met} but increase the T_{st} - T_{met} interval overall, such as phosphorus and arsenic (Fig. 7b)
- Strong carbide stabilizers that decrease T_{st} but increase T_{met}, such as chromium, vanadium, and manganese (Fig. 7c)
- Weak carbide stabilizers that decrease both T_{st} and T_{met}, such as molybdenum and tungsten (Fig. 7d)

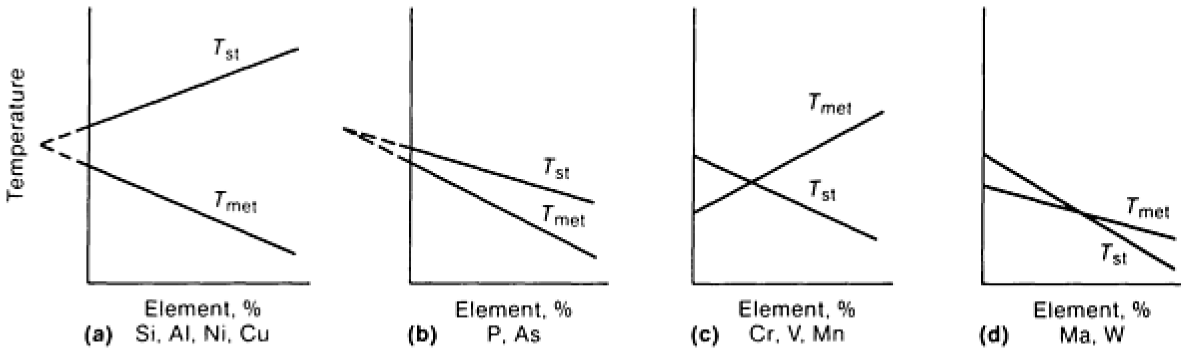

Fig. 7 Classification of the influence of a third element in the Fe-C-*X* system on the graphite- or carbide-promoting tendency in cast iron, based on their influence on the eutectic stable and metastable temperatures. (a) Strong graphitizers. (b) Weak graphitizers. (c) Strong carbide stabilizers. (d) Weak carbide stabilizers.

Real values for the ΔT_{met}^{st} = T_{st} - T_{met} interval for a number of elements can be calculated with the data given in Table 3, which also includes data on the influence of some elements on the eutectoid temperature and on the maximum solubility of carbon in austenite. Two examples of the use of data in Table 3 are provided below.

Example 1: Calculation of the value of the T_{st} - T_{met} eutectic interval for a cast iron having 2% Si, 0.5% Mn, and 1% Cu by weight:

$$T_{st} = 1154\ °C + 4\%\ Si - 2\%\ Mn + 5\%\ Cu - 1166\ °C$$

$$T_{met} = 1148\ °C\ 15\%\ Si + 3\%\ Mn - 2.3\%\ Cu - 117.2\ °C$$

$$\Delta T_{Fe\text{-}C} - 1154 - 1148 = 6\ °C$$

$$\Delta T_{Fe\text{-}C\text{-}Mn\text{-}Cu} = 1166 - 1117.2 = 48.8\ °C$$

Example 2: Calculation of the temperatures of the point of maximum carbon solubility in austenite, T_E and $T_{E'}$, for the above iron:

$$T_E = 1154\ °C - 10\% + 3.2\%\ Mn - 2\%\ Cu - 1133.5\ °C$$

$$T_{E'} = 1148\ °C + 2.5\%\ Si - 2\%\ Mn + 5.2\%\ Cu - 1157.2\ °C$$

Some typical experimental results for silicon, chromium, and vanadium are shown in Fig. 8. These results are in agreement with theoretical predictions.

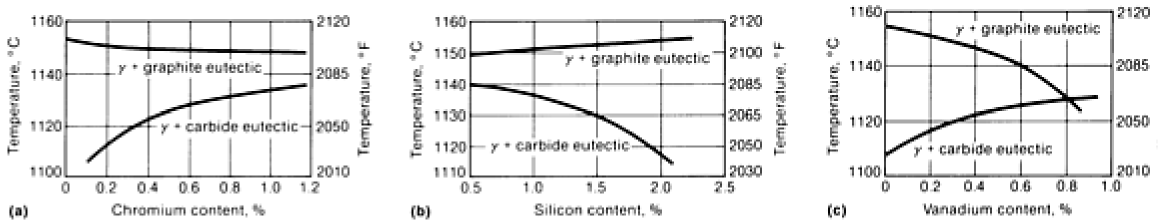

Fig. 8 Influence of chromium (a), silicon (b), and vanadium (c) on the equilibrium eutectic temperatures of cast irons.

Partition of a Third Element Between Various Phases in the Fe-C-*X* System. It has been established from the thermodynamic stability of phases involved in the eutectic solidification of Fe-C-*X* alloy that the differences in the equilibrium partition coefficients ΔP ($=P^M - P^S$, where P^M and P^S are the partition coefficients of element *X* between liquid and eutectic metastable or stable solid), the partition of element *X* between austenite and liquid, $P_X^{g/L}$, and the partition of element *X* between cementite and austenite, $P_X^{Fe_3C/g}$, are related to one another and have similar effects on graphitization during eutectic solidification (Ref 13). Calculated and experimental data for partition coefficients of various elements in phases of iron-carbon alloys are given in Table 4.

Table 4 Equilibrium partition coefficients of a third element *X* in the Fe-C-*X* system

(a) (a) calc, calculated; exp, experimental.

Figure 9 illustrates the correlation between the graphitizing influence of a third element (expressed by the normalized addition of each element required to increase or decrease the chill depth by a given amount) and the Δ*P* value. It is quite obvious that a definite correlation exists, although silicon, aluminum, and titanium deviate from the line. These three elements have a strong affinity for nitrogen; this may explain their higher-than-expected graphitizing influence. Indeed, it is accepted that the nitrides may act as nuclei for the stable eutectic, promoting gray solidification. This is why experiments show that titanium, for example, can act either as a carbide or graphite promoter, depending on the nitrogen content.

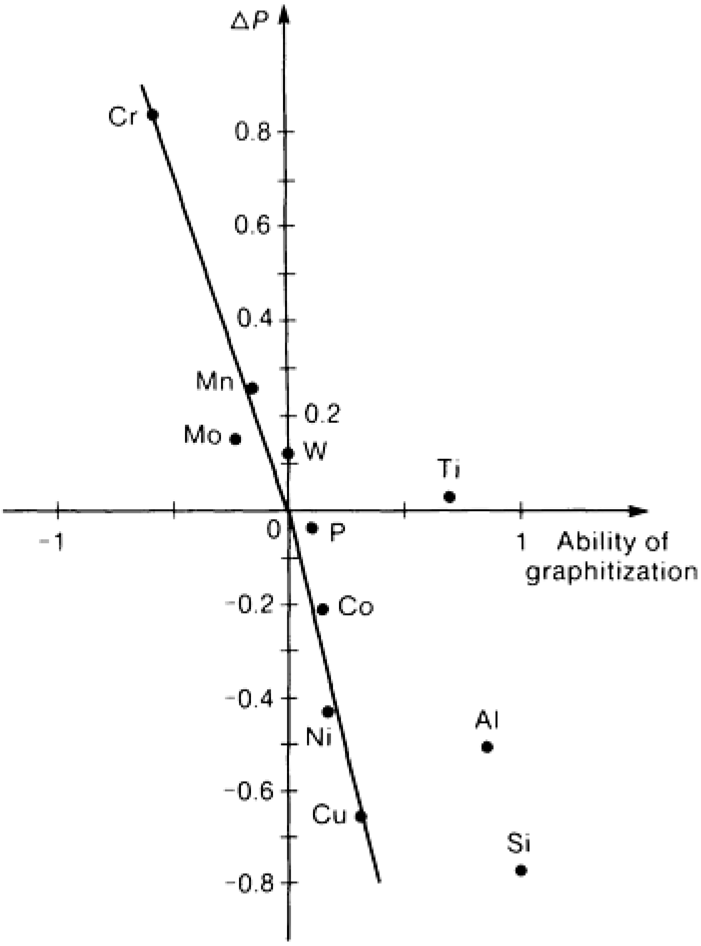

Fig. 9 Correlation between the partition coefficient, Δ*P*, and the graphitizing influence of a third element in the Fe-C-*X* system. Source: Ref 13.

Influence of a Third Element on Carbon Solubility in the Fe-C-*X* System. The influence of a third element on the solubility of carbon can be expressed by (Ref 2):

$$\Delta X_C^X = X_{max}^X - X_{cmax} \text{ (mole fraction)} \qquad \textbf{(Eq 23a)}$$

$$\Delta\%C^X = \%C_{max}^X - \%C_{max} - \%C_{max} \text{ (wt\%)} \qquad \textbf{(Eq 23b)}$$

where ΔX_C^X and $\Delta\%C^X$ represent the increase or decrease of carbon solubility in mole fraction or weight percent, respectively; X_{cmax} and $\%C_{max}$ represent the saturation concentration in the Fe-C system calculated from Eq 1 or 2; and $X_{C\max}^X$ and $\%C_{\max}^X$ are the saturation concentration in the Fe-C-*X* system.

The changes in carbon solubility resulting from additions of third elements, *X*, are shown in Fig. 10. These data are valid in the range from 1200 to 1700 °C (2190 to 3090 °F), with the exception of silicon and sulfur at high concentrations. In the region of low concentration of the third element (%*X* = 0 to 5%), the change in the solubility of carbon can be represented by the temperature-independent linear equation:

$$\Delta X_C^X = m \cdot X_X \qquad \textbf{(Eq 24a)}$$

or

$$\Delta\%C^X = m' \cdot \%X \qquad \textbf{(Eq 24b)}$$

where *m* and *m*' are solubility factors. In Eq 24a and 24b, *m* and *m*' as well as ΔX_C^X and $\Delta\%C^X$ are positive for an increase in the solubility of carbon and negative in the other case. It is also generally accepted that carbide-promoting elements increase the solubility of carbon (activity coefficient of carbon in solution is decreased), while graphite-promoting elements decrease it (activity coefficient of carbon in solution is increased). Therefore, third elements that have a negative solubility factor promote graphitization, while elements that have a positive solubility factor promote carbide formation. The value of the solubility factor is proportional to their effect. It must be noted, however, that the accuracy of the prediction of the behavior of elements based on solubility factor is questioned in Ref 13 for elements that have a strong influence on the austenite liquidus.

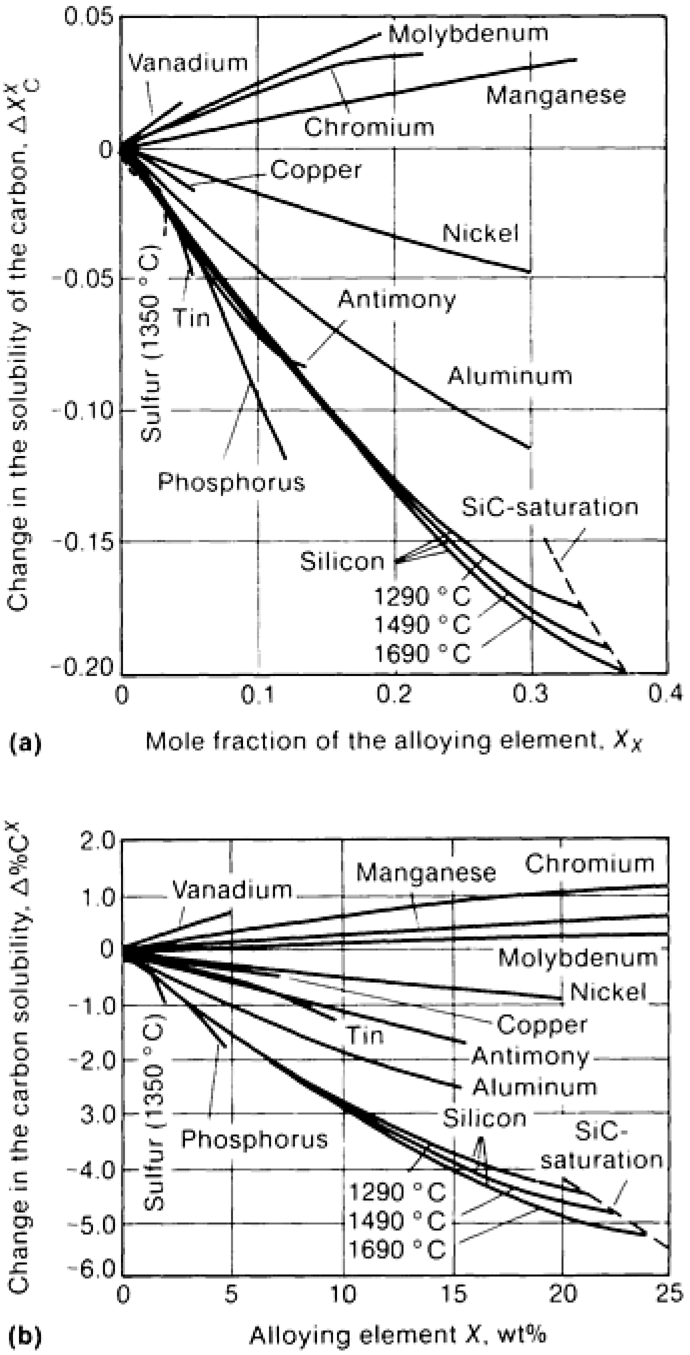

Fig. 10 Influence of third elements, *X*, on the solubility of carbon in molten iron. (a) In mole fraction. (b) In weight percent. Source: Ref 2.

As indicated in Table 5, experimental values are close to the theoretical values for many elements. Equations similar to Eq 24a and 24b can be used to calculate the change in the maximum solubility of carbon in austenite upon the addition of a third element:

$$\Delta\%C_E^X = m'\gamma \cdot \%X \qquad \textbf{(Eq 25)}$$

Data for $m'\gamma$ are also given in Table 5.

Thermodynamics of Multicomponent Fe-C Systems

Carbon Solubility in Multicomponent Systems. Assuming that the values in Table 5 for *m* and *m*', which were determined for the ternary Fe-C-*X* system, can be extended to multicomponent systems (in the case, the effect of alloying elements on the solubility of carbon can be considered to be additive, as shown in Eq 27, at least in the region of low concentrations), the saturation concentration of carbon in multicomponent systems can be calculated as (Ref 2):

$$\%C_{max}^{Si,Mn,P,S....} = \%C_{max} + \Delta\%C^{Si,Mn,P,S,...} \qquad \textbf{(Eq 26)}$$

which is Eq 23b rewritten for multicomponent systems. In turn:

$$\%C_{max}^{Si,Mn,P,S....} = \%C^{Si} + \Delta\%C^{Mn} + \Delta\%C^{P} + \Delta\%C^{S} + ... \qquad \textbf{(Eq 27)}$$

Then, using Eq 1 and data from Table 5, Eq 26 becomes:

$$\%C_{max}^{Si,Mn,P,S....} = 1.3 + 2.57 \times 10^{-3}\, t - 0.31\%Si + 0.027\%\, Mn - 0.33\%\, P - 0.4\%\, S \pm ... \qquad \textbf{(Eq 28)}$$

Saturation Degree and Carbon Equivalent. The Fe-C diagram with letter notations for critical points (Fig. 11) will be used in this section. It is well known that mechanical properties of cast iron strongly depend upon the amount and shape of graphite. In turn, for hypoeutectic gray irons, the amount of graphite depends on the amount of eutectic.

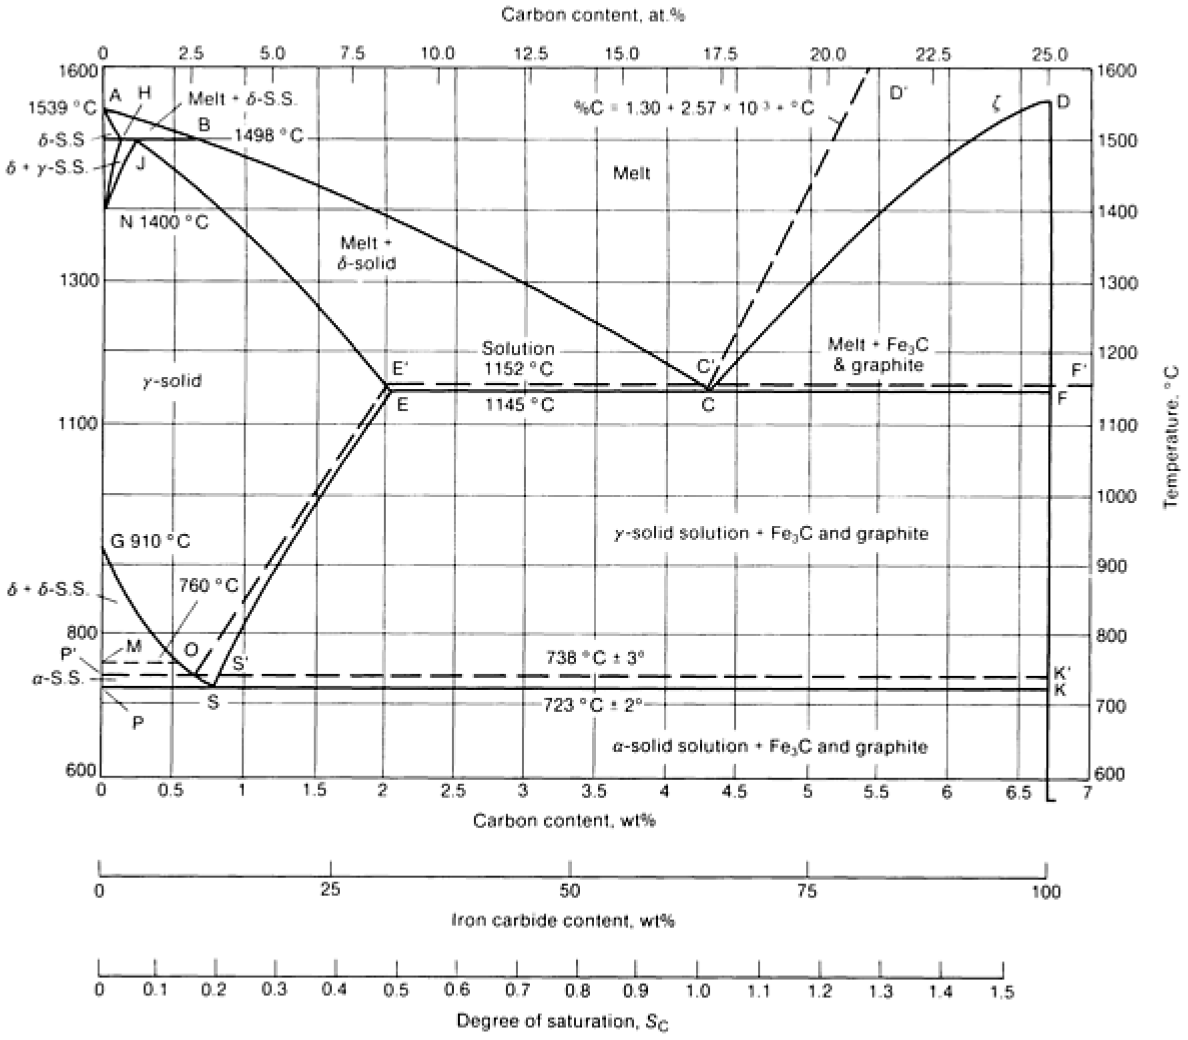

Fig. 11 The Fe-C diagram with letter notations. S.S., stainless steel.

The amount of eutectic can be calculated with the lever rule. For hypoeutectic irons one can write:

$$S_r = \frac{\text{Amount of eutectic}}{\text{Amount of eutectic + amount of austenite}} = \frac{\%C_{anal} - \%C'_E}{\%C_{anal} - \%C'_E + \%C'_C - \%C_{anal}} = \frac{\%C_{anal} - \%C'_E}{\%C'_C - \%C'_E} \qquad \textbf{(Eq 29)}$$

where S_r is the rectified saturation degree, $\%C_{anal}$ is the analyzed carbon content of cast iron, and $\%C'_C$ and $\%C'_E$ represent the carbon content of the eutectic and of the austenite, respectively, at the eutectic temperature in the multicomponent system (Fig. 11). Assuming the solubility factors can be extrapolated to the hypoeutectic region, $\%C'_C$ can be calculated with Eq. 28. A similar approach can be used to calculate $\%C'_E$ using data in Table 5 for $m'\gamma$:

$$\%C'_E = 2.11 - 0.11\%\ Si - 0.35\%\ P + 0.006\%\ Mn - 0.08\%\ S \qquad \textbf{(Eq 30)}$$

In foundry practice, the following simplified form of Eq 29 is used:

$$S_c = \frac{\%C_{anal}}{\%C'_C} = \frac{\%C_{anal}}{4.26 - 0.31\%Si - 0.33\%P + ...} \qquad \textbf{(Eq 31)}$$

For more accuracy, $\%C_{max}$ as a function of temperature rather than $\%C_{max} = 4.26$ can be used, where the temperature is the eutectic temperature of the multicomponent system. Further simplification gives:

$$S_c = \frac{\%C_{anal}}{4.25 - 0.3(Si + P)} \qquad \textbf{(Eq 32)}$$

where $S_C < 1$ for hypoeutectic irons, $S_C = 1$ for eutectic irons, and $S_C > 1$ for hypereutectic irons.

Saturation degree is used in most of the European literature. In the Anglo-Saxon literature and foundry practice, carbon equivalent rather than saturation degree is used. Carbon equivalent (CE) can be calculated as:

$$\begin{aligned} CE &= \%C_{anal} - \Delta\%C^{Si} - \Delta\%C^{Mn} - \Delta\%C^{P} - \Delta\%C^{S} - \ldots \\ &= \%C_{anal} + 0.31\%\ Si + 0.33\%\ P - 0.027\%\ Mn + 0.4\%\ S \end{aligned} \qquad \textbf{(Eq 33)}$$

A eutectic iron has CE = 4.26%. It must be noted that although S_r gives directly the amount of eutectic in the structure (for example, $S_r = 0.9$ means 90% eutectic), S_C and CE, although easier to calculate, do not allow for exact estimation of the amount of eutectic.

Structural Diagrams

For the practicing metallurgist involved in cast iron production, one of the main applications of the thermodynamics of the Fe-C system is the calculation of structure-composition correlations. The so-called structural diagrams are used for this purpose.

The first and simplest structural diagram is the Maurer diagram (Fig. 12a), in which the as-cast structure is considered to be solely the product of the carbon and silicon contents of cast iron. Because it was recognized long ago that solidification rate, as well as chemical composition, plays a significant role in the formation of the as-cast structure of casting, especially for cast iron, Laplanche (Ref 14) further developed the Maurer diagram to include the influence of cooling rate through the section size (or bar diameter) of the casting (Fig. 12b). The κ lines on the diagram are lines of same structure (same degree of graphitization) at a given cooling rate. The value κ is an empirical function of composition, as follows:

$$k = 4/3Si\left(1 - \frac{5}{3C + Si}\right) \quad \textbf{(Eq 34)}$$

The correlation between κ and cooling rate is given in Table 6. Thus, if one wants to produce a pearlitic iron in casting with equivalent section sizes of 10 to 30 mm (0.4 to 1.2 in.) bar diameters, Table 6 would suggest at κ of 0.85 to 2.35. For example, κ= 1.8 is then chosen. A saturation degree, S_C, is also selected depending on the required mechanical properties (for example, S_C = 0.8), and the intersection of the κ = 1.8 with S_C = 0.8 will then give the carbon and silicon required for the iron.

Table 6 κ lines for various structural ranges

Bar diameter		**κ for mottled structure**	**κ for pearlitic structure**	κ for pearlitic ferritic structure
mm	**in.**			
30	1.2	0.65-0.85	0.85-2.05	**2.05-3.10**
20	0.8	0.75-1.10	1.10-2.25	**2.25-3.40**

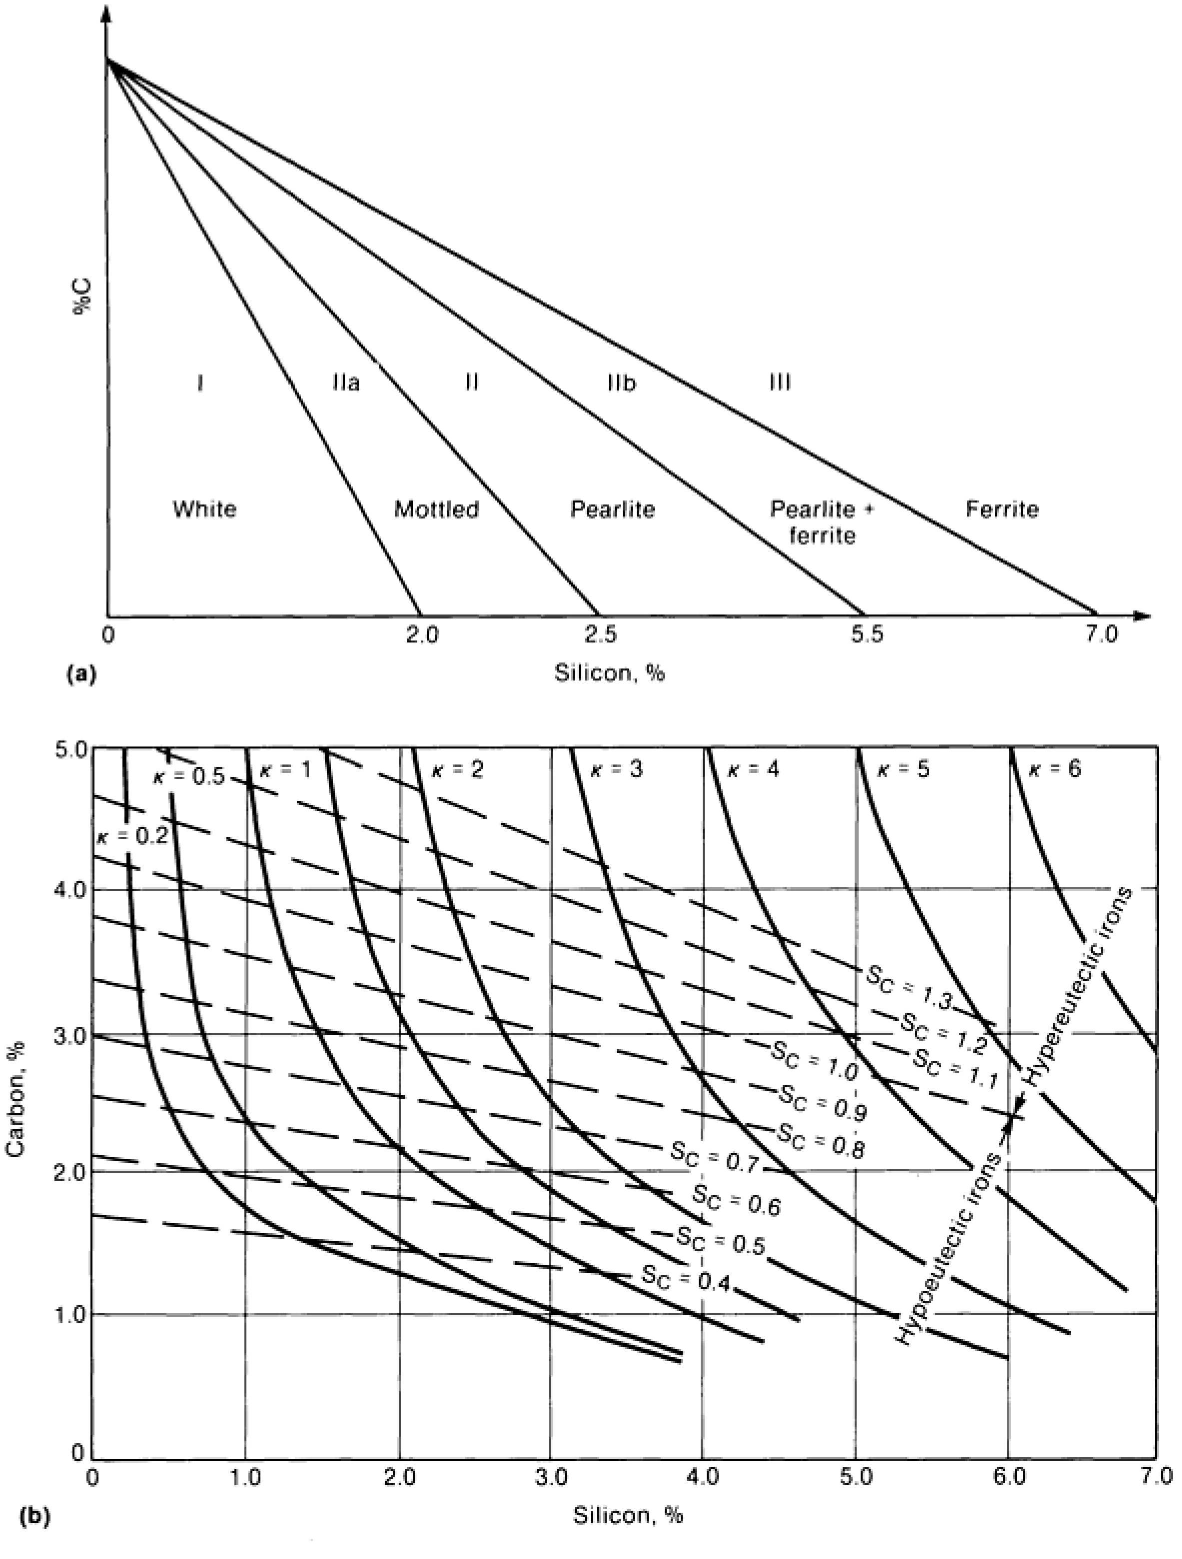

Fig. 12 Structural diagrams for cast iron. (a) Maurer diagram. (b) Laplanche diagram. See also Fig. 13. Source: Ref 14.

A further contribution to structural diagrams was made by Patterson and Doepp (Ref 15). This diagram (Fig. 13) encompasses not only structure, composition, and cooling rate but also a broad range of mechanical properties. Part of this diagram is based on Laplanche's κ lines.

Fig. 13 Patterson and Doepp structural diagram for cast iron. See the corresponding text for details. Source: Ref 15.

As an example of the way this diagram is used, assume it is desired to pour a 50 mm (2 in.) diam cast iron bar (or equivalent section size) with a pearlitic-ferritic structure. A heavy horizontal line is drawn from the *y*-axis at the 50 mm (2 in.) diam bar location to the middle of zone IIb. This corresponds to a determination of κ= 2.2. This κ line can be followed to the lower diagram until it intersects a preselected saturation degree--in this case S_C = 0.6. The composition is now read as C = 2.6% and Si = 3%, together with the equilibrium temperature for the $(SiO_2) + 2[C]$ € $[Si] + \{CO\}$ reaction, which is 1460 °C (2660 °F). An additional explanation on the significance of this reaction can be found in the article "Solidification of Eutectic Alloys: Cast Iron" in this Volume. It must be pointed out that foundry variables such as superheating and holding during melting, charge composition (raw materials), and inoculation can cause significant deviation from these calculations.

Composition Control

Seymour Katz, General Motors Research Laboratories

Introduction

COMPOSITION CONTROL is vital for the production of quality castings because the most common raw material used for iron and aluminum castings is scrap. By its nature, scrap is of uncertain composition, both with respect to concentrations of desirable alloy elements and the presence of deleterious elements. Thus, despite all precautions in melting, adjustments in melt composition are required. Composition control can be divided into two areas; alloy addition and melt purification. Both will be discussed in this article. The chemical and physical processes involved in alloy addition do not vary much with base metal; therefore, the subject can be treated generically. On the other hand, because melt purification processes tend to be material-specific, each base metal is treated separately.

Kinetics of Alloy Additions

There are two fundamental mechanisms governing the kinetics of alloy additions, depending on whether the alloy is liquid or solid at the temperature of the metal bath. These processes are schematically illustrated in Fig. 1.

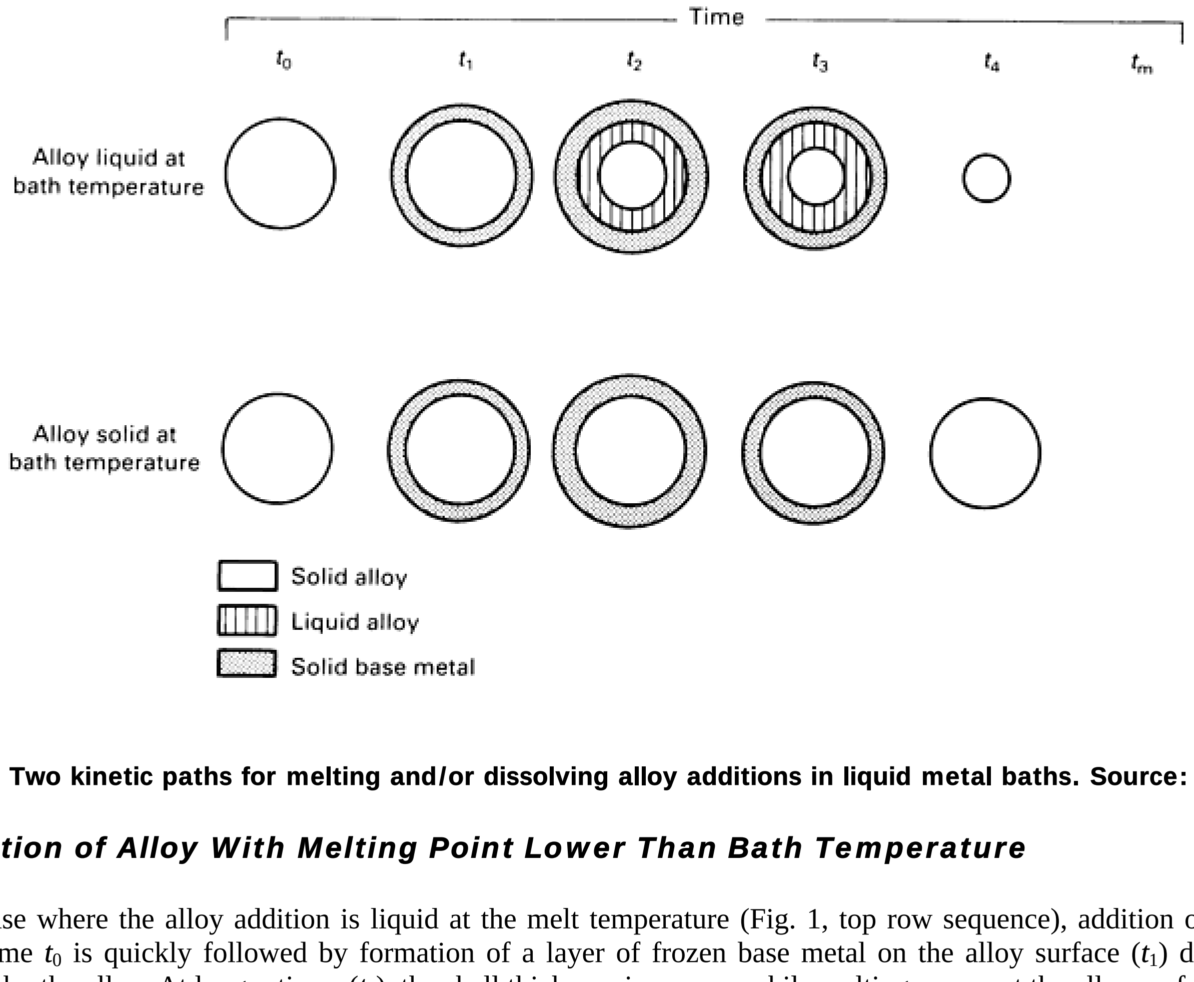

Fig. 1 Two kinetic paths for melting and/or dissolving alloy additions in liquid metal baths. Source: Ref 1.

Dissolution of Alloy With Melting Point Lower Than Bath Temperature

For the case where the alloy addition is liquid at the melt temperature (Fig. 1, top row sequence), addition of the cold alloy at time t_0 is quickly followed by formation of a layer of frozen base metal on the alloy surface (t_1) due to heat extraction by the alloy. At longer times (t_2), the shell thickness increases, while melting occurs at the alloy surface. As the interior of the alloy heats up, the thermal demand decreases. As a result, the frozen base metal shell begins to redissolve while the thickness of the liquid annulus increases (t_3). In the final stage, beginning at t_4, the redissolution of the base metal shell is complete, and as a result, the liquid alloy held in the annular space is released to the melt. Any alloy that remains solid is exposed directly to the liquid metal bath and is progressively incorporated into the melt by the surface melting and convection. Dissolution is completed at t_m (melting time).

The length of the incubation period (t_0 - t_4) and the length of the alloy dissolution period (t_4 - t_m) are governed by heat transfer. Conditions favoring rapid alloy dissolution are high superheat temperatures, small alloy particle size (large surface for heat transfer), and low alloy thermal conductivity. The heat flux to the alloy particle is given by:

$$Q = h\,(T_L^B - T^*_L) \qquad \textbf{(Eq 1)}$$

where Q is the heat flux (J · m^{-2} · s^{-1}), h is the convective heat transfer coefficient (J · m^{-2} · s^{-1} · K^{-1}), T_L^B is the temperature of the bulk liquid (in degrees Kelvin), T^*_L is the melting point temperature of the alloy at the solid/liquid interface (in degrees Kelvin), and (T_L^B - T^*_L) is the superheat temperature (in degrees Kelvin).

During the incubation period, the superheat temperature is less than that in the alloy dissolution period because T^*_L corresponds to the melting point of the base metal and alloy in the former and latter cases, respectively. For steel and aluminum melts, superheat temperatures in the incubation period are generally smaller (20 to 100 K) than for cast iron (200 to 300 K). In the alloy dissolution period, the superheat temperature for a given alloy addition increases with increasing melting point of the base metal. Thus, superheat temperatures, and therefore dissolution rates, increase in the following order: aluminum < copper < cast iron < steel.

Melting times t_m can be estimated by assuming that t_m is equal to the total heat requirement for melting, divided by the rate at which heat is supplied from the bath (Ref 1), that is:

$$t_m = \frac{\Delta H\, r_o V_o}{Q A_o} \qquad \textbf{(Eq 2)}$$

where ΔH is the heat supplied to 1 g of alloy at the time it dissolves and ρ_0, V_0, and A_0 are the density, volume, and surface area of the alloy particle. The variable Q is defined by Eq 1.

Equation 2 is most accurate when applied at the extremes of possible superheat temperatures. For small superheat temperatures, it can be assumed that by the time the frozen shell redissolves the alloy is a liquid at the melting point of the base metal. At high superheat temperatures, it can be assumed that no frozen layer forms and that the alloy liquefies at its melting point.

These two cases have been examined for the dissolution of a 100 mm (4 in.) particle diameter (d_p) sphere of silicomanganese in a steel melt (T_L^B = 1823 K). Data for the calculations are given in Table 1. The very long melting time of 1200 s obtained by restricting the calculations to a small superheat temperature (20 K) is in good agreement with the 900 s obtained with a more sophisticated model (Fig. 2). The difference in t_m for the two extreme cases considered in Table 2 underscores the importance of superheat temperature in alloy dissolution processes. This is clearly illustrated in Fig. 2, in which the role of particle diameter is also demonstrated. It is apparent from Fig. 2 that large value of t_m in Table 1 for the case (T_L^B - T^*_L) = 20 and d_p = 100 mm can be substantially reduced with moderate changes in (T_L^B - T^*_L) and d_p.

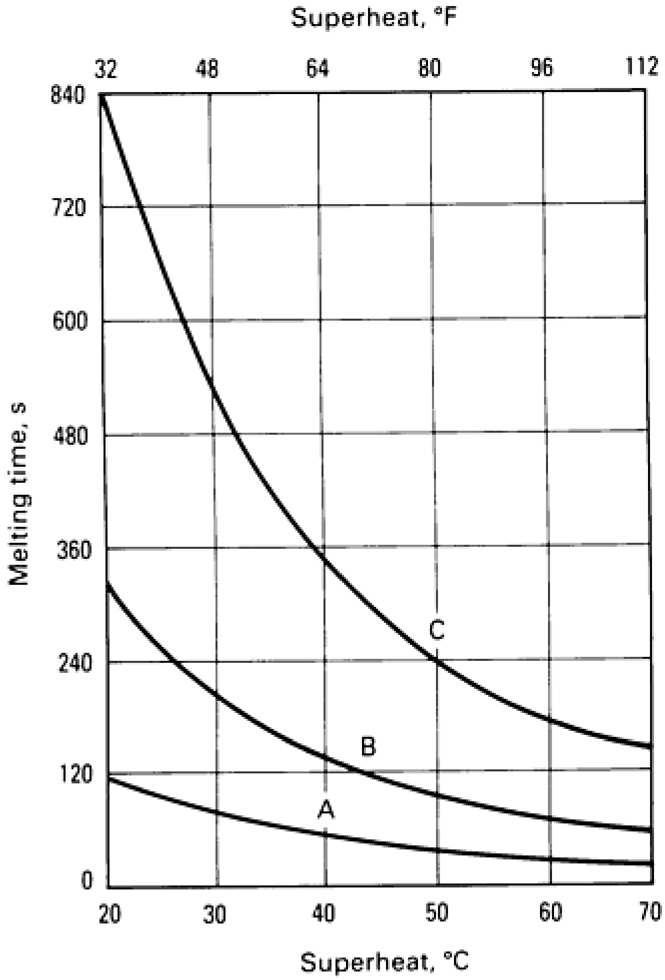

Fig. 2 Predicted melting/dissolution times for silicomanganese spheres in quiescent steel baths versus steel superheat temperature. Particle diameters of the spheres are as follows: A, 25 mm (1 in.); B, 50 mm (2 in.); C, 100 mm (4 in.). Source: Ref 1.

The range of melting times obtained with the addition of an alloy to different base metals is examined below. Consider the addition of pure aluminum to melts of steel, cast iron, copper, and aluminum under conditions where no frozen shell is formed. In this case, T^*_L is the same (933 K), but T_L^B varies. Pertinent data for the calculation and the calculated melting

times are given in Table 2. It is clear from Table 2 that the duration of alloy melting becomes a more serious problem as the melting point of the base metal decreases.

The short melting times predicted for steel and cast iron melts in Table 2 highlight another important consideration in alloy addition, namely, immersion time due to alloy buoyancy. Because iron is denser than common alloy additions such is carbon, silicon, and aluminum, buoyant forces prevent these alloys from being easily submerged for times approaching t_m. This is illustrated in Fig. 3, which plots immersion times versus the density ratio, $\rho_{alloy}/\rho_{base\ metal}$. For 10 mm (0.4 in.) aluminum particles (density ratio: 0.39) that are dropped a distance of 3 m (10 ft) to the surface of an iron bath, the immersion time is less than 1 s, while the melting time (from Table 2) is 1.9 s. Immersion times can be increased by entraining particles in strong recirculating flows or by wire and rod feeding (Ref 2, 3). These conditions have higher associated heat transfer coefficients, which further facilitate dissolution.

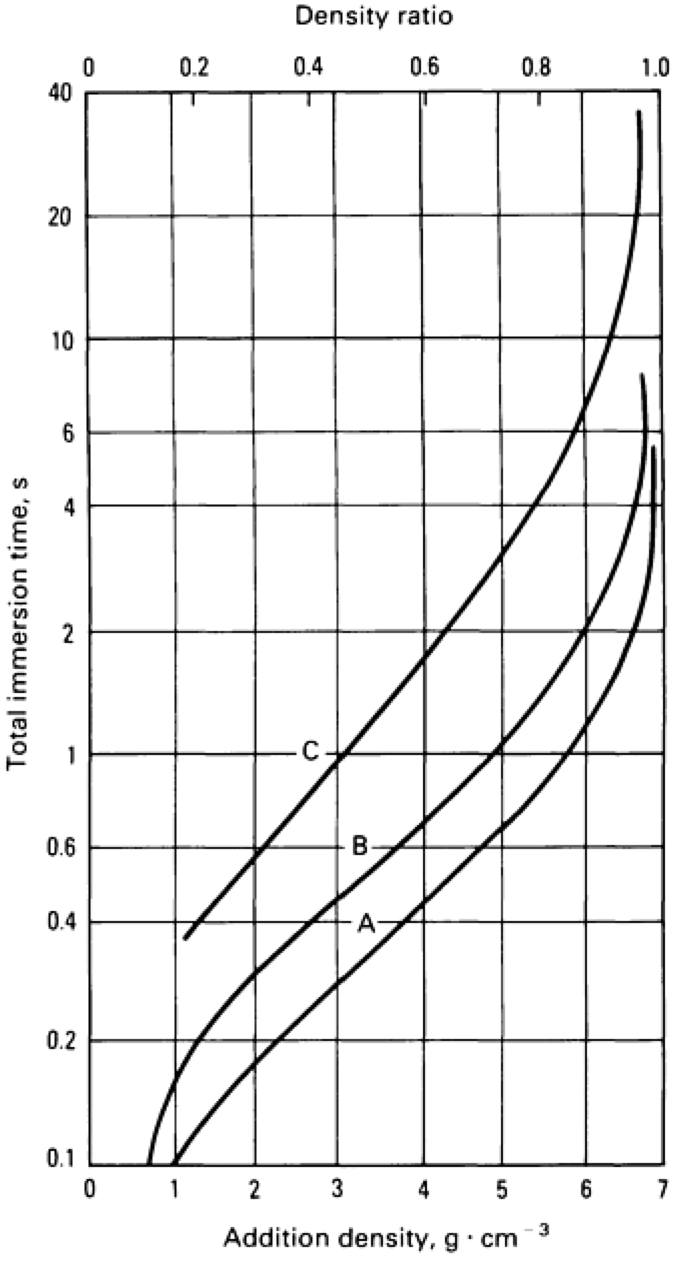

Fig. 3 Total immersion times versus density ratio for alloys entering a stagnant steel bath at 7.67 m · s^{-1} (25.2 ft · s^{-1}) (drop height: 3.0 m, or 10 ft). Particle diameters are as follows: A, 10 mm (0.4 in.); B, 50 mm (2 in.); C, 250 mm (10 in.). Source: Ref 1.

Dissolution of Alloy That Is Solid at Bath Temperatures

The process involved in the dissolution of this type of addition are schematically illustrated in the bottom row sequence in Fig. 1. As in the previous case, heat transfer controls the duration of the incubation period (t_0 - t_4). However, in this case, mass transfer is the controlling factor in the alloy dissolution period (t_4 - t_m). In general, mass transfer controlled dissolution is slower than heat transfer controlled dissolution, and the number of variables controlling the rate is greater. For mass transfer control, melt temperature and fluid dynamic considerations are important, as in the heat transfer controlled case. However, melt composition and diffusion variables are also important. The flux of alloy element to the melt is given by:

$$J = k_m (C^*_L - C_L^B) \qquad \textbf{(Eq 3)}$$

where J is the mass flux of alloy element (g · cm^{-2} · s^{-1}), k_m is the mass transfer coefficient (cm · s^{-1}), C_L^B is the concentration of the alloy element in the bulk melt (g · cm^{-3}), and C^*_L is the concentration of the alloy element in the melt at the solid/liquid interface (g · cm^{-3}). To illustrate mass transfer limited dissolution processes, two industrially important examples will be examined below.

Carbon Dissolution in Cast Iron. Carbon is the most important alloy element in cast iron. The addition of carbon to iron-carbon melts is a common foundry practice that is necessary for control of cast iron composition. The rate at which carbon dissolves in cast iron is controlled by the rate of diffusion of carbon from carbon-saturated iron at the carbon/iron interface into the bulk liquid (Ref 4, 5, 6). Thus, Eq 3 can be written:

$$J = k_m (C^*_{sat} - C_L^B) \qquad \textbf{(Eq 4)}$$

where C^*_{sat} indicates carbon-saturated conditions at the carbon/melt interface. The conditions in the melt are qualitatively described in Fig. 4. Referring to Fig. 4 and Eq 4, the flux of carbon, and therefore the dissolution rate, increases with decreasing bulk carbon concentration C_L^B, increasing carbon concentration at saturation C^*_{sat} (increasing bath temperature), and decreasing boundary layer thickness δ. The boundary layer thickness is a function of the fluid velocity, and it affects the value of k_m.

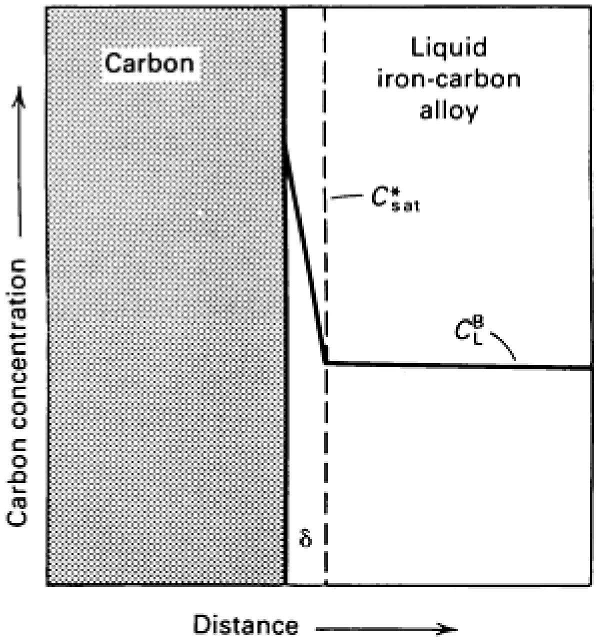

Fig. 4 Carbon concentration profiles for a carbon rod dissolving in an iron-carbon melt.

The effect of the difference (C^*_{sat} - C_L^B) on the dissolution rate of carbon is illustrated in Fig. 5 with data for the dissolution of graphite granules in induction-stirred cast iron melts. Theoretical curves are drawn for different rate constants *k* and particle shape factors λ, where λ is defined as:

$$l = \frac{S_{particle}}{S_{sphere}} \qquad \textbf{(Eq 5)}$$

where $S_{particle}$ is the surface-to-volume ratio of the graphite particles and S_{sphere} is the equivalent surface-to-volume ratio if the particles are spherical.

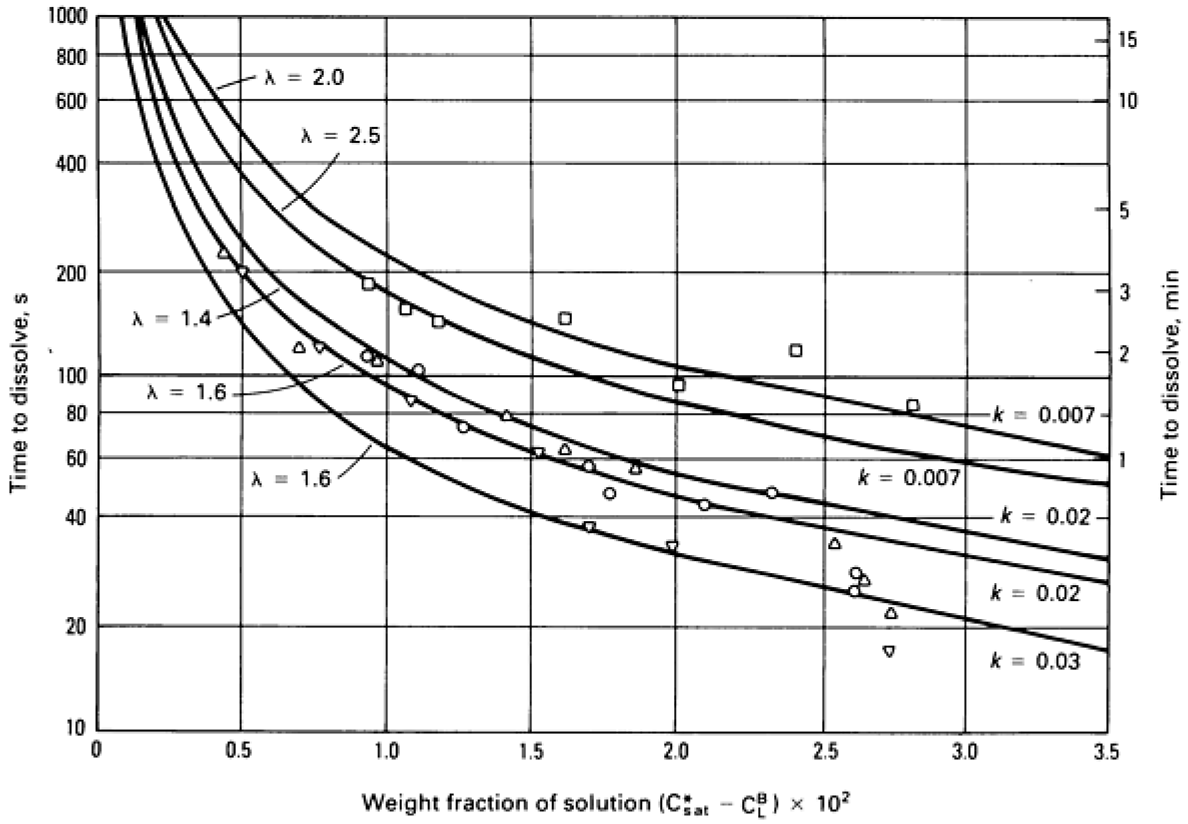

Fig. 5 Time of dissolution of carbon particles (-10 + 14 mesh) versus (C^*_{sat} - C_L^B). Source: Ref 6.

The role of boundary layer thickness (fluid dynamics) on dissolution kinetics is illustrated in Fig. 6, which indicates the variation of the rate constant (dissolution rate) with the peripheral velocity (rotational speed) of a cylindrical graphite rod. The line drawn through the data has a slope of 0.7, which is expected from earlier correlations (Ref 7).

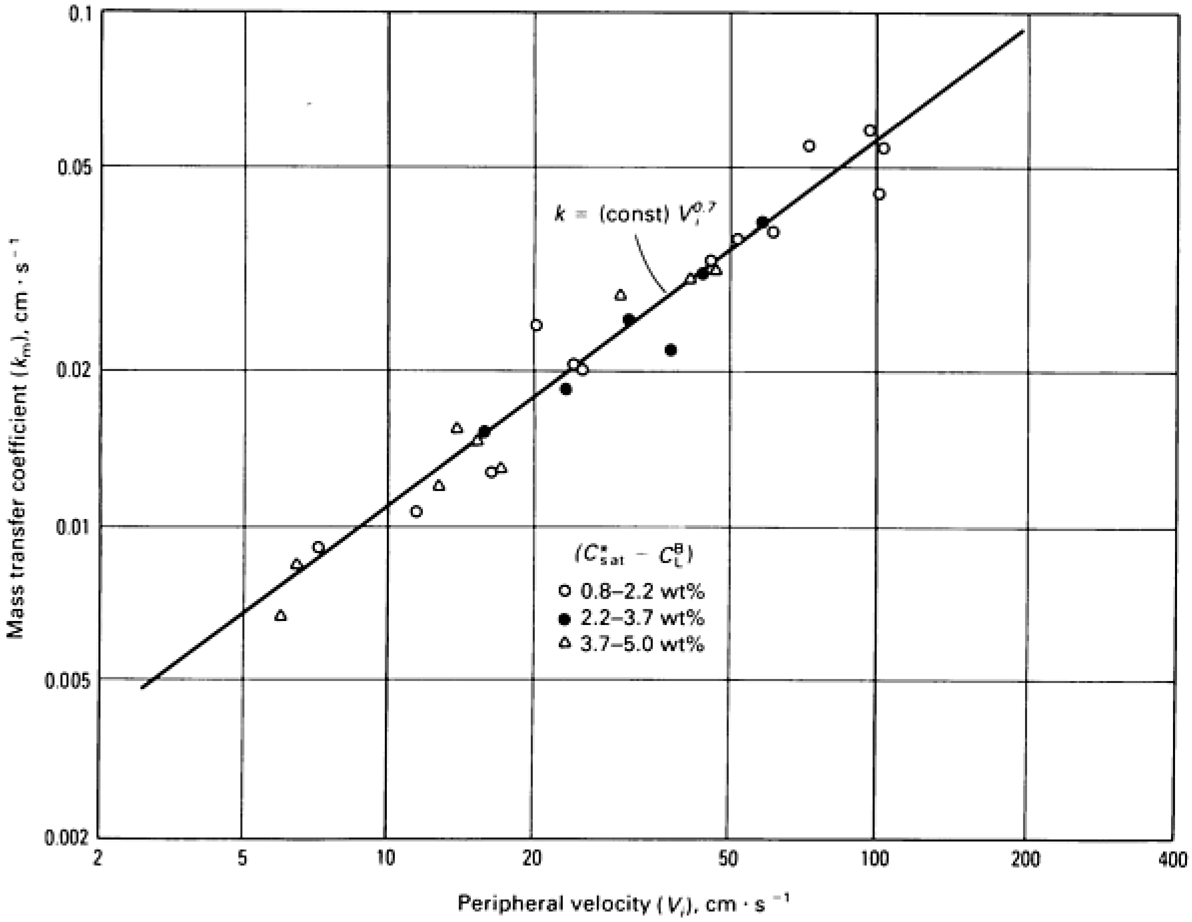

Fig. 6 Experimental mass transfer coefficient versus peripheral velocity for the dissolution of a rotating carbon rod in an iron-carbon melt. Source: Ref 5.

Dissolution of Steel in Iron-Carbon Melts. Another well-established case of mass transfer controlled dissolution is the dissolution of steel in iron-carbon melts (Ref 8, 9, 10, 11). This process is critical in the electric melting of steel and cast iron. For this case, the rate of steel dissolution increases with melt carbon concentration (Fig. 7), melt temperature (Ref 10), and bath velocity (Ref 8, 9, 11) (affecting the boundary layer thickness). The data can be accounted for on the basis that carbon diffuses from the bulk of the melt to the steel/liquid iron interface, where steel is isothermally converted to a liquid with a liquidus composition, $C^{*\ell}_L$.

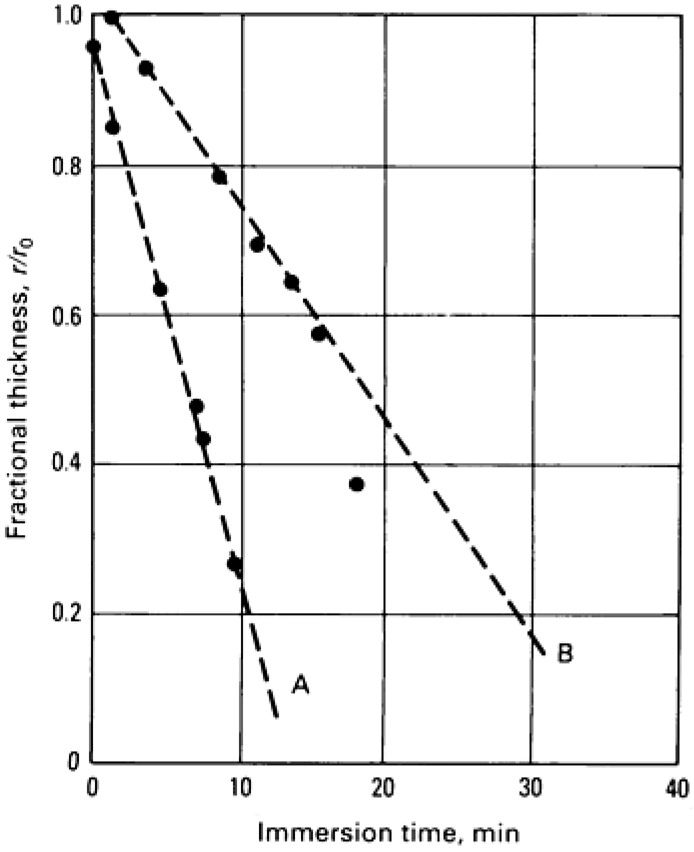

Fig. 7 Melting curves for 75 mm (3.0 in.) diam steel rods immersed in iron-carbon baths. A, high (4.6% C) iron-carbon bath; B, low (2.1% C) iron-carbon bath. Plotted is the fractional thickness (the fraction of the rod diameter remaining undissolved) versus immersion time. Source: Ref 10.

The conditions existing in the bath are illustrated in Fig. 8. Figure 8(a) shows the carbon concentration profiles in the liquid bath in the vicinity of a dissolving steel bar. The meaning of the carbon concentration notation is indicated in Fig. 8(b). As indicated in Fig. 8(a), carbon diffuses across the liquid boundary layer, while equilibrium conditions are maintained at the solid/liquid interface. Thus, the carbon concentrations in the solid and the liquid at the interface are the isothermal solidus C^{*s}_{S} and the liquidus $C^{*\ell}_{L}$ concentrations, respectively. Dissolution takes place by isothermal conversion of the steel into a liquid, that is, by a chemical melting process. It is clear from Fig. 8(b) that as temperature increases, $C^{*\ell}_{L}$ decreases significantly. Thus, the driving force for diffusion increases with temperature.

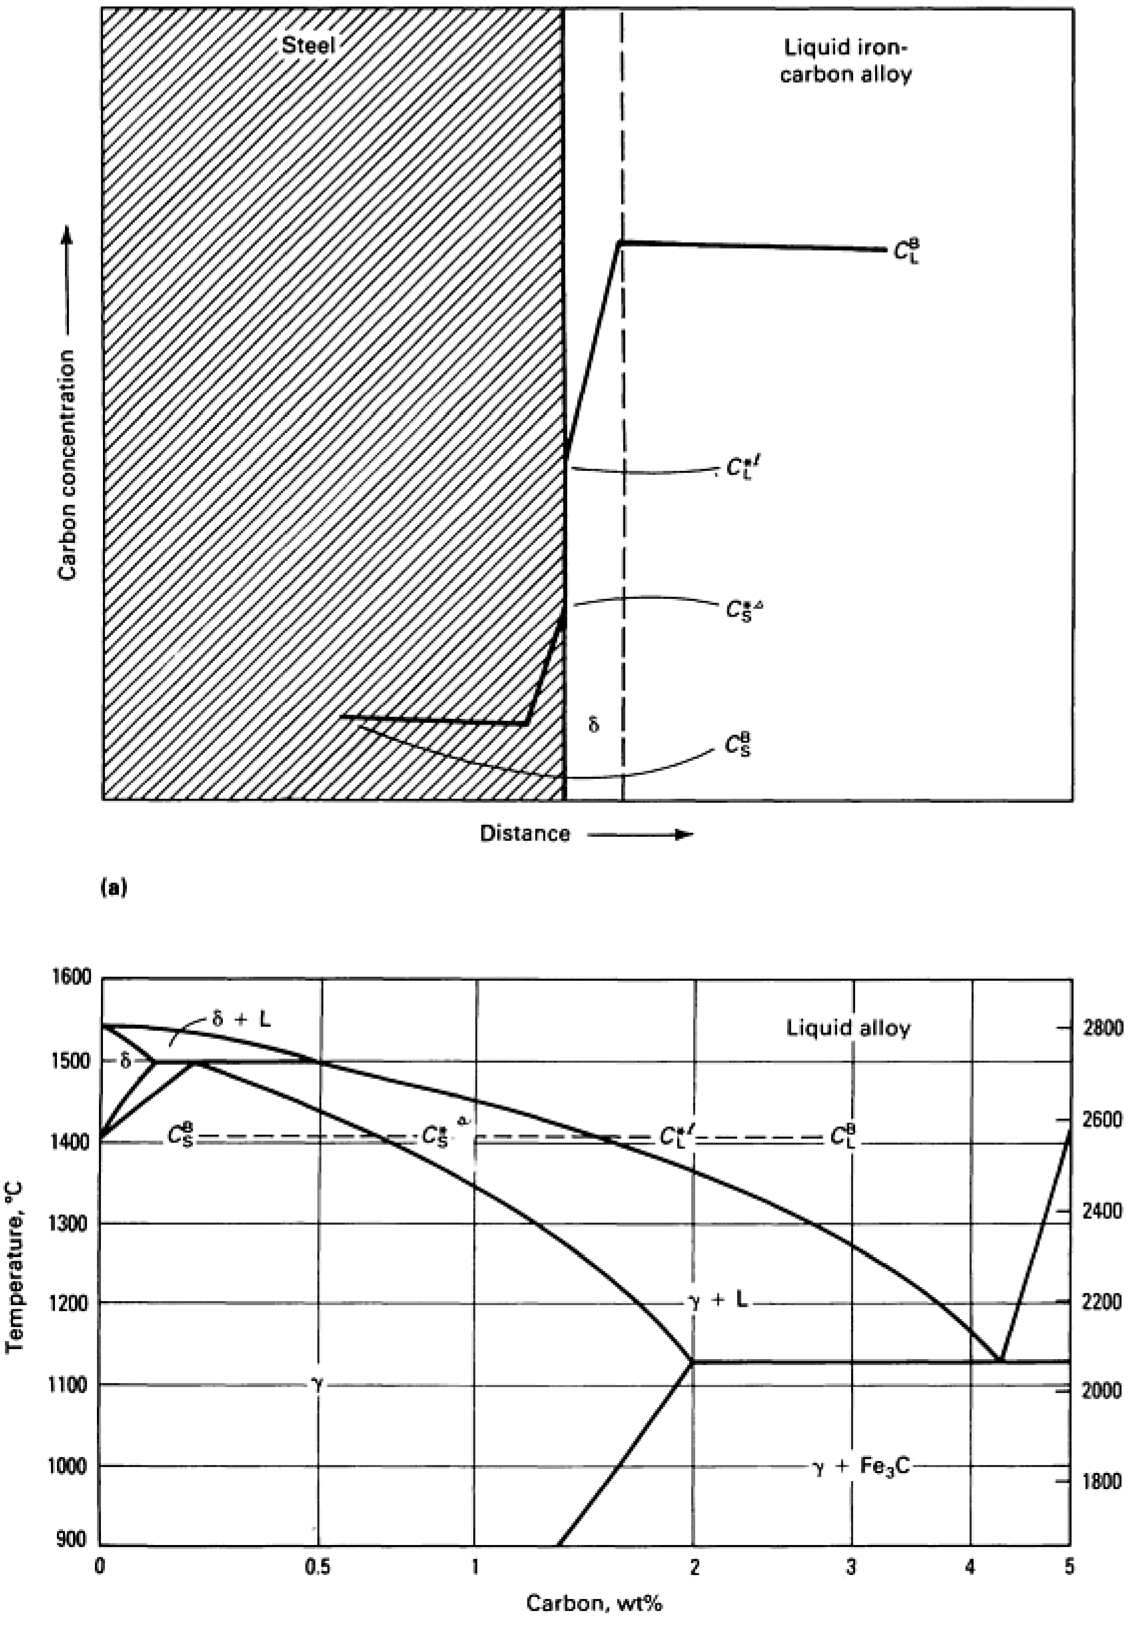

Fig. 8 Carbon concentration profiles (a) for a steel rod dissolving in an iron-carbon melt. (b) Iron-carbon phase diagram defining the carbon concentrations noted in (a). Source: Ref 10.

Based on Eq 3 and Fig. 4, the flux of carbon entering the steel is:

$$J = k_m \left(C_L^B - C^{*\ell}{}_L \right) \qquad \textbf{(Eq 6)}$$

The carbon flux can also be defined in terms of a carbon balance:

$$J = -\left(\frac{r_S^B C_L^{*l}}{P_L^{*l}} - C_S^B \right) \frac{dr}{dt} \qquad \textbf{(Eq 7)}$$

where r_S^B and $\rho^{*\ell}{}_L$ are the respective densities of solid steel and liquid iron at the liquidus composition, C_S^B is the bulk carbon concentration of solid steel, and dr/dt is the rate of change of the radius or thickness of the steel with time. By combining Eq 6 and 7 and integrating between the limits $r = r_0$ at $t = 0$ and $r = 0$ at $t = t_m$, the isothermal melting time t_m is given as:

$$t_m = \frac{(r_S^B C_L^{*l} / r_L^{*l}) - C_S^B}{k_m (C_L^B - C_L^{*l})} r_o \qquad \textbf{(Eq 8)}$$

In laboratory studies, Eq 8 accurately predicted steel dissolution rates in a stagnant bath (Ref 10). Research has suggested that melting times are reduced by about a factor of two in induction-stirred melts (Ref 9). Other work has indicated that t_m can be reduced by an order of magnitude with strong convection (Ref 11).

On the basis of Eq 8 and the mass transfer correlation for rapidly dissolving rods (Ref 12), correlations were developed relating t_m to bath temperature and to carbon concentration (Ref 10). This is given in Fig. 9 for a steel thickness of 2.5 mm (0.098 in.). Because t_m is directly proportional to the thickness of the steel, Fig. 9 can be used to estimate t_m for a wide range of steel thickness by making the appropriate thickness correction. Checks of the predictions from Fig. 9 in production operations have indicated that predicted t_m values are realistic (Ref 10).

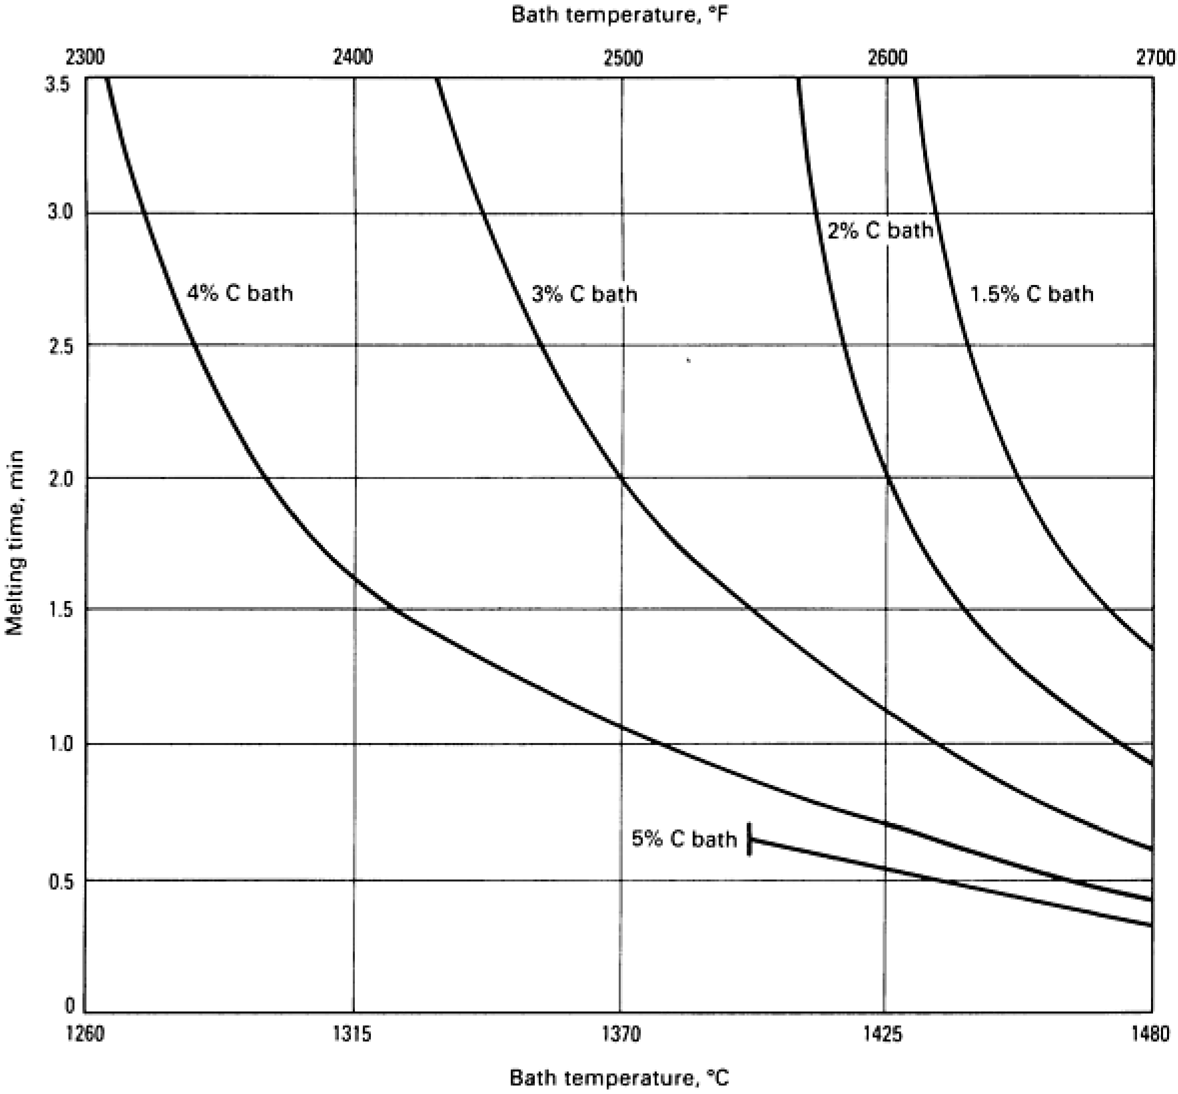

Fig. 9 Predicted melting times for vertical steel plates and cylinders, 2.5 mm (0.098 in.) scrap thickness and 0.1% C composition, [(%S)$_i$ = 0.03] immersed in stagnant iron-carbon baths at different bath temperatures. Source: Ref 10.

Purification of Metals

The structure and properties of cast metals are sensitive to numerous impurities. Because purification of melts generally adds considerable cost to castings, the lowest cost and surest defense against contamination is careful selection of scrap. Purification is generally reserved for elements that are so pervasive that avoidance is impossible. This is exemplified by sulfur and oxygen removal from cast iron and steel, respectively, and removal of alkali and alkaline earth elements from aluminum. Because of their immediate importance, aspects of the physical chemistry of these processes are reviewed.

Ferrous Melts

One of the most important processes involved in cast iron and steel production is desulfurization. For steels, desulfurization is necessary to reduce the level of inclusions, leading to stronger and more fatigue-resistant steels. For cast iron, desulfurization is practiced in the manufacture of ductile iron castings in order to develop spherical graphite morphology. Ductile iron is used in applications where high fracture toughness is needed.

Sulfur is removed from iron and steel when the metals are liquid. Although a variety of reagents are employed to remove sulfur, namely, calcium, magnesium, sodium, and rare earths, the most important is calcium. Common forms of calcium include the metal; alloys such as calcium silicon (CaSi); the oxide, calcium oxide (CaO); and the carbide, calcium carbide (CaC_2). Despite the use of various forms of calcium, the governing chemical reaction in all cases appears to be the same (Ref 13, 14):

$$CaO + S = CaS + O \qquad \textbf{(Eq 9)}$$

The equilibrium constant for the reaction (Eq 9) is:

$$k_9 = \frac{a_{CaS} h_o}{a_{CaO} h_S} \qquad \textbf{(Eq 10)}$$

For both cast iron and steel, target sulfur concentrations after desulfurization are in the range of 0.006 to 0.010% S. In electric-melted cast iron and steel, the sulfur levels before desulfurization are 0.02 to 0.03% S, while input sulfur levels to the cupola are generally much higher--0.1 to 0.2% S.

Requirements for Desulfurization. For reasons related to reaction kinetics and thermodynamics, the final sulfur $(\%S)_f$ concentration achieved in desulfurization processes depends on three factors:

- Initial sulfur concentrations $(\%S)_i$
- Amount of desulfurizer used, usually expressed as the weight fraction of desulfurizer to metal, *W*
- Extraction efficiency of the desulfurizer, which is measured by the desulfurization ratio (DR), that is, the ratio of sulfur concentrations: desulfurizer to metal

The three variables can be related as follows through a mass balance on sulfur:

$$(\%S)_f = \frac{(\%S)_i}{1+W(DR)} \qquad \textbf{(Eq 11)}$$

For liquid-desulfurizing slags that are not saturated with respect to calcium sulfide (CaS), the maximum value of DR, that is, the equilibrium value, can be predicted from thermodynamic considerations:

$$(DR)_{\max} = \left(\frac{(\%S)_{slag}}{(\%S)_f}\right)_{\max} = \frac{c_s f_s k_{14}}{k_{15} h_o} \qquad \textbf{(Eq 12)}$$

where C_S is the slag sulfide capacity, defined as (Ref 15):

$$C_s = (\%S)_{slag}\left(\frac{p_{O_2}}{p_{S_2}}\right)^{1/2} \qquad \textbf{(Eq 13)}$$

and K_{14} and K_{15} are the respective equilibrium constant for the reaction:

$$\frac{1}{2}O_2 = \underline{\mathbf{O}} \qquad \textbf{(Eq 14)}$$

$$\frac{1}{2}S_2 = \underline{\mathbf{S}} \qquad \textbf{(Eq 15)}$$

and f_S is the activity coefficient for 1 wt% S in the standard state.

Equation 12 can be derived from Eq 10. Using known input and desired output sulfur values, Eq 11 gives the required desulfurization ratios as a function of weight fraction desulfurizer. These data are plotted in Fig. 10 for two cases. In the electric-melting case, initial and final sulfur concentrations were assumed to be 0.03 and 0.008% S, respectively, In cupola-melting case, the equivalent concentrations were 0.10% S and 0.008% S. The cupola line applies for both cupola iron and ladle-desulfurized cupola iron.

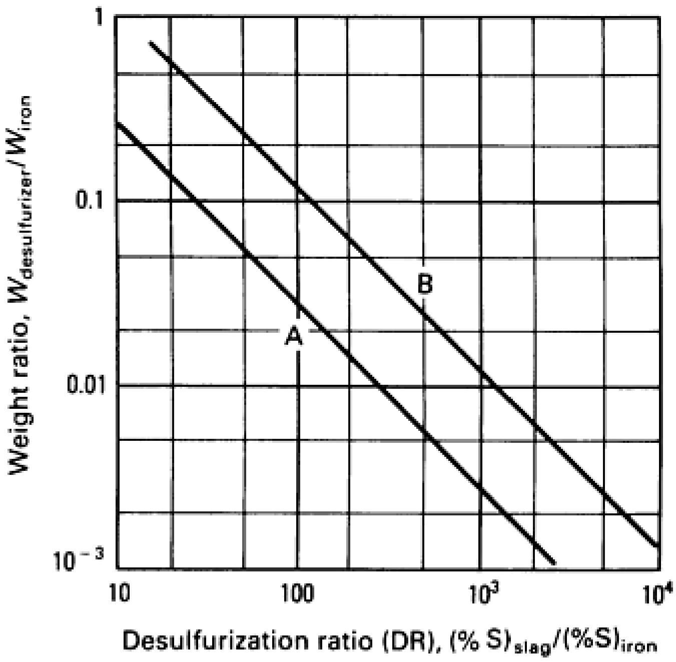

Fig. 10 Weight fraction desulfurizer required to achieve given desulfurization ratios. Plots for electric-melted iron and steel (curve A) assume initial sulfur concentrations [$\%(S)_i$ = 0.03] different from those of cupola-melted iron [$(\%S)_i$ = 0.10] (curve B).

The relationships illustrated in Fig. 10 are useful in defining systems that will provide the necessary desulfurization conditions. Four systems are compared in Table 3. These cover cupola- and electric-melted cast iron and electric-melted steel. Also examined are two liquid slag systems: a basic cupola slag (dicalcium silicate saturated) and a CaO-saturated $CaO-Al_2O_3$ slag.

Table 3 Theoretical weight ratios: desulfurizer to iron to achieve 0.008% S in various systems

Type of melt	**Slag composition**	***T*, K**	C_S (× 10^4)[(a)]	f_S	h_O (× 10^4)[(b)]	$(DR)_{max}$[(c)]	*W*
A. cast iron--cupola	44 $CaO-15MgO-5Al_2O_3-36SiO_2$	1773	2.7	5	1.3	90	**0.13**
B. cast iron--cupola (ladle desulfurized)	$CaO_{sat}-Al_2O_3$	1773	59	5	5.0	417	**0.027**
C. cast iron--electric	$CaO_{sat}-Al_2O_3$	1773	59	5	5.0	417	**0.0065**
D. steel--electric	**$CaO_{sat}-Al_2O_3$**	**1873**	**316**	**1**	**0.45**	**5280**	**0.00052**

(a) C_S is obtained from optical basicity correlations (Ref 15). f_S is based on iron composition (Ref 16).

(b) Case A: h_O is governed by Si/SiO_2 equilibrium based on respective concentration in iron and slag (Ref 17). Cases B and C: h_O is governed by Si/SiO_2 equilibrium with $aSiO_2$ = 1 due to ladle exposure to air (Ref 18). Case D: h_O is governed by Al/Al_2O_3 equilibrium with % Al = 0.05 (Ref 19), assumed no contact with air.

(c) K_{14} and K_{15} data from Ref 20

Table 3 shows that:

- The best desulfurizing cupola slags have lower sulfide capacity and desulfurization ratio than slags used in ladle desulfurization; the consequence is the need for much larger quantities of slag*
- Compared to steel, cast iron desulfurization benefits from higher f_S because of the presence of relatively high concentrations of carbon and silicon in cast iron
- Ladle desulfurization systems that are exposed to air suffer higher h_O and, as a result, poorer desulfurization than might otherwise be anticipated

For the cupola slag case in Table 3, the thermodynamically predicted value of $(DR)_{max}$ = 90 is in good agreement with measured data (Fig. 11). This indicates that the cupola desulfurization process operates close to equilibrium levels. Further evidence for this is given Fig. 12, which plots desulfurization data for a cupola operated with varying amounts of municipal ferrous refuse in the charge. The upper portion of Fig. 12 plots C_S and oxygen activity. The latter is expressed as the partial pressure of oxygen. The lower portion of Fig. 12 is a comparison of (DR), measured and calculated. The good agreement found is evidence that near-equilibrium conditions existed.

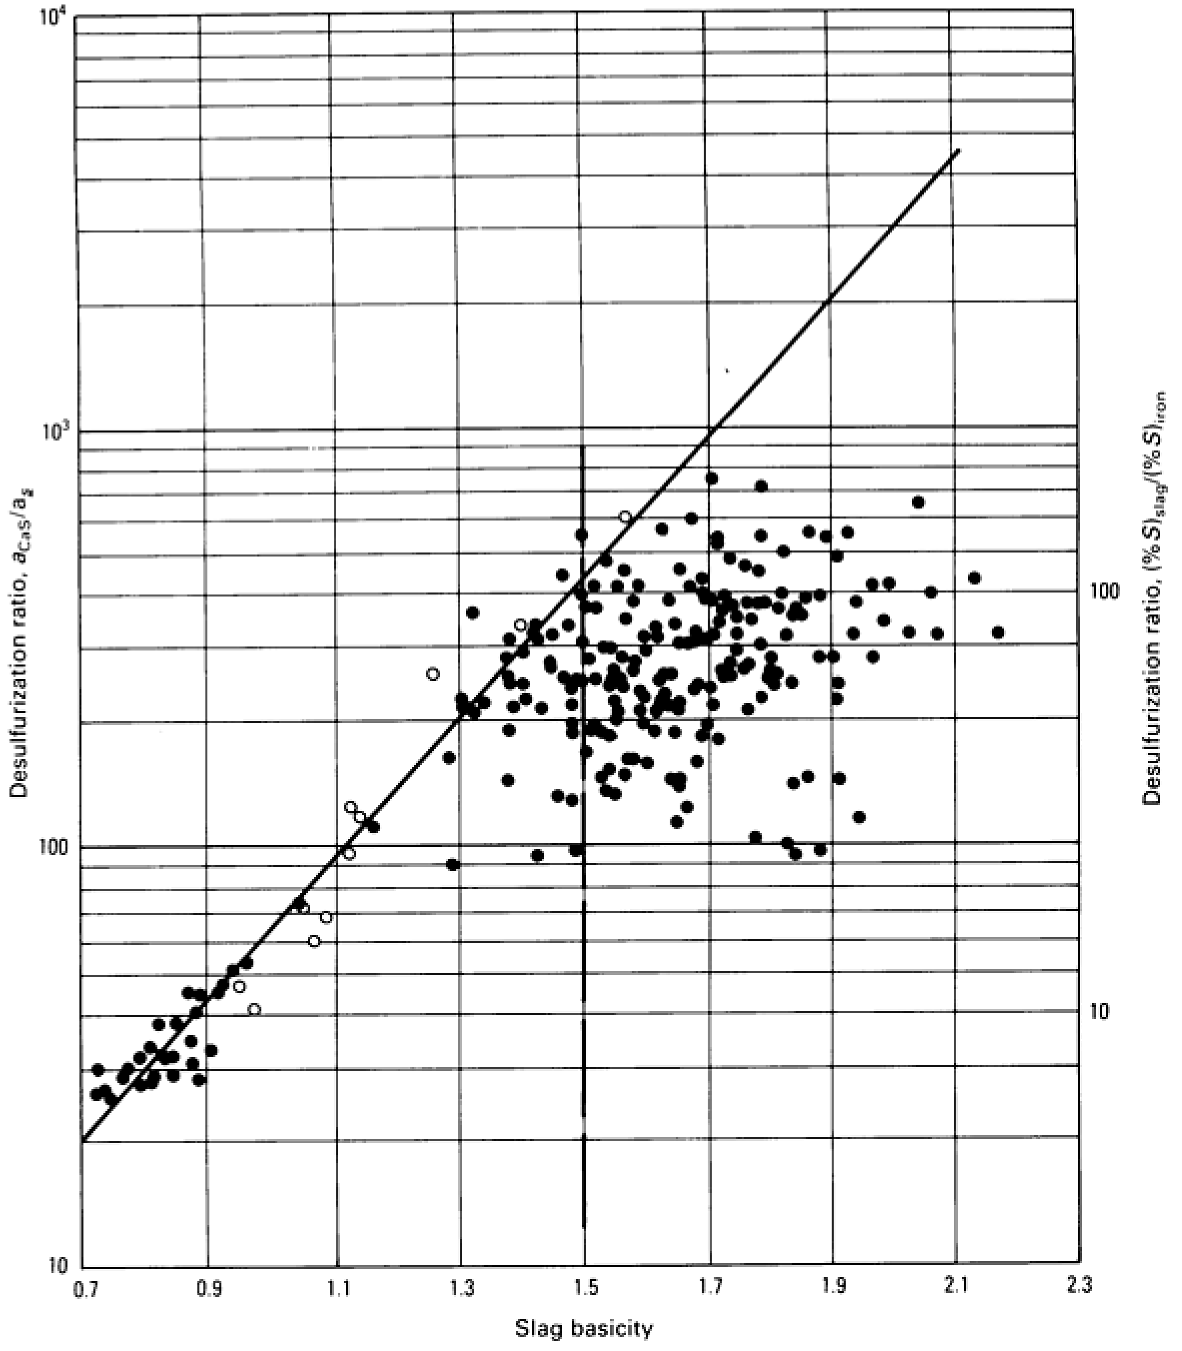

Fig. 11 Desulfurization ratio-basicity comparisons for cupola (closed circles) and laboratory data (open circles). Equilibrium values are indicated by the angled line. The vertical line indicates the slag basicity above which slags are saturated at 1500 °C (2730 °F), with respect to dicalcium silicate. This is the point at which the observed DR should equal $(DR)_{max}$. Source: Ref 14.

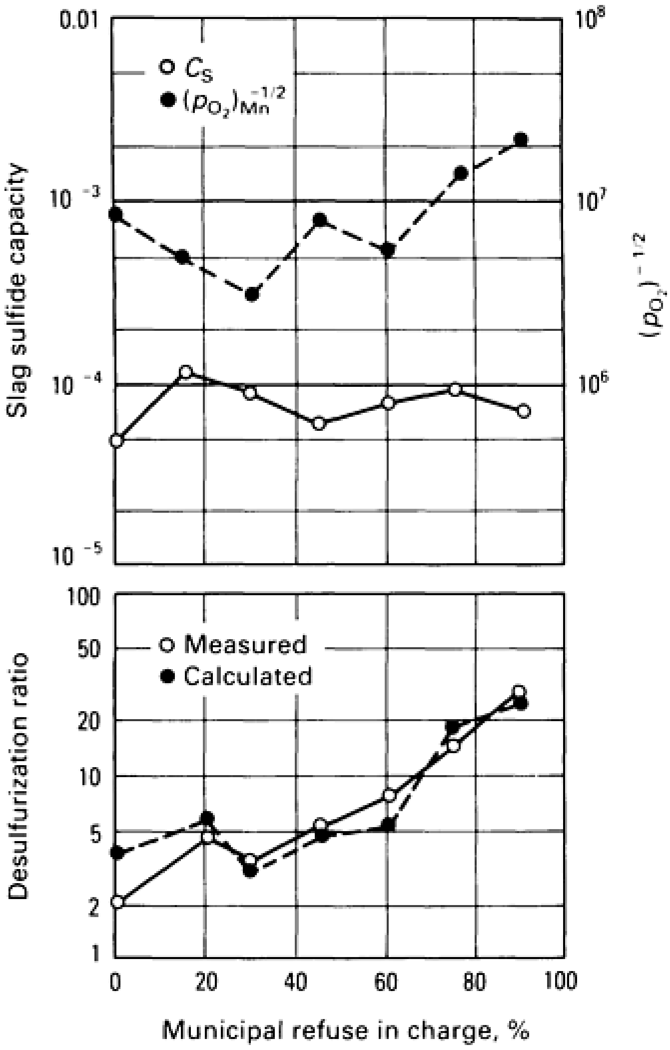

Fig. 12 Slag sulfide capacities, oxygen activities, and desulfurization ratios, measured and calculated, for a cupola operated with municipal ferrous refuse as a charge material. Source: Ref 21.

For the cases discussed above, the oxygen activity in cupola iron has been found to be governed by the reaction (Ref 17, 21):

$$\underline{\mathbf{Mn}} + \underline{\mathbf{O}} = \text{MnO} \qquad \textbf{(Eq 16)}$$

Therefore, the overall cupola desulfurization reaction is:

$$\text{CaO} + \underline{\mathbf{S}} + \underline{\mathbf{Mn}} = \text{CaS} + \text{MnO} \qquad \textbf{(Eq 17)}$$

Considerably lower sulfur could be achieved (Ref 14) if h_O were governed by:

$$\underline{\mathbf{C}} + \underline{\mathbf{O}} = \text{CO} \qquad \textbf{(Eq 18)}$$

However, equilibrium for this reaction has not been observed.

This discussion has concerned CaS-unsaturated slags. However, a desulfurizing slag, saturated with CaS, can in many cases continue to desulfurize as long CaO is present. In this case, the ultimate sulfur levels are not as low as those for

CaS-unsaturated slags. Nevertheless, CaS-saturated slags can produce sulfur levels that are more than sufficient for cast iron and steel applications. In fact, CaS-saturated conditions are often employed in industrial applications because much less desulfurizer is required.

In addition to the CaS-saturated liquid slags, totally solid slags such as CaO and CaC_2 are in the same category because CaS does not form solid solutions with these materials. Also in this category are desulfurizers containing small amounts of liquid phase. These materials possess the desirable properties of liquid and solid slags. That is, they combine the fast reaction rates of liquid slags with the large desulfurizing capacities (high CaO concentration) of solid slags.

The final sulfur concentrations attainable under CaS-saturated conditions can be obtained from Eq 10 by setting $a_{CaS} = 1$. For ladle desulfurization, the most important industrial desulfurizers are also CaO-saturated, that is, $a_{CaO} = 1$. Applying the condition of double saturation to Eq 10 yields:

$$(\%S) = \frac{ho}{k_9 f_s} \qquad \textbf{(Eq 19)}$$

In the ladle desulfurization of cast iron, h_O is governed by the reaction (Ref 14):

$$\frac{1}{2}\underline{\mathrm{Si}} + \underline{\mathrm{O}} = \frac{1}{2}\mathrm{SiO_2} \qquad \textbf{(Eq 20)}$$

where $a\mathbf{SiO_2} = 1$. This is attributed to the exposure of the iron to air (Ref 14). Sulfur concentrations obtained with Eq 19, assuming silicon-silicon dioxide (Si-SiO_2) equilibrium and $aSiO_2 = 1$, are given in Fig. 13. In continuous ladle-desulfurization processes, equilibrium sulfur levels are achieved when input sulfur levels are low, but are only approached when input levels are high. This is illustrated in Fig. 14 with desulfurization data for CaC_2 (Ref 14). Other desulfurizers such as CaO-CaF_2 behave similarly.

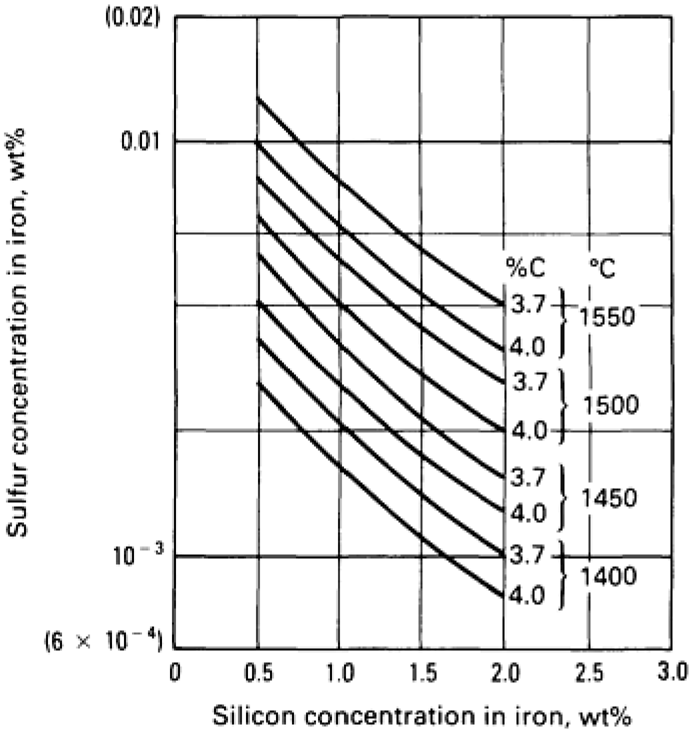

Fig. 13 Equilibrium sulfur concentrations for CaO desulfurization calculated with Eq 19 and 20, assuming $a_{CaO} = a_{CaS} = aSiO_2 = 1$. Source: Ref 14.

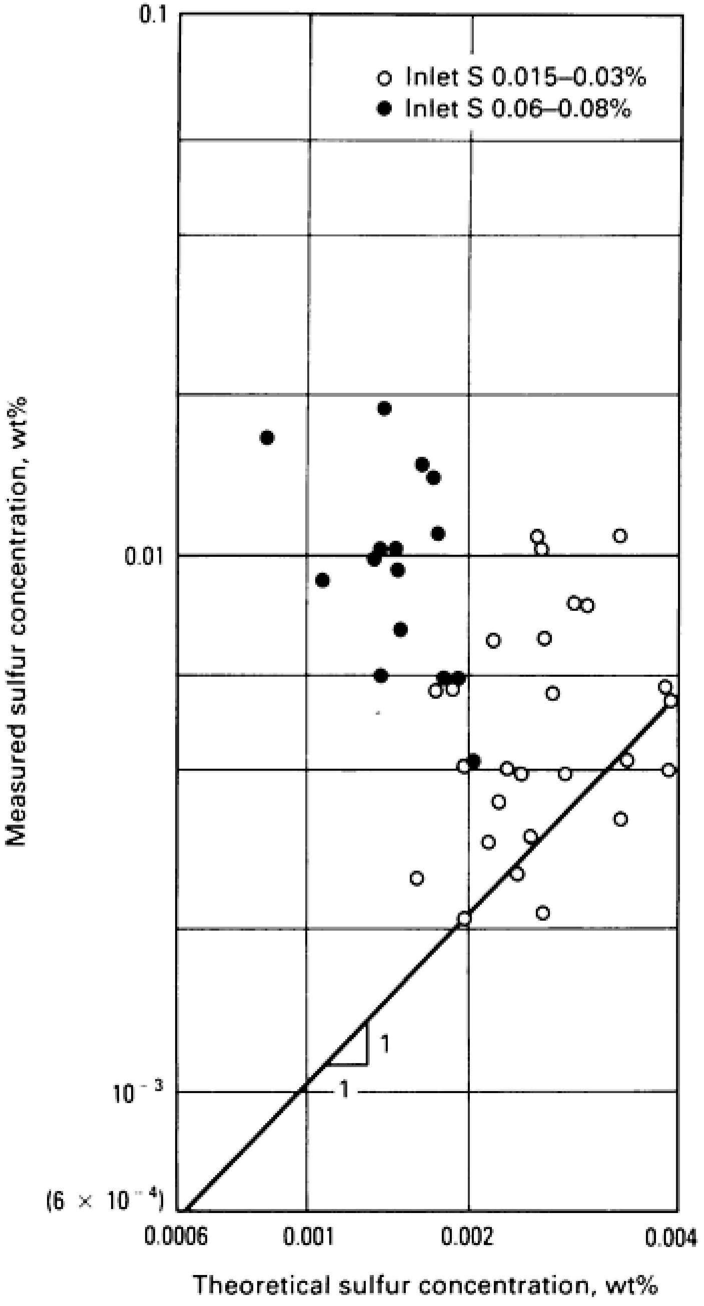

Fig. 14 Comparisons of the sulfur concentrations in production-continuous desulfurization using CaC_2 with the sulfur concentrations from Eq 19 and 20. Open circles indicate electric-melted iron. Closed circles indicate cupola iron. Source: Ref 14.

High desulfurization rates are needed for effective desulfurization in the short times required. For CaO-base desulfurizers, the presence of relatively small amounts of liquid phase (<25 vol%) significantly increases the rate of desulfurization. This is illustrated in Fig. 15, in which the rates of desulfurization by CaO with varying amounts of calcium fluoride (CaF_2) are compared. The faster rates obtained with CaF_2 additions were due to the formation of a CaO-CaF_2 liquid phase that provided a path for CaS diffusion from the reaction interface into the porous CaO particle. This prevented the normal rapid development of an impervious CaS coating on the CaO surface (Ref 23, 24). A similar explanation, involving liquid-phase formation, was used to account for the higher CaO desulfurization rates of steel when aluminum was concurrently added (Ref 25, 26).

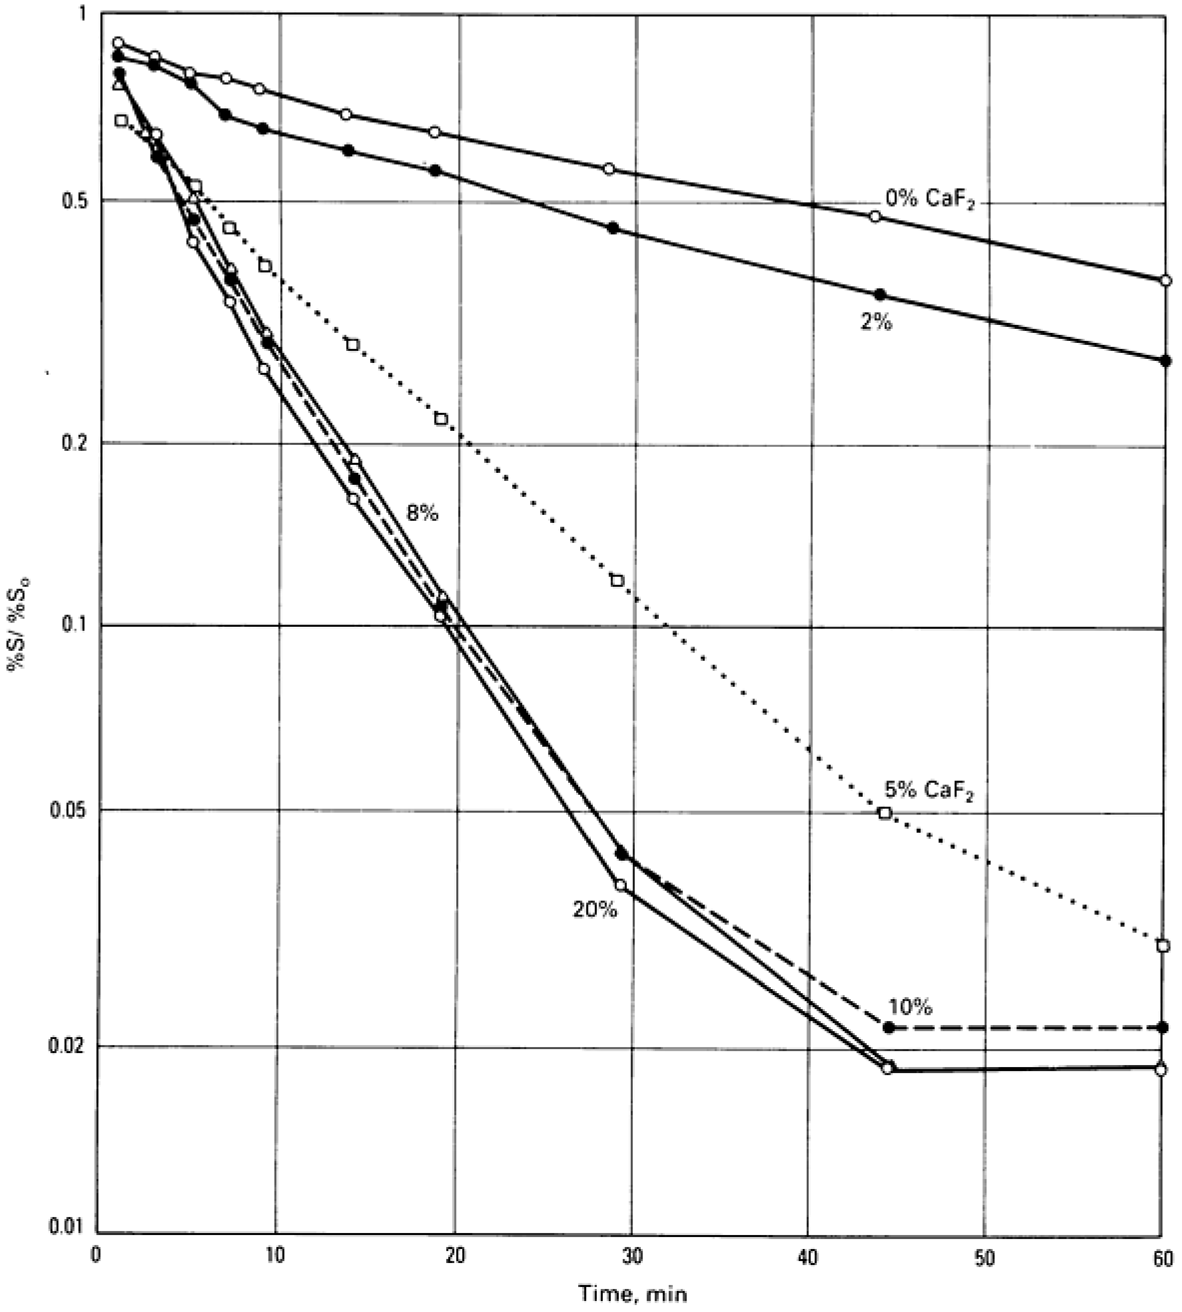

Fig. 15 Desulfurization rates of carbon-saturated iron, containing 0.4% Si, with CaO and varying amounts of CaF_2 at 1450 °C (2640 °F). Source: Ref 22.

Another rate-controlling variable in ladle desulfurization is bath agitation. For gas-stirred melts, the desulfurization rate constant k is a function of gas flow rate $\dot{Q}$, that is, $k \propto \dot{Q}^n$. For well-dispersed solid-liquid mixtures, the rate of diffusion-controlled interphase reaction is a relatively weak function of $\dot{Q}$, that is, n ~0.2 to 0.4 (Ref 27, 28, 29). For a poorly dispersed system, such as a ladle of iron with a cover slag of desulfurizer, agitation has a much greater influence on the rate constant, with n typically in the range of 1.0 to 2.5 (Ref 27, 28, 29). This is due to the entrainment of increasing amounts of top slag into the liquid metal with increasing $\dot{Q}$. This effect is illustrated in Fig. 16, which plots the apparent mass transfer coefficient for desulfurization versus the gas flow rate.

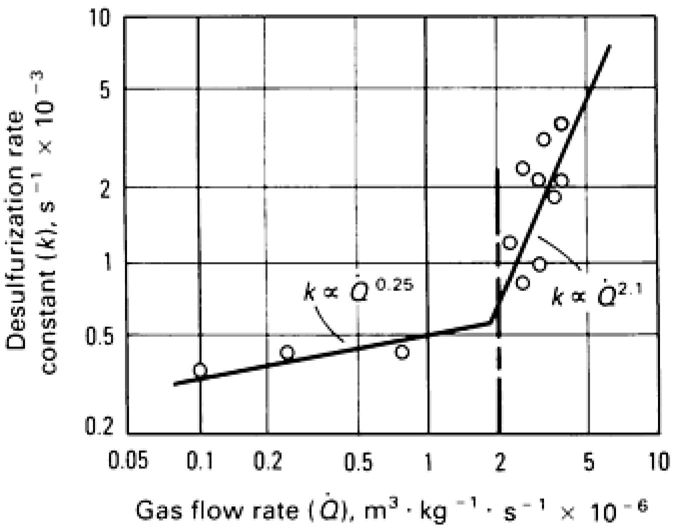

Fig. 16 Dependence of CaO desulfurization rate constant on the rate of gas flow through a reactor. Source: Ref 29.

Deoxidation. In the manufacture of steel, FeO-saturated conditions (~0.2% O) are approached as a result of oxygen blowing to remove carbon and silicon as the respective oxides. To make a steel product, the oxygen levels are subsequently lowered to 0.005 to 0.02% O by reactive alloy additions of electropositive elements. The low oxygen concentrations are necessary to maintain the number of oxide inclusions at a suitable low level, to prevent the formation of CO blow-holes, and to ensure effective desulfurization.

For single-element deoxidation, expressed by:

$$x\underline{\mathbf{M}} + y\underline{\mathbf{O}} = \mathrm{M}_x\mathrm{O}_y \quad \textbf{(Eq 21)}$$

the equilibrium oxygen concentration in the liquid steel, obtained by rearranging the equilibrium constant expression, is:

$$(\%O) = \left(\frac{{}^{a}M_xO_y}{K_{22}(\%M)^x f_M^x f_O^y} \right)^{y^{-1}} \quad \textbf{(Eq 22)}$$

The calculated equilibrium values of oxygen solubility in liquid iron at 1600 °C (2910 °F), based on Eq 22, are given in Fig. 17 for several elements as a function of the concentration of the element, assuming $a\mathrm{M_xO_y} = 1$. As seen among the common deoxidizers, aluminum produces the lowest oxygen. Although not shown, rare-earth metals produce even lower oxygen (Ref 30). Figure 17 plots data for oxygen concentration and oxygen activity. In all cases, oxygen activity decreases with increasing levels of deoxidizer, but the oxygen concentration can go through a minimum. This occurs in cases where the interaction coefficient e_O^M is a large negative number, and as a result, f_O decreases significantly even at relatively low concentrations of M. To obtain exact values for [%O] or h_O, equations for K_{22} can be found in Ref 13 and 20.

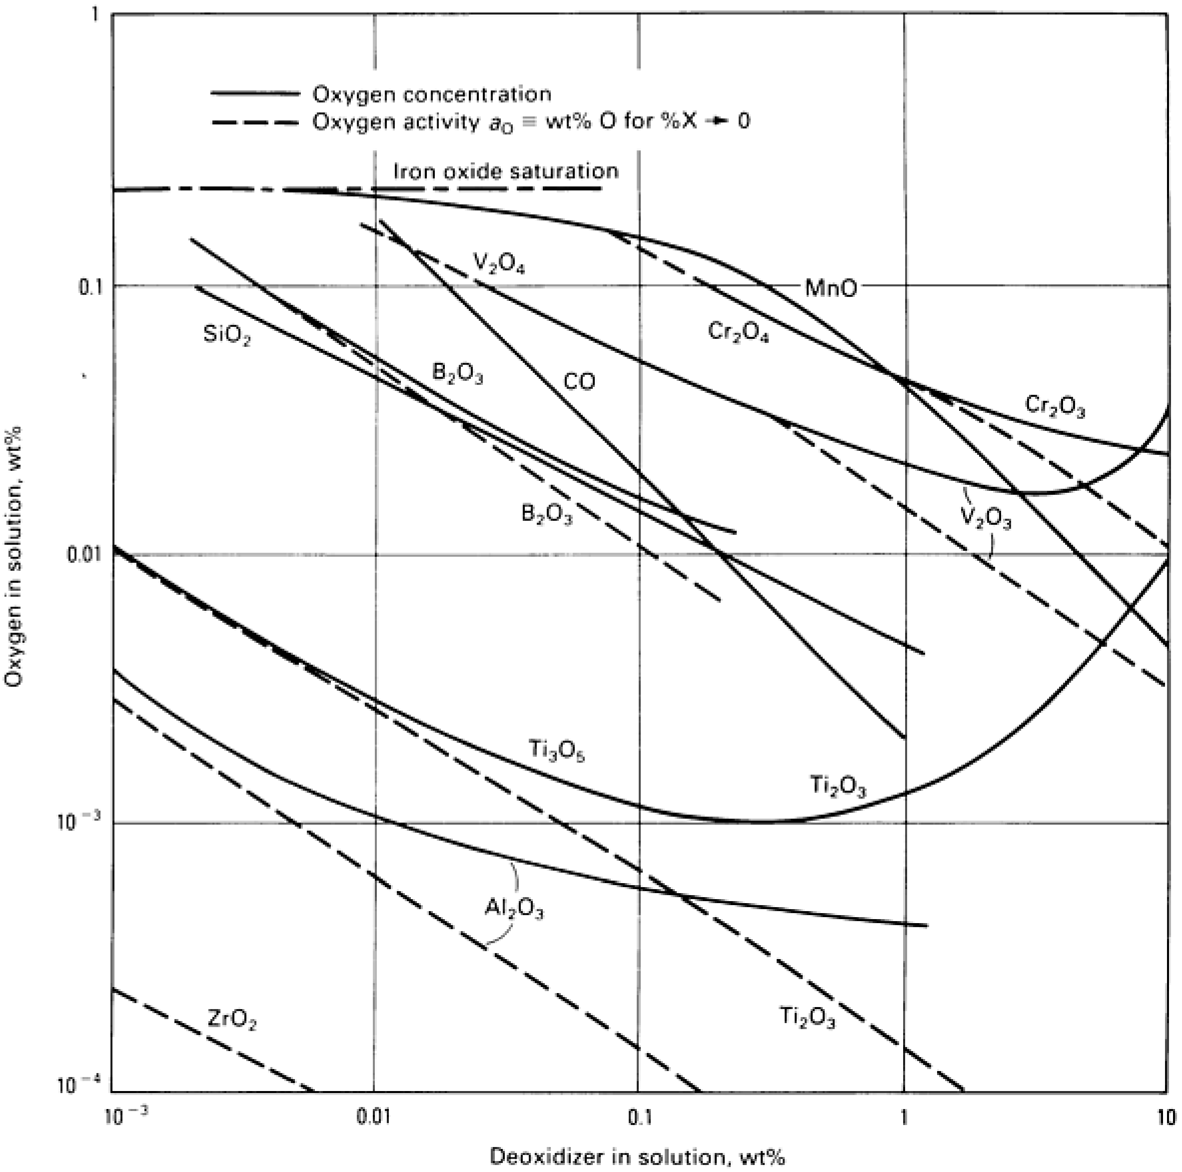

Fig. 17 Deoxidation equilibria in liquid iron alloys at 1600 °C (2910 °F). Source: Ref 30.

As indicated by Eq 22, the oxygen concentration can be reduced if a complex deoxidation product is formed so that $aM_xO_y < 1$. Common deoxidation systems of this type are Si-Mn, Al-Si-Mn, or Al-CaO. An advantage, in addition to lower oxygen, is that less deoxidizer is required in solution to achieve a given level of oxygen. This is illustrated in Fig. 18, which plots the oxygen activity of iron as a function of the concentration of CaO in the calcium aluminate inclusion. Separate lines are given for aluminum concentrations ranging from 0.001 to 0.05% Al. Also indicated is the oxygen activity when pure aluminum oxide (Al_2O_3) is the reaction product. The data in Fig. 18 show that an oxygen activity of 4 ppm can be produced at three aluminum levels--0.002%, 0.005%, or 0.01%--depending on whether the respective deoxidation product was CaO-saturated calcium aluminate, $CaAl_2O_4$-saturated calcium aluminate, or Al_2O_3.

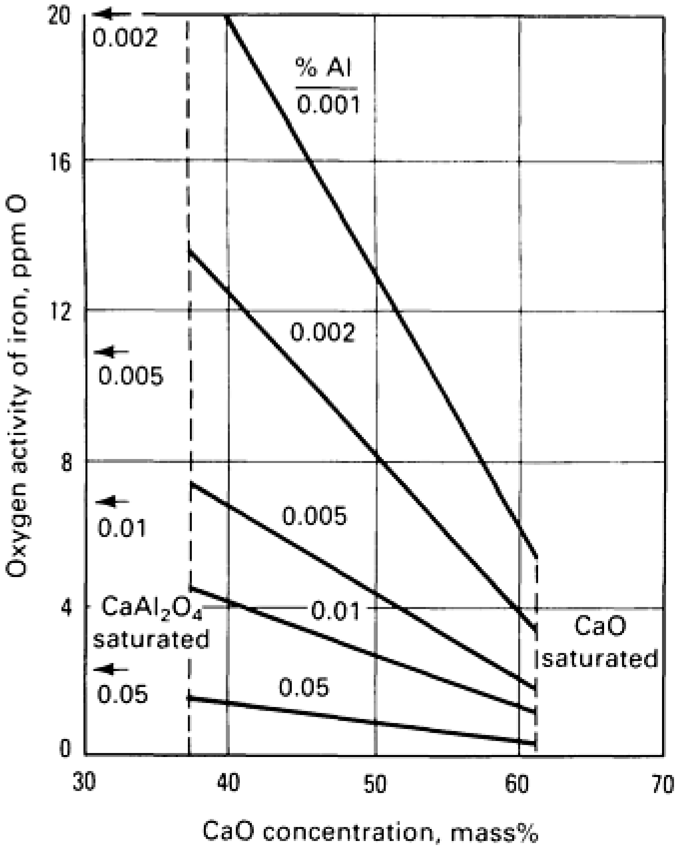

Fig. 18 Concentration of oxygen and aluminum in liquid steel in equilibrium with calcium aluminate at 1600 °C (2910 °F); arrows indicate oxygen values when the reaction product is pure Al_2O_3. Source: Ref 31.

The levels of total oxygen measured in steel melts considerably exceed equilibrium levels (Ref 20). Two possible explanations are the kinetic limitations in the deoxidation reaction and the ineffective separation of deoxidation products from the melt. Consideration of the first possibility suggests that the most important kinetic limitation would be oxygen and/or deoxidant solute diffusion to inclusions in the melt (Ref 20). Considering the presence of 10^5 to 10^7 inclusion particles in a cubic centimeter of melt, deoxidation to equilibrium levels of 10 to 20 ppm would require a few minutes. Appreciably longer times would be needed to reduce oxygen to less than 1 ppm, as with rare-earth additions. For most cases, oxide formation appears faster than oxide particle separation from the bath. Thus, for applications that depend on dissolved oxygen, such as desulfurization or CO blowhole formation, equilibrium oxygen values can be assumed to exist after relatively short reaction periods. For considerations of the inclusion content of steel, the kinetics of particle separation need to be considered.

The limiting case of particle flotation at velocities obtained from Stokes' law calculations is shown in Fig. 19. Inclusion size versus time of flotation is plotted. The particles produced during deoxidation are generally small (<5 μm, or 200 μin.); accordingly, separation times are long. The times indicated in Fig. 19 are representative of conditions in a quiescent bath. Times are considerably shorter for stirred melts because articles grow by collision and coalescence to sizes of 30 to 100 μm (Ref 20). The efficiency of coalescence of particles is material dependent. The energy of adhesion of particles is determined by the wetting characteristics of the particle, measured by wetting angle. For example, the force of adhesion of Al_2O_3 particles with a wetting angle of 140° is twice that for SiO_2 with a wetting angle of 115°. On this basis, Al_2O_3 inclusions are expected to cluster more easily than SiO_2 inclusions, a phenomenon that has been observed in practice (Ref 20).

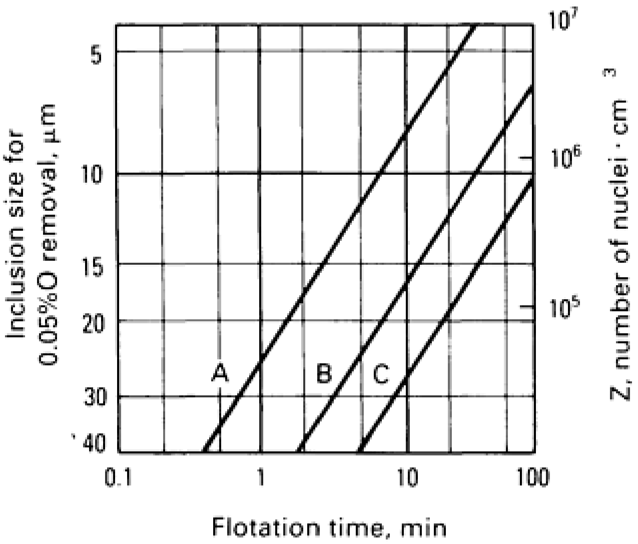

Fig. 19 Calculated time of flotation of inclusions in stagnant melts as a function of inclusion size. Melt depth: A, 50 mm (2 in.); B, 500 mm (20 in.); C, 2000 mm (80 in.). Source: Ref 20.

Aluminum Melts

The principal alloying elements in all cast irons, namely, carbon and silicon, are always the same, but the situation for aluminum is different because there are a number of different important aluminum alloy systems, such as Al-Si, Al-Cu, Al-Mg, and Al-Zn (Ref 32). As a result, the preparation of casting alloys from aluminum scrap holds greater risk of contamination than cast iron alloy preparation. In addition to the different elements present in aluminum alloy classes, minor elements are commonly present that are beneficial to some alloy systems but harmful to others. These elements must also be controlled in alloy preparation.

An example of minor element control is the case of silicon modifiers: sodium, strontium, antimony, and phosphorus. These elements favorably alter the nucleation and growth kinetics of silicon in aluminum-silicon alloys to produce a more compact form of the precipitate. Contamination of sodium- or strontium-modified alloys with alloys containing phosphorus or antimony negates the modification. Therefore, control must be exercised over these elements.

Another contaminant that can have positive and negative impact on aluminum castings is hydrogen. Because aluminum reacts readily with atmospheric moisture, hydrogen contamination is common in aluminum alloys (Ref 32). Although the solubility of hydrogen in liquid aluminum is only of the order of 1.0 ppm, most of the hydrogen precipitates during solidification, producing 0.03 volume fraction of gas porosity. This is a serious problem for castings having high strength requirements. On the other hand, for castings that are not subjected to high stress, hydrogen-generated porosity is often a desirable condition because it is used to counter the large solidification shrinkage (0.065 volume fraction) associated with aluminum castings.

The control of cast aluminum alloy composition is difficult. Few but the largest foundries attempt to process purchased scrap; instead they rely on secondary alloy producers with special equipment to perform this function (Ref 33). Because of the wide range of elements involved in aluminum alloy casting, the first line in composition control is the separation of scrap into alloy type and the accurate characterization of the composition of the batch by chemical analysis. Next, compatible batches are combined, and necessary alloy additions are made. This process avoids the difficult task of removing unwanted elements. Chemical purification is commonly practiced for hydrogen and for elements that are more electropositive than aluminum, namely, the alkali and alkaline earth elements. These separations are usually performed in a single process, with small bubbles of inert or reactive gas removing the undesired elements by evaporation and/or oxidation (Ref 34).

Refining Aluminum by Evaporation Treatment. Some elements dissolved in aluminum have higher vapor pressures than aluminum and can therefore be separated from aluminum melts by inert gas flushing or vacuum treatment. For the evaporation reaction:

$$m \quad = M_m(g) \qquad \textbf{(Eq 23)}$$

the equilibrium constant is:

$$K_{24} = \frac{^{p}M_m}{(h_M)^m} \qquad \textbf{(Eq 24)}$$

and for the condition $h_M = 1$, that is, at the hypothetical 1 wt% standard state, the vapor pressure is only a function of K. Using the thermodynamic data given in the article "Thermodynamic Properties of Aluminum-Base and Copper-Base Alloys" in this Volume, the vapor pressures of selected elements were calculated. The results are plotted in Fig. 20. The vapor pressure of aluminum is also shown because it represents a practical lower limit to which impurity vapor pressures can be reduced without incurring significant losses of aluminum. Making this assumption with regard to limiting the impurity vapor pressure, it can be seen in Table 4 that elements with higher vapor pressures than calcium can be effectively removed.

Volatile impurities approach their equilibrium vapor pressures in purge gas bubbles (Ref 35); therefore, the rate of impurity removal depends on the vapor pressure of the element and the volumetric gas flow rate (see the article "Gases in Metals" in this Volume). For elements other than hydrogen, the volumetric ratio of purge gas to impurity vapor is so large that the economics of the process are jeopardized (Ref 35). For alkali and alkaline earth metals, this situation is rectified by adding a reactive gas to the purge gas.

Refining Aluminum With Reactive Gases. Alkali and alkaline earth metals form more stable halides and oxides than aluminum; therefore, by adding F_2, Cl_2, or O_2 to the purge gas, these elements can be separated from aluminum.

Because the reaction products in this case are condensed phases, the rate of impurity removal no longer depends on but on the gas/liquid interfacial area, where the reactions take place. For the generalized reaction between a metal M and halogen or oxygen X_2 gas:

$$M + xX_2 = \frac{1}{m} M_m X_{2mx} \qquad \textbf{(Eq 25)}$$

the equilibrium constant is:

$$K_{26} = \frac{({}^{a}M_m X_{2mx})^{1/m}}{h_M (p_{x2})^x} \qquad \textbf{(Eq 26)}$$

and the equilibrium X_2 pressure is:

$$p_{x2} = \left[\frac{\left({}^{a}M_m X_{2mx}\right)^{1/m}}{K_{26} h_M} \right]^{1/y} \qquad \textbf{(Eq 27)}$$

If p_{x2} for an impurity element is less than p_{x2} for the corresponding reaction with aluminum, then impurity removal is theoretically possible. Conversely, if p_{x2} for the impurity element is greater than p_{x2} for aluminum, the aluminum compound will separate in preference to the impurity. Figure 21 and 22 plot p_{x2} versus h_M, respectively, for reactions with chlorine and fluorine. The oxide data were not included, because oxygen is much less effective than the halides (Ref 35). The data in Fig. 21 and 22 assume $aM_mX_{2mx} = 1$.

Table 5 compares the minimum impurity concentrations that are possible by treatment with Cl_2, F_2, and O_2. For all the cases examined, chlorine appears to be the best reagent. Chlorine is the most commonly used reagent for removing these elements from aluminum melts. In practice, the thermodynamically predicted levels are not achieved (Ref 35).

The use of halogens has a disadvantage in terms of the environmental precautions that need to be taken. This has prompted the development of numerous electrochemical separation processes.

Electrochemical Refining of Aluminum. An electrochemical process for separating magnesium from molten aluminum is illustrated in Fig. 23. Through the application of a potential, magnesium in the aluminum melt (anode) dissolves in the electrolyte, while pure magnesium deposits at the cathode. As seen at left in Fig. 23, densities of the three phases form a convenient system for cell construction, with the aluminum phase having the highest density and the magnesium phase having the lowest. Therefore, liquid magnesium is easily removed from the top of the cell. An advantage of the electrochemical method is that the recovered metallic magnesium has high commercial value compared to the $MgCl_2$ produced by reactive gas separations.

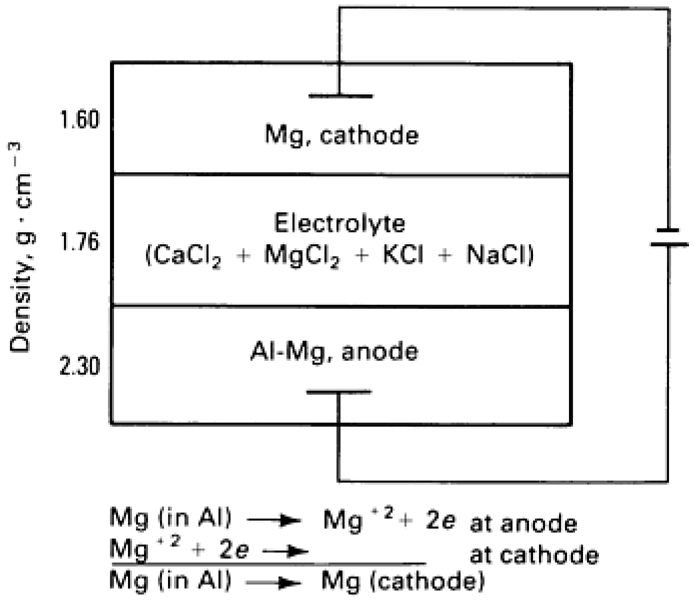

Fig. 23 Schematic of an electrochemical magnesium separation apparatus. Source: Ref 36.

The open-circuit cell potential ε for this system can be estimated from the Nernst equation:

$$\mathcal{E} = -\frac{RT}{2\mathcal{F}} \ln \frac{(a_{Mg})_{anode}}{(a_{Mg})_{cathode}} \quad \textbf{(Eq 28)}$$

where $\mathcal{F}$ is Faraday's constant and $(a_{Mg})_{cathode} = 1$. For producing alloys with less than 0.1% Mg, as required for a number of important casting alloys, such as 319 and 380, Eq 28 predicts that a cell potential of 0.32 V is required (Ref 36). This voltage must not be greatly exceeded, because aluminum will be transferred from anode to cathode at a potential of 0.5 V.

Gases in Metals

Richard J. Fruehan, Carnegie Mellon University

Introduction

GAS POROSITY is one of the most serious problems in the casting of cast iron, aluminum, and copper. It is generally caused by the evolution of gases during the casting and solidification process. The gases may be result of a reaction between the casting sand or mold and the metal, or they may result from the evolution of gases dissolved in the liquid metal during solidification.

An example of a chemical reaction evolving gas and causing porosity is the reaction of moisture (H_2O) in the sand with elements in the cast iron, such as carbon, silicon, aluminum, or iron itself. For example, aluminum in cast iron often causes porosity problems, and the reaction responsible for the gas evolution is:

$$3H_2O + 2\underline{\mathbf{Al}} = Al_2O_3 + 3H_2 \quad \textbf{(Eq 1)}$$

where the underlining of aluminum ($\underline{\mathbf{Al}}$) indicates that it is dissolved in the metal. The free energy for reaction (Eq 1) is highly negative even for very low concentrations of aluminum, indicating that the thermodynamics for the reaction are highly favorable. Similar reactions can be written for silicon, carbon, and iron. For carbon, carbon monoxide is also evolved, according to the reaction:

$$H_2O + \underline{\mathbf{C}} = H_2 + CO \quad \textbf{(Eq 2)}$$

For the casting of aluminum, the reaction is even more favorable. Whether or not the reaction will actually occur depends on many complex factors, including liquid-phase mass transfer and surface tension; therefore, its occurrence is difficult to predict. However, if there is excessive moisture in the sand, the reaction is highly likely to occur.

The other major cause of gas porosity is the evolution of dissolved gases during casting. For example, liquid cast iron may have dissolved hydrogen and nitrogen. The solubility of these gases in the solid may be less than that in the liquid, and the gases may therefore be evolved during solidification. Whether or not this will occur depends on the amount of

hydrogen and nitrogen present, the alloy being cast, chemical kinetics, and the surface tension of the alloy. Similarly, hydrogen can dissolve in liquid aluminum, but its solubility is much lower in solid aluminum and can cause porosity. For copper, the evolution of hydrogen, water vapor, or carbon monoxide could cause gas porosity.

In the article, the solubilities of the common gases present in cast iron, aluminum, and copper will be reviewed. The kinetics of the relevant reactions and the reactions during solidification will be discussed. Finally, possible methods of control or removal of the dissolved gases will be analyzed. The discussion will primarily focus on cast iron because more is known about the thermodynamics and kinetics of iron than other elements. However, the same basic principles also apply to aluminum and copper.

Cast Iron (Ref 1)

Solubility of Hydrogen and Nitrogen. The gases in cast iron that can cause porosity are hydrogen and nitrogen. Castings from iron produced in a cupola are nearly saturated with nitrogen; therefore, the presence of nitrogen a is a major concern (Ref 2). Hydrogen and nitrogen dissolve in liquid iron alloys as atomic species according to:

$$\frac{1}{2} H_2 = \underline{\mathbf{H}} \qquad \textbf{(Eq 3)}$$

$$\frac{1}{2} N_2 = \underline{\mathbf{N}} \qquad \textbf{(Eq 4)}$$

The solubilities of both elements in liquid and solid iron alloys have been extensively measured, and the results have been adequately summarized (Ref 3). The solubility of nitrogen and hydrogen in liquid iron is decreased by carbon. The nitrogen and hydrogen contents in iron-carbon alloys in equilibrium with 1 atm pressure of the respective gases are shown in Fig. 1 as a function of carbon content. The solubility of nitrogen at 1823 K decreases from about 450 ppm for pure iron to about 80 ppm for an alloy containing 4.5% C. The solubilities of hydrogen for the same metals are 24 and 10 ppm, respectively. The hydrogen solubility decreases with temperature and at eutectic temperature is 6.5 ppm; temperature has only a small effect on the solubility of nitrogen. Silicon decreases the solubility of nitrogen even further. For a 4C-1Si melt, the solubility of nitrogen is about 75 ppm.

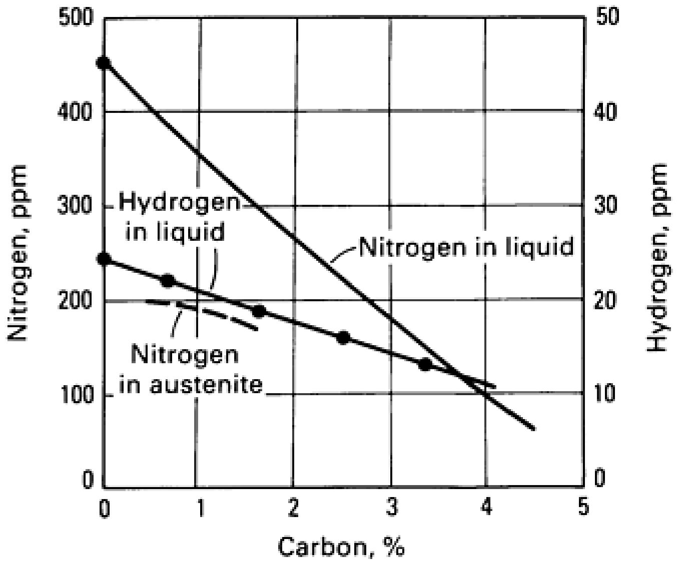

Fig. 1 Solubility of hydrogen and nitrogen (1 atm) in iron-carbon alloys at 1823 K in the liquid and 1500 K for austenite.

When the cast iron solidifies, it forms austenite and graphite or cementite. The solubility of nitrogen in austenite (Ref 3) is also shown in Fig. 1. For austenite containing about 1.8% C, the solubility is about 150 ppm. Therefore, when the liquid

cast iron freezes, the solubility in the solid is higher than that in the liquid; this interesting phenomenon will be discussed later in detail. There is some solubility of nitrogen in cementite (Ref 4). The exact amount is not known, but is about the same as that in austenite. The solubility of hydrogen in austenite is about 7 ppm; therefore, the solubility of hydrogen in the liquid and solid are about equal, and there is little segregation of hydrogen during solidification (Ref 3).

Kinetics of Gas-Liquid Reactions. The absorption of hydrogen and nitrogen is controlled by one of the following steps:

- Diffusion of the gas to the surface
- Chemical reaction on the surface
- Diffusion of the element in the liquid away from the surface

For the desorption of a gas, the same three steps are important but occur in reverse order. The process need not to be controlled by only one of the above steps; it can be controlled by two or more steps in series. For liquid cast iron, nitrogen is the more important of the gases, and it will be considered in detail.

Gas diffusion is usually not rate controlling for nitrogen absorption from the atmosphere because of the pressure of N_2; consequently, the driving force for diffusion is high. As a result, one of the other steps is slower and rate controlling. However, for nitrogen or hydrogen removal by an inert gas, diffusion on N_2 or H_2 must be considered. The flux of nitrogen J_{N_2} away from the surface is given by:

$$J_{N_2} = \frac{K_m}{RT}(p^S_{N_2} - p^B_{N_2}) \qquad \textbf{(Eq 5)}$$

where k_m is the mass transfer coefficient $p^B_{N_2}$ is the pressure of nitrogen in the bulk gas, and $p^S_{N_2}$ is the surface pressure of nitrogen in equilibrium with the melt where:

$$p^S_{N_2} = K^2_N f^2_N \ (\%N)^2 \qquad \textbf{(Eq 6)}$$

where K_N is the equilibrium constant for Eq 4 and f_N is the activity coefficient of nitrogen with respect to 1 wt%. However, in general, gas diffusion for these reactions is faster than the chemical reaction or liquid-phase diffusion and can be neglected in most cases.

The rate of the chemical reaction is controlled by the dissociation of the nitrogen molecule on the surface, and the rate is given by:

$$\frac{dn_{N_2}}{dt} = K_B A(1-q)(p_{N_2} - p^e_{N_2}) \qquad \textbf{(Eq 7)}$$

where k_B is the rate constant for pure iron, A is the surface area, $p^e_{N_2}$ is the equilibrium nitrogen pressure given by an expression similar to Eq 6, and (1 - θ) is the fraction of vacant sites not occupied by surface-active elements. Certain elements are surface active on liquid iron in that they lower the surface tension of iron by covering most of the surface. For example, oxygen and sulfur are surface active on iron, and for bulk concentrations of 0.03% O or 0.03% S, over 90% of the surface sites will be covered by oxygen or sulfur. These elements therefore retard the rate of chemical reaction. At high coverage, the surface-active element (1 - θ) is inversely proportional to the activity a of the element. Therefore, the rate is given by:

$$\frac{dn_{N_2}}{dt} = \frac{K_B K_A A}{a}(r_{N_2} - r^e_{N_2}) \qquad \textbf{(Eq 8)}$$

where k_A is related to the adsorption coefficient of the element on the surface and the quantity $k_B k_A/a$ is the overall rate constant k. For dilute solutions, the activity of the surface-active element is proportional to its concentration. Therefore, the overall rate constant is inversely proportional to the weight percent of the surface-active element in iron.

Liquid-Phase Mass Transfer. If the rate is controlled by liquid-phase mass transfer, the flux of nitrogen atoms is given by:

$$J_N = k_{mN} (C_N^B - C_N^S) \qquad \textbf{(Eq 9)}$$

where k_{mN} is the liquid-phase mass transfer coefficient of nitrogen and C_N^B and C_N^S are the bulk and surface concentrations of nitrogen. The integrated form of Eq 7 is:

$$\ln\left[\frac{\%N - \%N_c}{\%N_0 - \%N_c}\right] = -\frac{Ar\,k_{mN}t}{W} \qquad \textbf{(Eq 10)}$$

where ρ is the density of iron, W is the weight of the metal, and $\%N_e$ and $\%N_o$ are the equilibrium and initial nitrogen contents, respectively.

The rate is often controlled by two processes in series--usually the chemical reaction and liquid-phase mass transfer. The rate in this case can be obtained by equating the fluxes given by Eq 8 and 9 and solving for the surface concentration as indicated in Ref 5.

The rate of the nitrogen reaction with iron alloys containing oxygen, sulfur, chromium, and other elements has been measured by many investigators, and there is good agreement in most cases (Ref 6, 7, 8, 9, 10, 11). However, the rate for carbon-saturated iron containing other elements was not investigated until recently (Ref 12).

In this work, an isotope exchange technique was used to measure the rate of dissociation of the nitrogen molecule (N_2). In particular, the effects of carbon, sulfur, phosphorus, lead, tin, bismuth, and tellurium on the rate were investigated.

Sulfur, phosphorus, lead, bismuth, and tellurium decreased the rate, while carbon and tin had no significant effect. For example, the effect of sulfur is shown in Fig. 2 as the rate constant versus the reciprocal of the activity of sulfur (Ref 11). The activity of sulfur is in weight percent, and the activity coefficient of sulfur in carbon-saturated iron is 6.3. The rate for carbon-saturated iron with no sulfur is about 10^{-5} mol/cm^2 · s · atm at 1450 °C (2640 °F). For example, for 0.009% S ($1/a_s$ = 18), the rate is decreased to 8×10^{-7} mol/cm^2 · s · atm. Bismuth and tellurium had an even larger effect (Ref 12), as shown in Fig. 3 and 4. The activities are relative to pure bismuth and tellurium, respectively, which have larger deviations from ideal behavior. As little as 50 ppm Te reduced the rate by 90%, and 50 ppm Bi decreased it by 80%.

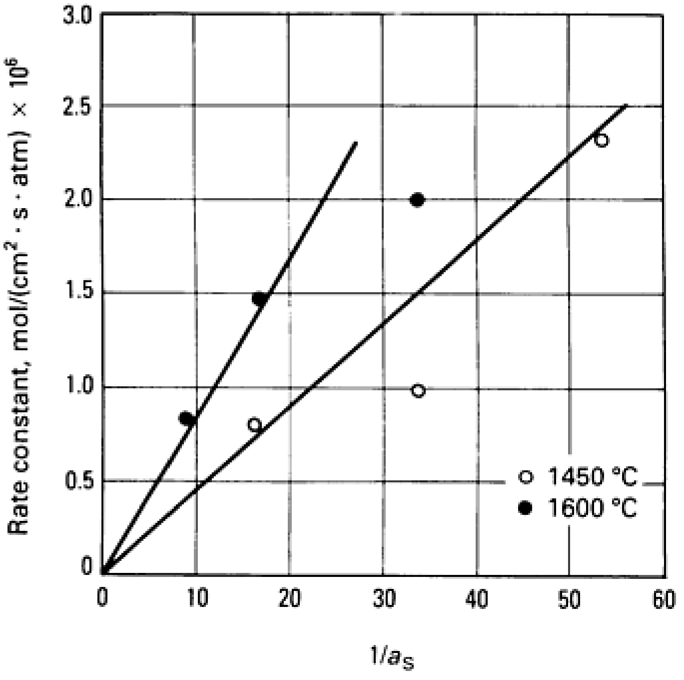

Fig. 2 Effect of sulfur in the rate of the nitrogen reaction on Fe-C_{SAT}-S alloys.

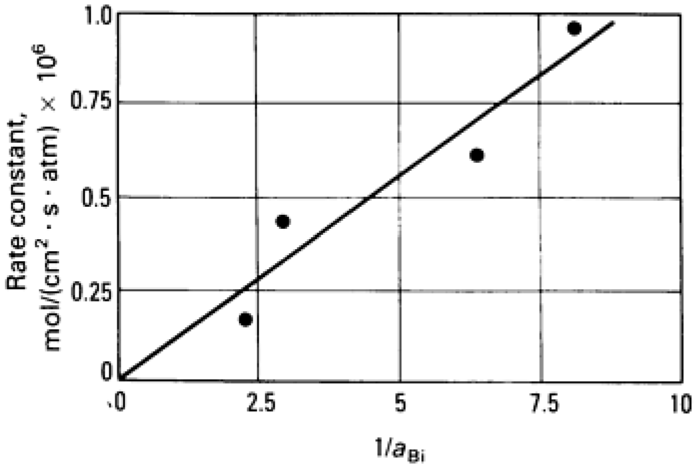

Fig. 3 Effect of bismuth on the nitrogen reaction with Fe-C_{SAT}-Bi alloys at 1450 °C (2640 °F).

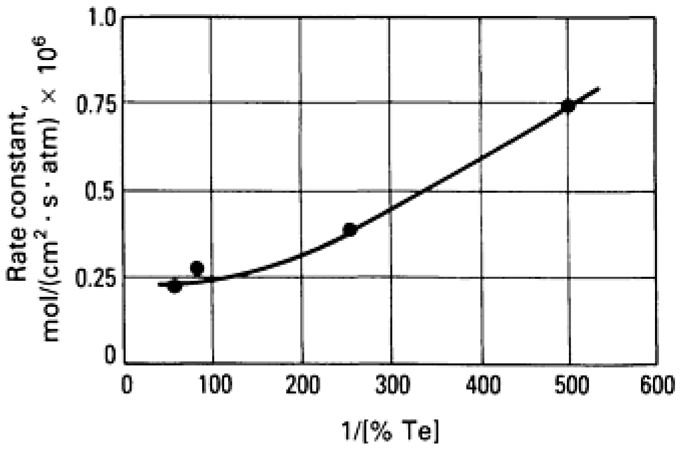

Fig. 4 Effect of tellurium on the nitrogen reaction with Fe-C_{SAT}-Te alloys at 1450 °C (2640 °F).

On the other hand, carbon is not surface active and does not affect the rate at moderate sulfur contents (0.017% S) up to 4.5% C (Ref 12), as shown in Fig. 5. Therefore, the initial rate of nitrogen formation is primarily controlled by chemical kinetics at the surface, and surface-active elements, such as sulfur and tellurium, can reduce the rate. This information can be helpful in controlling the rate of the reaction. For example, if it is desired to remove nitrogen by argon gas flushing, the concentrations of these elements should be as low as possible. On the other hand, it may be possible to retard nitrogen evolution during solidification by the deliberate addition of these elements.

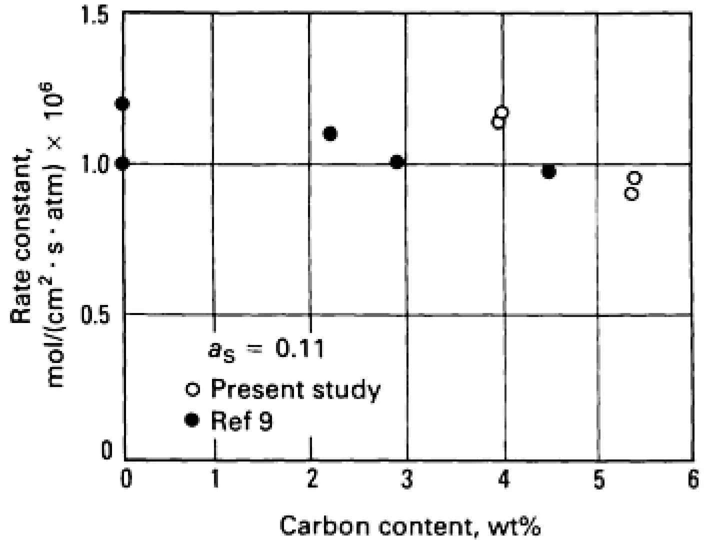

Fig. 5 Effect of carbon on the nitrogen reaction on Fe-C-S alloys at constant sulfur activity.

Reactions During Solidification. During the solidification of most simple iron alloys, there is enrichment of the alloying element because there is greater solubility in the liquid than in the solid. The difference in the solubilities is expressed by the partition ratio $k^{S/L}$, which is determined from the slopes of the solidus to liquidus lines on the phase diagram. For most simple alloys, the partition ratio is less than 1, resulting in liquid enrichment during solidification. For example, for an Fe-0.02N alloy, the last portion of liquid to solidify will be enriched and will have a concentration of 0.045% N, which is the solubility of nitrogen in liquid iron at 1 atm (Ref 13). Therefore, even though the liquid alloy is far from being saturated with nitrogen, during solidification, the concentration will increase to the point where the solubility is exceeded and nitrogen gas will be evolved.

Researchers have measured the partition ratio for nitrogen in high-carbon iron alloys (Ref 4). The partition ratio was found to be 1.9 and 2.2 for stable and metastable eutectic solidification, indicating that there is greater solubility in the solid than in the liquid. Therefore, in this case, as the alloy solidifies, nitrogen is actually enriched in the solid, and the nitrogen content decreases in the liquid. It may appear that, because there is no enrichment during solidification, the thermodynamic pressure of nitrogen cannot increase. The thermodynamic pressure is defined by an expression similar to Eq 6. Carbon greatly increases the activity coefficient of nitrogen in the liquid and decreases its solubility; therefore, the thermodynamic pressure may increase because the carbon content of the liquid is increasing during solidification.

For example, for an alloy containing 3.8% C that is saturated at 1500 °C (2730 °F) with 110 ppm N just prior to eutectic solidification, the concentration in the liquid will decrease to 97.5 ppm because of enrichment in the austenite. However, the solubility of nitrogen in the liquid has decreased to 90 ppm primarily because of the increase in the carbon content. Consequently, the thermodynamic pressure of nitrogen exceeds 1 atm, and the evolution of nitrogen may cause a pinhole.

When determining the possibility of pinhole formation, one must consider the total thermodynamic pressure of all the gases, and if the total pressure p_T exceeds 1 atm, a gas pinhole may result. For example, for hydrogen and nitrogen, the total pressure is given by:

$$p_T = K_H^2 f_H^2 (\%H)^2 + K_N^2 f_N^2 (\%N)^2 \quad \textbf{(Eq 11)}$$

where K_i is the equilibrium constant for the gas reaction and f_i is the activity coefficient. At the end of solidification, the concentrations will be as indicated in Eq 11. Even a small amount of hydrogen may be important. For example, in the case of an Fe-3.8C alloy containing only 4 ppm H, the hydrogen content in the liquid will increase slightly, because of the enrichment, to about 4.5 ppm just prior to the eutectic reaction. However, even for this small amount of hydrogen, its thermodynamic pressure is 0.4 atm. Therefore, if the thermodynamic pressure of nitrogen exceeds 0.6 atm, a gas pinhole may result. Calculations indicate that iron with as little as 80 ppm N and 4 ppm H may have a gas pressure exceeding 1 atm.

Figure 6 shows a plot of the total pressure of hydrogen and nitrogen just prior to final solidification equal to 1 atm as a function of bulk nitrogen and hydrogen contents in an Fe-3.8C alloy. If the hydrogen and nitrogen contents are such that they are below the line, the pressure will not exceed 1 atm, and a pinhole due to gas evolution will not occur; if above the line and the pressure exceeds 1 atm, a pinhole from this source is possible.

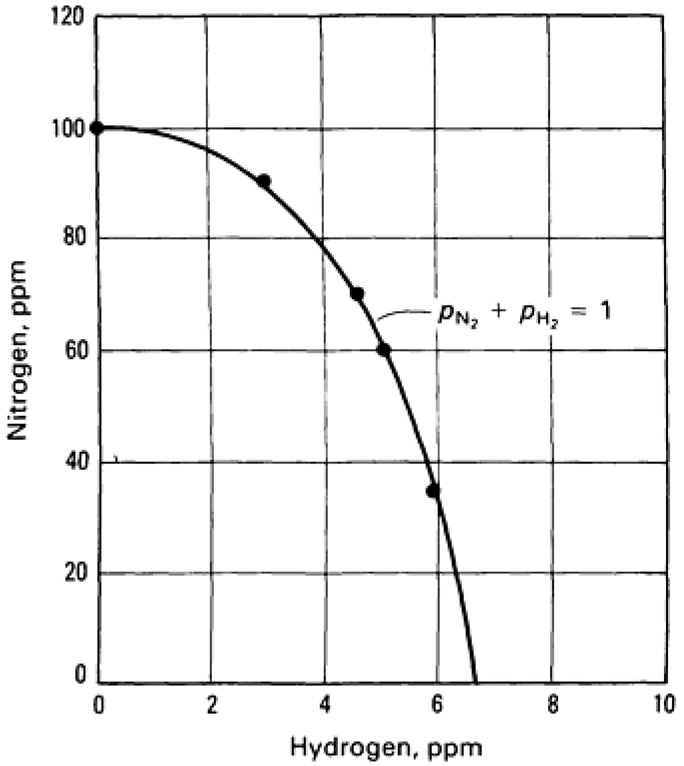

Fig. 6 The thermodynamic pressure of nitrogen and hydrogen at the end of solidification equal to 1 atm for an Fe-3.8C alloy.

For pinholes to develop, it is also necessary to nucleate a bubble. Bubble nucleation is a complex phenomenon and is influenced by surface tension. For melts with low surface tension, bubble nucleation is favored. On the other hand, elements that reduce the surface tension also reduce the rate of N_2 formation. Therefore, it is difficult to predict the net effect on the probability of bubble formation of an alloying element that reduces the surface tension of iron.

Nitrogen and Hydrogen Removal by Inert Gas Flushing. The preceding discussion indicates that nitrogen and hydrogen evolution during solidification may be a cause of pinholes in castings. Therefore, it would be desirable to remove a portion of these gases if possible. One method is by argon bubbling in the desulfurization reactor or ladle. The desulfurization reactor is a continuous reactor with metal flowing in and out almost continuously. However, for the present calculation it will be assumed to be a batch reactor. Because this is only an order of magnitude calculation, this assumption is not unreasonable.

When argon is bubbled through the melt, nitrogen atoms combine on the bubble surface to form N_2. The rate is controlled by the chemical reaction on the surface and the liquid-phase mass transfer of nitrogen to the surface in series. For the purpose of the present calculations, the following were assumed:

- 10 Mg (11 ton) reactor 1 m (3.3 ft) deep
- Argon flow rate of 0.005 m^3/s (10 scfm) through the melt
- Initial nitrogen content of 100 ppm
- 60 mm (2.4 in.) diam bubbles

The rate constant for iron containing a relatively small amount of sulfur is about 1.5×10^{-6} mol/cm^2 · s · atm, and the mass transfer coefficient k_m is about 0.1 cm/s. The gas velocity, retention time, and surface area were estimated as done previously (Ref 5). Equations 8 and 9 were solved simultaneously, and the results are given in Fig. 7. The calculations demonstrate that the rate is truly mixed control, as indicated by the surface concentration being between zero and the bulk concentration. The results indicate that it would take about 40 min to remove 20 ppm; if the argon flow were doubled, it would still take over 20 min to remove 20 ppm. Although these calculations are rather crude, they indicate that it would be difficult to remove nitrogen by argon bubbling.

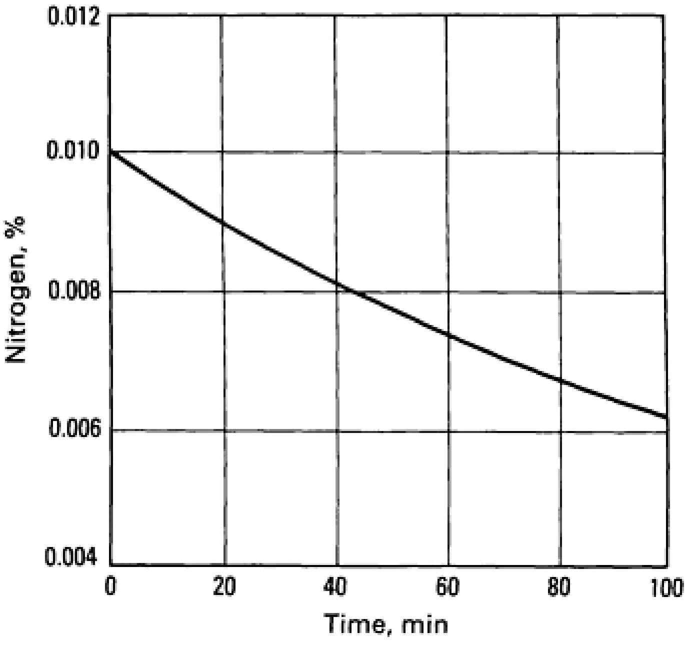

Fig. 7 Rate of removal of nitrogen from an Fe-3.8C alloy with argon bubbling at 0.005 m^3/s (10 scfm) in a 10

Mg (11 ton) reactor.

For hydrogen, the chemical reaction and mass transfer are considerably faster than for nitrogen. If equilibrium between the metal and the gas bubbles leaving the system is assumed, it is possible to calculate the amount of hydrogen that can be removed by gas bubbling from thermodynamic considerations alone. The equations are developed similarly to those for steel (Ref 13), taking the form:

$$\frac{1}{[H]} - \frac{1}{[H_o]} = k_H V \quad \textbf{(Eq 12)}$$

where [H] and [H_o] are the hydrogen content after bubbling and the initial hydrogen content, respectively, and *V* is the total volume of gas used per ton of metal. The constant k_H is related to the solubility of hydrogen and therefore depends on the alloy composition. For example, 10 Mg (11 tons) of an Fe-4.5%C melt at 1773 K containing 4 ppm H bubbling argon for 20 min at 0.005 m^3/s (10 scfm) will reduce the hydrogen content to 1.6 ppm. The above calculation assumes equilibrium and therefore the fastest rate possible and may be an overestimation of the amount of hydrogen removed. Generally, the efficiency of the flushing gas would be roughly 50% for the conditions encountered in practice. However, the calculation does indicate that it is possible to remove significant amounts of hydrogen by gas bubbling.

Aluminum

The gas primarily responsible for porosity in aluminum casting is hydrogen. Hydrogen can enter the liquid alloy by the reaction of the aluminum with water vapor:

$$H_2O(v) + \frac{2}{3}\underline{Al} = \frac{1}{3}Al_2O_3 + 2\underline{H} \text{ (in Al)} \quad \textbf{(Eq 13)}$$

Details of the reactions of hydrogen with aluminum alloys and the factors influencing hydrogen removal can be found in Ref 14.

Hydrogen Solubility and Reactions During Solidification. Researchers have measured the solubility of hydrogen in cubic centimeters per 100 g of alloy or in weight percent in equilibrium with 1 atm of hydrogen (Ref 15, 16).

These results are given in Fig. 8. Alloying elements affect the solubility of hydrogen. The solubilities for selected alloys at 750 °C (1382 °F) are given in Table 1. Generally, the common alloying elements decrease the solubility of hydrogen.

Table 1 The solubility of hydrogen in aluminum and its alloys

Alloy	Hydrogen solubility, ppm
Pure aluminum	**1.20**
Al-7Si-0.3Mg	**0.81**
Al-4.5Cu	**0.88**
Al-6Si-3.5Cu	**0.67**
Al-4Mg-2Si	**1.15**

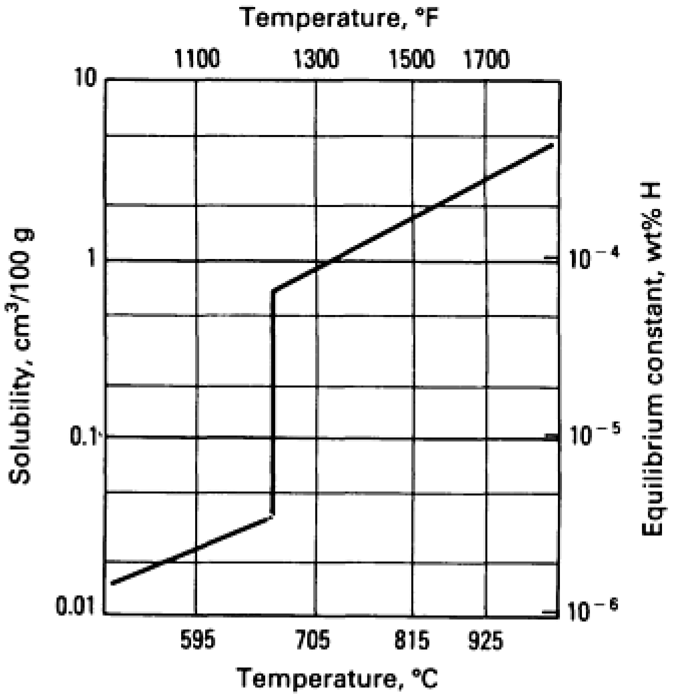

Fig. 8 Solubility of hydrogen (pH_2 = 1 atm) in aluminum.

Because the solubility of hydrogen is significantly higher in the liquid aluminum as compared with the solid, there will be enrichment of the liquid during solidification. Assuming no solid diffusion and complete liquid diffusion, at the end of solidification there will be a large increase in the hydrogen concentration. Therefore, even when the hydrogen content is far below the solubility for the bulk liquid during solidification, the concentration in the enriched liquid will increase, and the solubility limit may be exceeded. For example, consider pure aluminum containing 0.4 ppm H at 750 °C (1382 °F). By the time the alloy is 90% solidified, the concentration in the remaining liquid will be about 3.6 ppm H, which will exceed the hydrogen solubility for 1 atm, resulting in the formation of hydrogen bubbles.

Inert Gas Flushing. It is possible to remove hydrogen from liquid aluminum by inert gas (argon or nitrogen) flushing. As discussed previously for cast iron, it is possible to calculate the fastest possible rate, or the minimum amount of purge gas needed to remove hydrogen. The general form of the equation is:

$$\frac{1}{[H]} - \frac{1}{[H_o]} = \frac{k_H V t}{W} \quad \textbf{(Eq 14)}$$

where [H] and [H_o] are the hydrogen content in ppm at time *t* and the initial hydrogen content, respectively; *W* is the weight (in kilograms); *t* is the time (in minutes); k_H is a constant related to the solubility; and *V* is the flow rate (in $m^3_{STP} \cdot s^{-1}$). In practical units, at 750 °C (1380 °F):

$$k_H = 6.2 \text{ x } 10^4 \frac{kg.m^3{}_{(STP)}}{(ppm).s} \quad \textbf{(Eq 15)}$$

For example, for 10 Mg (2.2×10^4 lb) of aluminum, a gas purge rate of 0.01 m^3/s (0.35 ft^3/s) for 100 s could reduce the hydrogen from 0.2 to 0.09 ppm. As the hydrogen content decreases, it becomes increasingly difficult to remove hydrogen (Ref 14), as indicated in Fig. 9. As the hydrogen content decreases, the ratio *R* of the purge gas to the hydrogen gas removed increases from about 15 at 0.4 ppm to over 500 at 0.1 ppm (1 cm^3/100 g = 0.9 ppm). It should be emphasized that this calculation indicates the theoretical minimum amount of purge gas required. Due to kinetic factors, the amount of purge gas can be significantly higher.

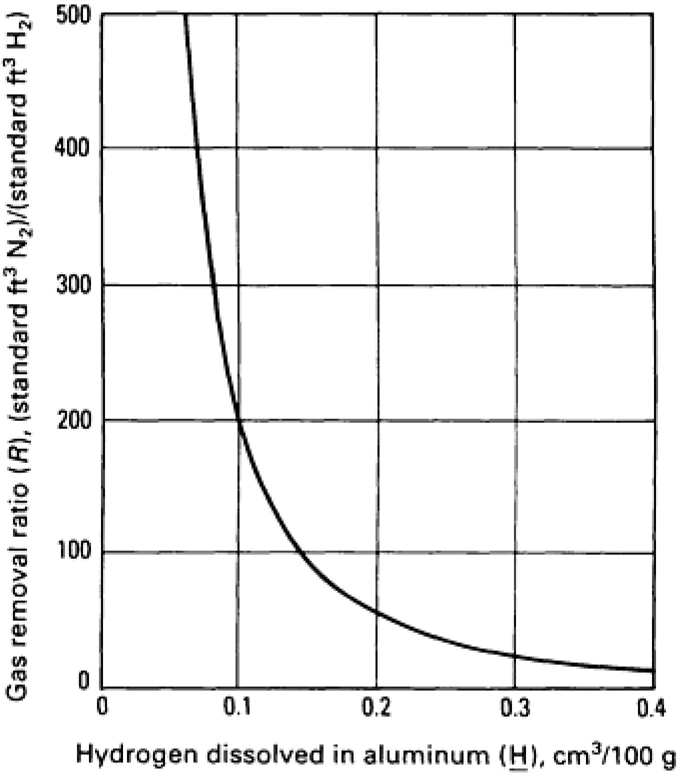

Fig. 9 Gas removal ratio for equilibrium in aluminum at 760 °C (1400 °F).

There are two limiting cases with respect to hydrogen removal: the thermodynamic limit discussed above and the diffusion in the liquid film boundary layer surrounding the gas bubble. For the limiting case of diffusion control, the rate equations are similar to those discussed previously for nitrogen in iron, and the rate can be expressed by:

$$\ln \frac{\%H}{\%H_i} = -\frac{K_{mH} r^A}{W} t \qquad \textbf{(Eq 16)}$$

where $\%H_i$ is the initial hydrogen content, ρ is the liquid density, k_{mH} is the mass transfer coefficient for hydrogen, *A* is the bubble surface area, and *W* is the weight of the melt. Both *A* and k_{mH} increase with decreasing bubble size; consequently, the rate is sensitive to bubble size, with the hydrogen removal favored by small bubbles.

In general, the rate will be controlled by both diffusion and the thermodynamic limit in series. In an analysis of the case of mixed control, it was found that the purging efficiency--the ratio of the actual amount of gas required to the theoretical minimums given by Eq 14--depends on the bubble size and hydrogen content (Ref 17), as shown in Fig. 10. Both the interfacial area and the mass transfer coefficient increase with decreasing bubble size; consequently, the rate of hydrogen removal is enhanced by having small bubbles. The use of porous plugs helps improve the rate by providing small bubbles, but the bubbles generally coalesce in the bath, reducing the beneficial effect. The use of an impeller with a porous plug improves the rate further by dispersing the bubbles.

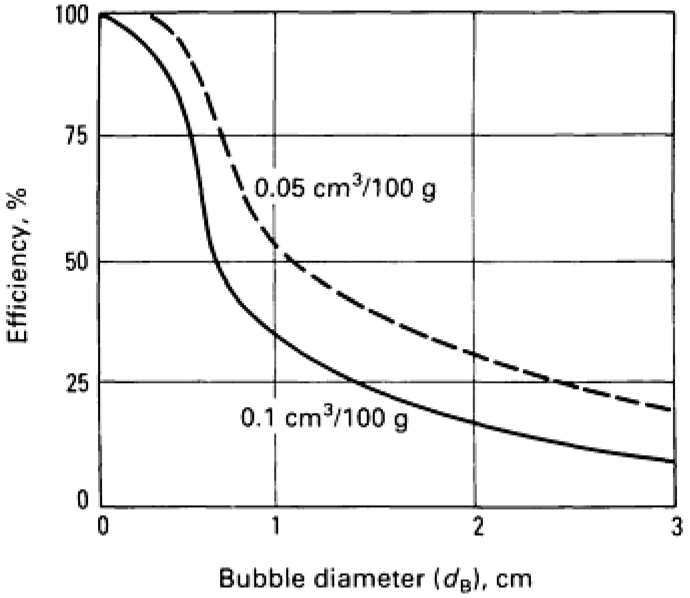

Fig. 10 Purging gas efficiency as a function of bubble size for 0.5 cm^3/100 g and 0.1 cm^3/100 g of hydrogen.

It has also been found that the addition of chlorine (Ref 18) or freon (Ref 19) improves the rate in some cases. These halogen gases increase the mass transfer coefficient k_m and the rate. However, if the rate is being primarily controlled by the thermodynamic limit, the addition of these gases will have little effect. It is also possible that the halogen is actually taking part in a hydrogen removal reaction:

$$2\underline{H} + Cl_2 = HCl \qquad \textbf{(Eq 17)}$$

Equation 17, under some circumstances, is thermodynamically favorable. This will increase the amount of hydrogen that can be present in the inert gas bubble; that is, hydrogen can be present as H_2 or hydrogen chloride gas, thus increasing the rate of removal.

Copper and Copper Alloys

Gas porosity is a problem in the casting of copper and copper alloys. The dissolved gas that is most important is hydrogen. However, gaseous compounds such as water vapor, carbon monixide, and sulfur dioxide can also evolve during solidification.

Hydrogen Solubility and Reactions. Hydrogen dissolves in copper and copper alloys as hydrogen atoms. The solubility in terms of cubic centimeters of H_2 per 100 g of metal is shown in Fig. 11 (1 cm^3/100 g = 0.9 ppm) (Ref 20, 21, 22). Recent work (Ref 23) has confirmed the results of earlier researchers (Ref 20), and these are the current accepted values. The most common alloying element for copper is tin, and as shown in Fig. 12, tin decreases the solubility of hydrogen (Ref 20). For example, in a 50Sn-50Cu alloy at 1200 °C (2190 °F), the solubility of hydrogen is only about 1 ppm as compared to 6.5 ppm for pure copper. On the other hand, nickel increases the solubility of hydrogen. For example, for a 10Ni-90Cu alloy, the solubility is about 10 ppm.

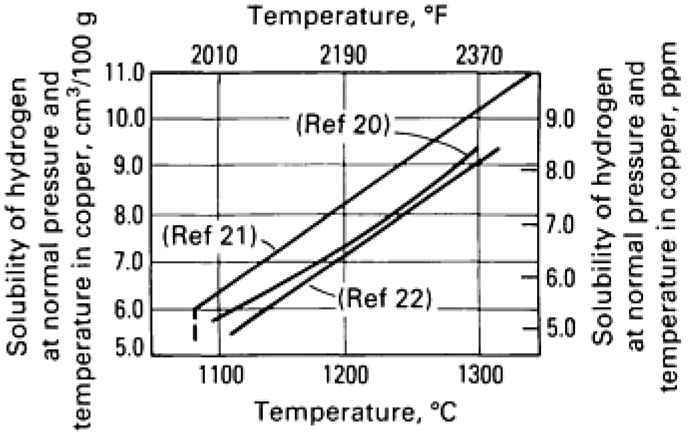

Fig. 11 Solubility of hydrogen in liquid copper as a function of temperature (pH_2 = 1 atm).

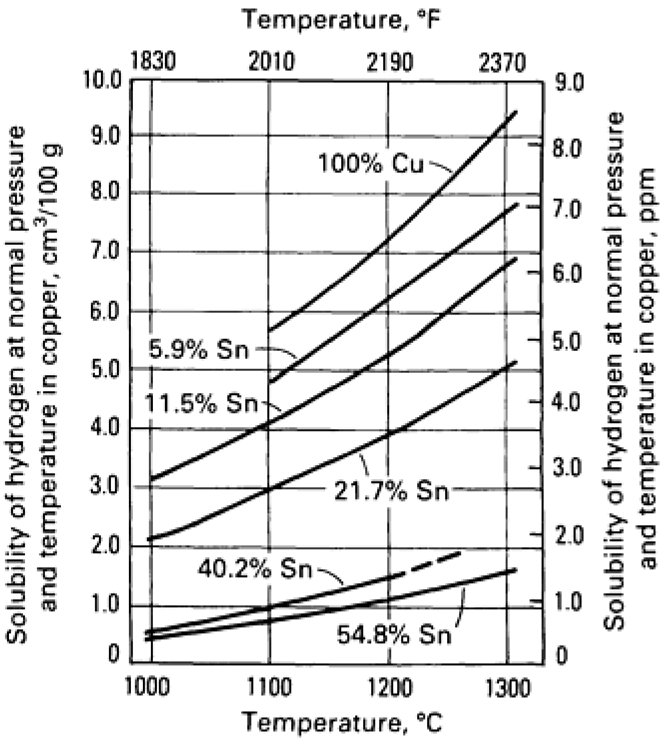

Fig. 12 Solubility of hydrogen in copper and copper-tin alloys (pH_2 = 1 atm) as a function of temperature.

Hydrogen can enter the copper directly from the hydrogen in the atmosphere, but most likely it enters according to:

$$2Cu + H_2O = Cu_2O + 2\underline{H} \qquad \textbf{(Eq 18)}$$

$$H_2O = 2\underline{H} + \underline{O} \qquad \textbf{(Eq 19)}$$

Equations 18 and 19 are favored by copper with low oxygen contents. If there are high concentrations of alloying elements with more stable oxides than cuprous oxide, such as tin, the alloying element may react to put hydrogen into solution, for example:

$$\underline{Sn} + H_2O = SnO + 2\underline{H} \qquad \textbf{(Eq 20)}$$

The main cause of porosity in the casting results from the evolution of hydrogen or water vapor during solidification. The hydrogen and oxygen contents increase because of enrichment during solidification, as described previously for cast iron. As the concentrations increase toward the end of the solidification, hydrogen or water vapor is evolved by the reverse reactions of Eq 18 and 19, which become thermodynamically favorable because the hydrogen and oxygen contents in the last liquid to solidify are high. This mechanism is supported by the observation that the voids in the casting are normally distributed along the grain boundaries, which are the last parts to solidify.

Other gases that can cause porosity are sulfur dioxide and carbon monoxide, which also form during solidification according to Eq 21 and 22, respectively:

$$S + 2\underline{O} = SO_2 \qquad \textbf{(Eq 21)}$$

$$\underline{C} + \underline{O} = CO \qquad \textbf{(Eq 22)}$$

The thermodynamic pressure of carbon monoxide gas can be very high even at moderate oxygen and carbon contents because the solubility of the carbon in copper is limited and therefore its chemical activity is high.

Porosity in Copper Alloys. In copper ingots, the gas porosity usually results from H_2 and water evolution. The evolution of as little as 1 ppm H results in a gas evolution in 44% of the volume of the metal. If the sulfur content exceeds 0.05%, the evolution of sulfur dioxide may also contribute to gas porosity. Only if the oxygen content exceeds 0.01% is carbon monoxide considered to be the cause of porosity (Ref 24). Because phosphorus deoxidizes copper significantly, the oxygen content of phosphorized copper is very low and water, carbon monoxide, and sulfur dioxide do not contribute to porosity; only H_2 need be of concern.

Copper-zinc alloys rarely have problems associated with gas porosity, primarily because zinc dioxidizes the metal. Zinc may also remove dissolved gases because of its high vapor pressure, which results in the zinc vapor flushing hydrogen out of the melt. For copper-tin alloys, hydrogen is the major concern because tin significantly increases the solubility of hydrogen.

Degassing of Copper Alloys. The two primary methods of removing dissolved gases from copper alloys are oxidation-reduction and inert gas flushing. Although vacuum degassing is theoretically possible, it is rarely used because it is not cost effective.

In oxidation-reduction, the first step is to remove the hydrogen by oxidation using an oxidizing slag or oxygen-rich copper. Then, just prior to pouring, the melt is deoxidized by adding phosphorus or other deoxidizers. Calcium boride, boron carbide, and lithium have also been used for deoxidation (Ref 25). A charcoal cover is often used for deoxidation and protection of the melt from reoxidation.

For copper alloys that contain strong deoxidizers, such as phosphorus, zinc, and tin, it is not possible to remove hydrogen by oxidation, because these elements will form stable oxides. For these alloys, inert gas flushing with nitrogen is commonly used. The theoretical minimum amount of inert gas is determined by using relationships similar to those derived for iron and aluminum. In practice, 150 to 250 L (5.3 to 8.8 ft^3) of nitrogen per 1000 kg (2200 lb) of copper alloy is generally recommended (Ref 26).

Overcoming Gas Porosity

Gas in cast iron, aluminum, and copper can be a major problem. The porosity results from reactions with the environment or the evolution of gases during solidification. In determining if gas evolution can cause porosity, the thermodynamics for the reactions must be favorable. In this article, the solubilities of the common gases and the reactions during solidification were discussed. Because of enrichment during solidification, the concentration of the elements increases to the extent that the thermodynamic pressure of the dissolved gases may exceed 1 atm. In addition to the thermodynamics, kinetic factors and interfacial energies determine if the gases will evolve.

The most common method for removing hydrogen from aluminum and copper, which can also be used for removing hydrogen and nitrogen from cast iron, is inert gas flushing. The theoretical minimum amount of flushing gas required for removing hydrogen and nitrogen can be computed. In practice, the amount of inert gas required is somewhat higher because of kinetic factors. The kinetics of inert gas flushing can be improved by the dispersion of small bubbles throughout the melt.

Inclusion-Forming Reactions

Paul K. Trojan, University of Michigan--Dearborn

Introduction

INCLUSIONS can be defined as nonmetallic and sometimes intermetallic phases embedded in a metallic matrix. They are usually simple oxides, sulfides, nitrides, or their complexes in ferrous alloys and can include intermetallic phases in nonferrous alloys. In almost all instances of metal casting, they are considered to be detrimental to the performance of the cast component.

For example, mechanical properties can be adversely influenced by inclusions, which act as stress raisers. There is no set pattern for the effect, but some properties are more sensitive to the presence of inclusions than others. Elongation or reduction in area is usually modified more significantly than ultimate tensile strength. As a result, ductility specifications are common quality control indices in cast products.

Similar observations are found with porosity due to gas or occluded shrinkage. The loss in casting properties measured by a tensile test may then reflect a combination of defects; of these defects, inclusions are only a single by very important source of poor performance.

Because imperfections become areas of higher stress concentration, the percentage of property loss becomes greater when the strength requirement is higher. An important example is the decrease in fracture toughness when inclusions are present in higher-strength lower-ductility alloys. Similar pronounced property degradation is observed in tests that reflect slow, rapid, or cyclic strain rates, such as creep, impact and fatigue testing.

In all cases, the degree of property loss will depend on the parameters that control the characteristics of all microstructures. These metallurgical phase controls are the nature, amount, size, shape, distribution, and orientation of the phases. If inclusions are to be controlled, these characteristics must be suitably modified to minimize their impact on casting performance.

Although inclusions generally considered to be detrimental, their intentional introduction in larger quantities can lead to unique dispersion-strengthened materials. An example would be the dispersion of insoluble silicon carbide whiskers or alumina (Al_2O_3) fibers in a molten aluminum alloy that is subsequently cast into a final shape by squeeze casting methods (Ref 1) (see the article "Cast Metal-Matrix Composites" in this Volume).

Inclusion Types

There are essentially two classifications for all inclusions:

- Exogenous: those derived from external causes
- Indigenous: those that are native, innate, or inherent in the molten metal treatment process

Exogenous Inclusion. Slag, dross, entrapped mold materials, and refractories are examples of inclusions that would be classified as exogenous. In most cases, these inclusions would be macroscopic or visible to the naked eye at the casting surface (Fig. 1). When the casting in sectioned, they may also appear beneath the external casting surface if they have had insufficient time to float out or settle due to density differences with respect to the molten metal.

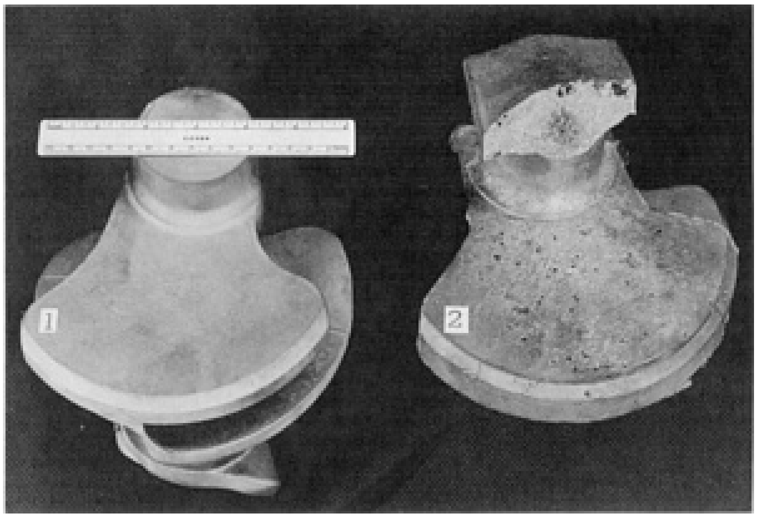

Fig. 1 Ductile iron crankshaft segment essentially free of exogenous inclusions (1, left) and with numerous exogenous inclusions (2, right). Low pouring temperature and poor mold filling practice were the cause of the inclusions in part 2.

Indigenous inclusions include sulfides, nitrides, and oxides derived from the chemical reaction of the molten metal with the local environment. Such inclusions are usually small and require microscopic magnification for identification. They are often uniformly distributed within the microstructure of indigenous inclusions (Fig. 2) can be particularly damaging to mechanical properties.

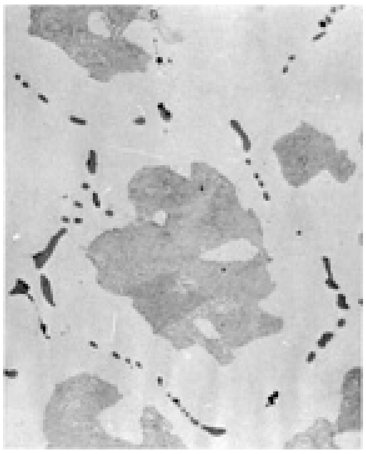

Fig. 2 Type II indigenous sulfide inclusions in a 0.25% C steel. Etched using 2% nital, 500×.

There are cases in which indigenous inclusions such as oxides may react with mold materials to promote an exogenous inclusions variety that otherwise might not appear in the absence of the indigenous oxide. To circumvent the strict definition as indigenous or exogenous, a number of investigators prefer to catalog all inclusions as either macroinclusions of microinclusions. Although such definitions describe the anticipated effect on mechanical properties, there can be a loss in source identification of the inclusion. Whatever definition is used, control of inclusions requires an understanding of their origin and the associated physical chemistry.

Physical Chemistry

Phase diagrams, thermochemical relationships, and reaction rates must all be considered for proper understanding of inclusion formation. The general concepts of each, along with their practical significance, are established in the following sections in this article.

Phase Equilibria. Phase diagrams map the occurrence of phases to be expected under equilibrium conditions. Equilibrium also requires long periods of time to achieve. This is certainly not the case in castings, in which even moderate cooling rates may inhibit equilibrium phases.

For example, in the Fe-O system shown in Fig. 3, wustite (FeO) produced at high temperatures should break down to α-iron and magnetite (Fe_3O_4) at 560 °C (1040 °F). However, iron scales may show considerable amounts of retired FeO at room temperature.

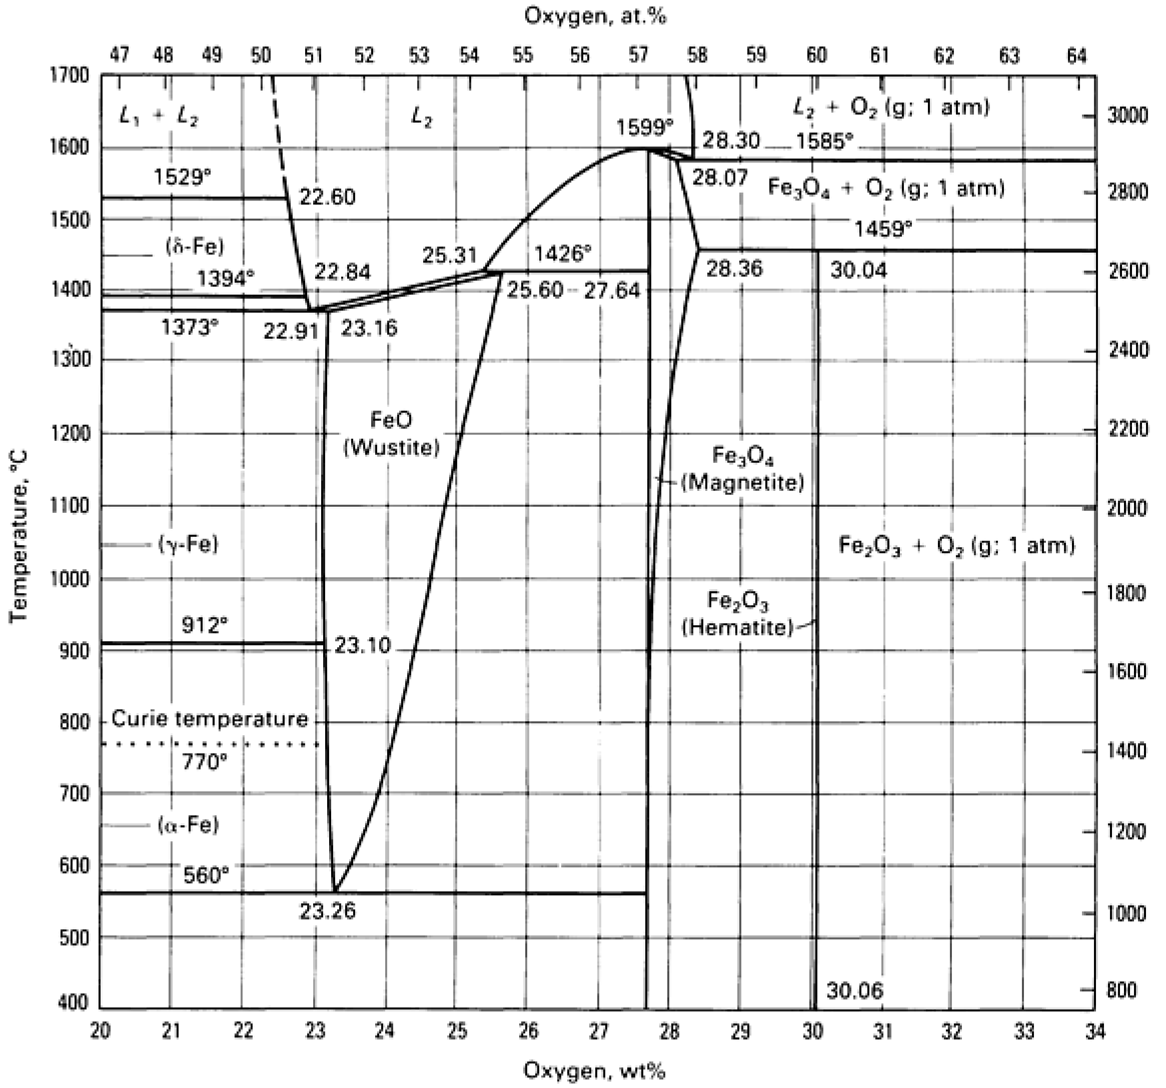

Fig. 3 Iron-oxygen phase diagram.

A further limitation is that pure elements seldom exist in the casting process, and more than two elemental species are usually present. In Fig. 3, pure oxygen is one component while air (20% O) is more likely to be the oxidizing source during casting. Furthermore, a cast steel will contain carbon and other elements such as silicon or aluminum that will have a greater affinity for oxygen than iron. Therefore, phase diagrams become a tool for understanding, but the predicted equilibrium for inclusion occurrence may not always be observed for the casting cooled under nonequilibrium conditions.

Thermochemistry. Any chemical reaction will occur if the products are at a lower energy level than the reactants. The energy measurement is the chemical free energy, which can be treated simply as the energy of chemical position. Free energy values can be obtained directly from numerous sources or can be calculated from tabulated enthalpy, entropy, and heat capacity data. An equilibrium is then established between the products and reactants such that very little remaining reactant indicates a more or less complete reaction. A more thorough discussion of chemical free energy is provided in the article "Principle of Physical Chemistry" in this Volume and in standard textbooks on chemical thermodynamics.

By way of example, assume pure molten iron contains dissolved oxygen at 1600 °C (2910 °F). A small amount of aluminum is added to the melt, and the chemical reaction is:

$$2Al + 3O \rightarrow Al_2O_3(s)$$

where the (s) indicates that Al_2O_3 is solid at 1600 °C (2910 °F). (The melting point of Al_2O_3 is 2072 °C, or 3762 °F.)

For the reaction to occur, the standard free energy exchange at 1600 °C (2910 °F) must be negative. However, the quantity of each component in the reaction is also important, and the chemical activity of each species must be known. An overabundance of aluminum will react stoichiometrically with oxygen, and the remainder may go into solid solution or react with the surroundings.

In the above example, the Al_2O_3, product is insoluble in the molten iron and can result as inclusions trapped in the solidified casting. It is then possible to calculate the free energy exchange for the occurrence of various inclusion chemistries. Their relative stability is dictated by the most negative value of free energy. In the above example, iron oxide would not occur, because Al_2O_3 has a lower free energy of formation. In fact, iron oxide would be predictably reduced by aluminum to form Al_2O_3. As with phase equilibria, thermochemical calculations are again based on equilibrium data, and castings may not be at equilibrium throughout the solidification process.

Kinetics. There are several reasons why inclusion-forming reaction are usually incomplete and why reaction are therefore become the most important practical consideration. Much of the understanding of reaction rates is associated with the following observations:

- Not all species diffuse at the same rate; when coupled with the dependence of diffusion rates on temperature, nonuniform inclusion formation and distribution might be anticipated
- Chemical free energy is also temperature dependent and may not vary in the same fashion for all of the species under consideration
- Available phase equilibrium data may predict the relative solubility of inclusion-forming species in the liquid state, but may not treat decreasing solubility in the cooling liquid or the effects of the solidification process on the equilibrium
- The surface energy of species will change with temperature and will influence the ability of an inclusion to float, sink, agglomerate, or react secondarily with its surroundings
- Reaction products at a surface can become a barrier to further reaction and can block completion of the chemical reaction

Experimental kinetic data can be presented in several ways, including mathematical relationships associated with activation energy and first-order kinetic reaction rate theory. Perhaps more familiar are isothermal and continuous cooling transformation graphical interpretations consistent with nucleation and growth-controlled phenomena.

Control of Inclusions

The previous discussion suggests several practical means of controlling the occurrence of inclusions in any cast metal. All of the control methods can be cataloged as chemical, mechanical, or a combination of these. Several of the more common techniques are discussed separately below.

Chemistry Control. Although control of alloy chemistry may be obvious, composition cannot always be modified to minimize inclusions. The metal compositions may be inherently reactive with the local environment. For example, the presence of magnesium is required in nodular cast iron; the propensity for inclusions is greater than for the same nominal chemistry of a gray cast iron.

Similarly, the existence of inclusions is accepted because the alternative is worse. Aluminum added to steels may result in Al_2O_3 inclusions, but the lack of deoxidation if aluminum were not used would result in gas holes with a greater negative effect on casting performance.

However, this does not imply that if a small addition is good then more is better. Phosphorus added to a copper-base alloy can be an effective deoxidizer, but excess phosphorus can be very aggressive and can react with mold materials commonly used with this alloy family. Therefore, the importance of chemistry control cannot be over-emphasized if inclusions are to be controlled.

Mold/Metal Interface and Refractory Control. Another chemical variable that can lead to inclusions is that of the mold materials and refractories. The SiO_2-Al_2O_3 phase diagram is shown in Fig. 4. It is obvious that the solidus temperature increases with Al_2O_3 content. Even if a refractory is to be used well below the solidus temperature, a high-Al_2O_3 refractory may still be preferred because Al_2O_3 plus mullite would be present rather than the silica (SiO_2) plus

mullite that would be present at compositions less than 72% Al_2O_3. The SiO_2 does not possess the same thermochemical stability as Al_2O_3; therefore, aggressive liquid metals or oxides may react more readily with SiO_2.

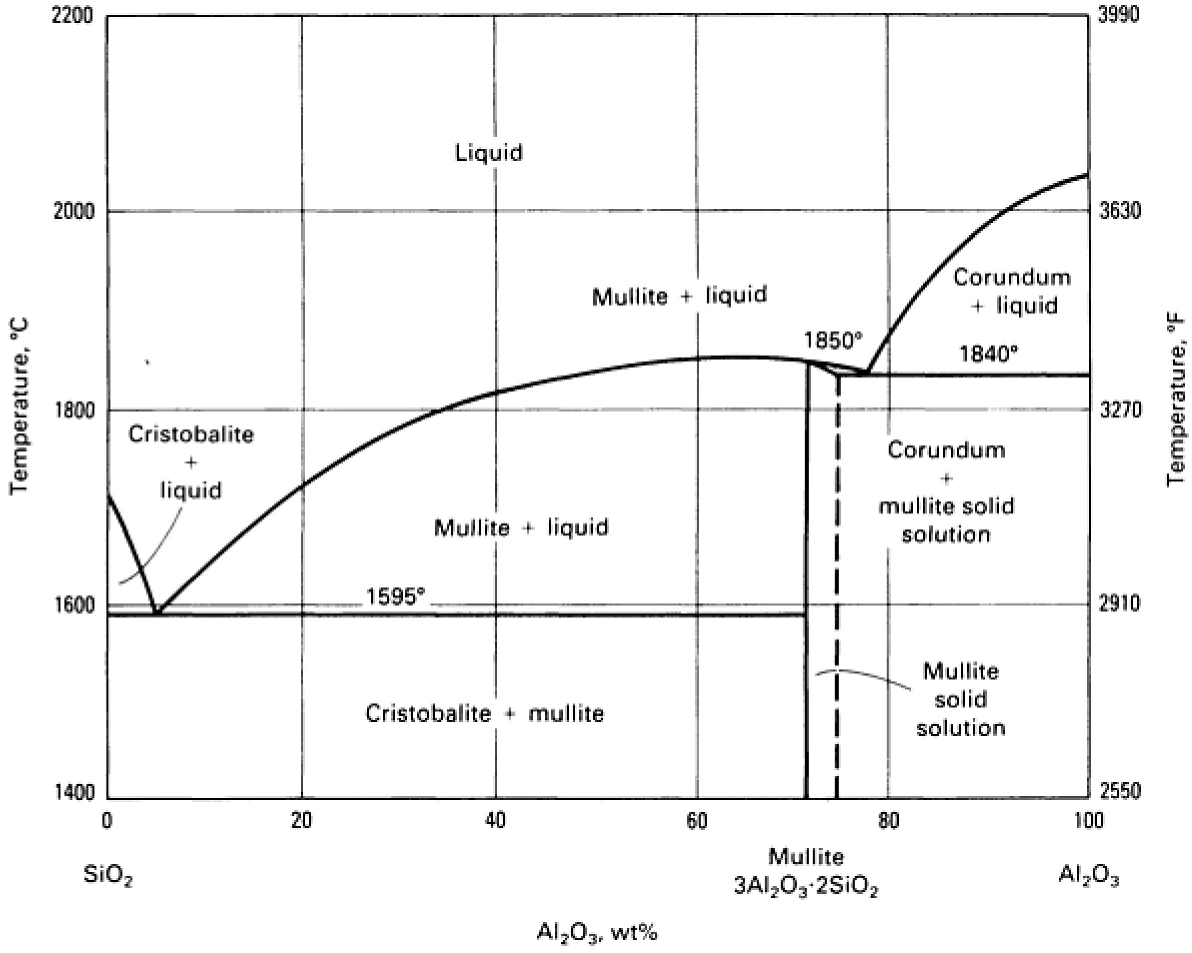

Fig. 4 SiO_2-Al_2O_3 phase diagram. Source: Ref 2.

Higher temperatures and longer holding times at temperature increase the possibility for reaction and the production of inclusions associated with refractory wear and erosion. Therefore, melt overheating, especially for long periods of time, is to be avoided.

The scale on scrap surfaces can also lead to refractory erosion and exogenous inclusions. Rust or ferrous scrap can be considered a hydrated iron oxide that, when heated and dehydrated, can form low-melting complex oxides with the refractories.

Inclusion difficulties have also been known to increase when adhering mold materials remain on charged revert scrap. The severity depends on the nature of the mold bonding agent; bentonite and organically bonded mold materials would display different tendencies toward refractory attack.

The above observations can be applied to reaction between the mold materials and the molten metal. This is not to be confused with metal penetration, in which molten metal merely fills the void spaces between grains of the mold material. However, the solution to the problem--for example, a mold wash--may be the same. In this case, the wash fills the voids between sand grains and isolates the mold material from contact with a potentially aggressive molten metal or oxide. Longer solidification times merely increase the possibility for mold-metal reaction and the accompanying inclusion-forming tendency.

Separation Techniques. The choice for inclusion separation is between removal before the molten metal enters the mold or use of a removal system as a component part of the mold. Gating systems will be discussed in the next section in this article. In both cases, inclusion control is basically mechanical.

External methods include simple skimming of ladle slag or dross to minimize exogenous inclusion sources before pouring of the castings. A teapot ladle can be very effective for decanting clean metal from beneath a layer of floating slag or dross.

Screens or sieves have been used in gating systems to filter inclusions. In general, metallic filters suffer from the tendency to alloy with the poured metal, and they are difficult to separate from the charge returns. Ceramic foam filters with consistent pore size and structural integrity are being increasingly used for those alloys from which definite cost benefits can be derived (Ref 3, 4, 5) (see also the article "Nonferrous Molten Metal Processes" in this Volume).

Gating Methods. Gating and pouring practice has been known to create and to solve inclusion problems in castings. If exogenous inclusions leave the ladle because of inadequate upstream control, the gating system should be designed to remove such inclusions in the pouring basin or in the runner system.

Too often, a pouring basin is not designed to fill easily or to remain filled, and inclusions that might float are forced into the casting cavity. Whirl gates can be used to collect the inclusions and to ensure a better opportunity to have clean metal enter the casting proper (Ref 6). In addition, runners can have dead-end extensions that collect the first metal to enter the mold, which is the most likely to contain slag or dross (Ref 7).

Pressurized gating systems are often recommended for preventing the aspiration of air that can cause the formation of inclusions during the pouring process. This technique is more important when the metal or alloys has a great tendency toward inclusion formation because of so-called secondary oxidation. More detailed information on correct gating is available in the article "Gating Design" in this Volume; many of the gating practices discussed in that article are used to minimize inclusions.

Inclusion Shape Control. As pointed out previously, mechanical properties suffer when inclusions are present, with a more pronounced degradation in strain rate sensitive applications. For example, an inclusion at the surface of a casting subjected to cyclic strain can become a source for fracture initiation in fatigue.

The most conservative approach in design is to determine the smallest inclusion at the surface that might be present without casting rejection. With no variation in inclusion continuity or size, a spherical shape (lower microstress concentration) would be less damaging than more angular shapes. Inclusions beneath the surface would exhibit the same dependence on shape for fracture propagation rather than initiation.

As shown in Fig. 5, calcium treatment of a steel provides longer life under cyclic loading due to inclusion shape modification. Although the data in Fig. 5 are for a rolled constructional steel, similar results would be anticipated for a cast steel, where anisotropy also exists due to directional solidification.

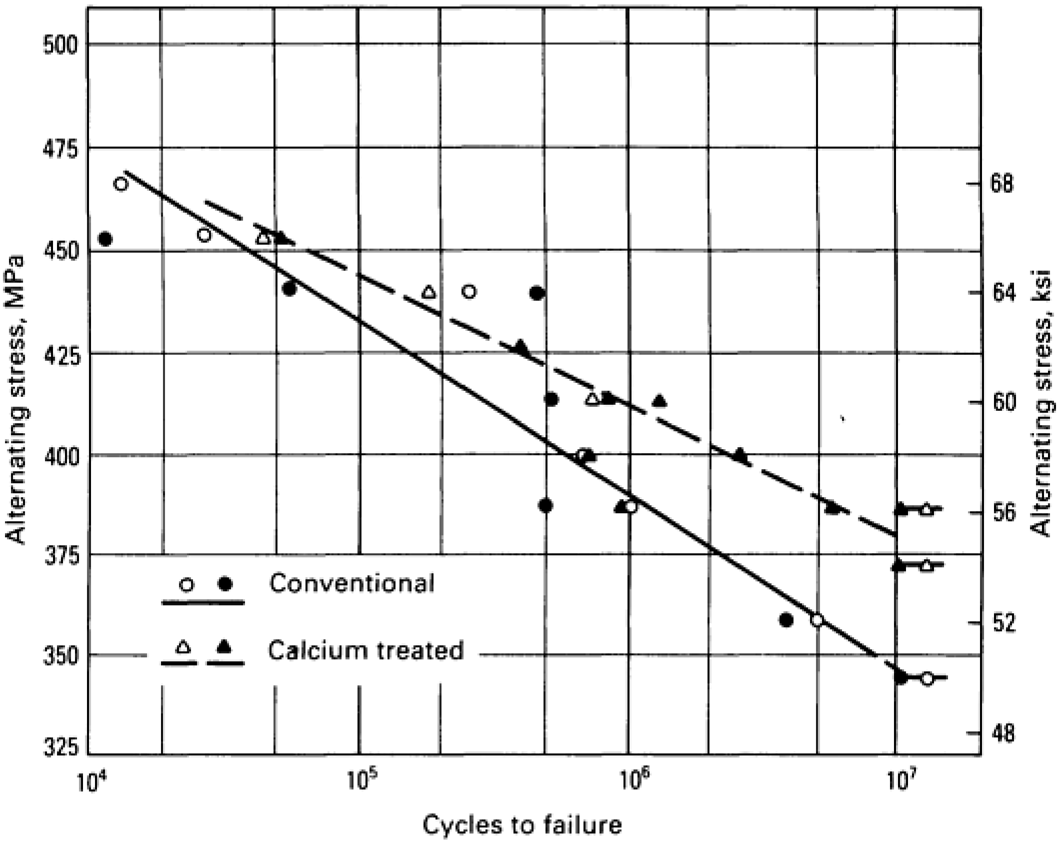

Fig. 5 Comparison of axial fatigue data for untreated and calcium-treated rolled ASTM A516 steel. 51 mm (2 in.) thick plates tested with alternating stress ratio of 0.1. Source: Ref 8.

The advantage of a spherical inclusion shape is possibly more evident in Charpy V-notch impact data for constructional steels (Fig. 6). SEM fractographs show a pronounced difference in deformation mode with an inclusion shape modification (Fig. 7). Local ductility increases adjacent to the inclusions when the shape is spherical.

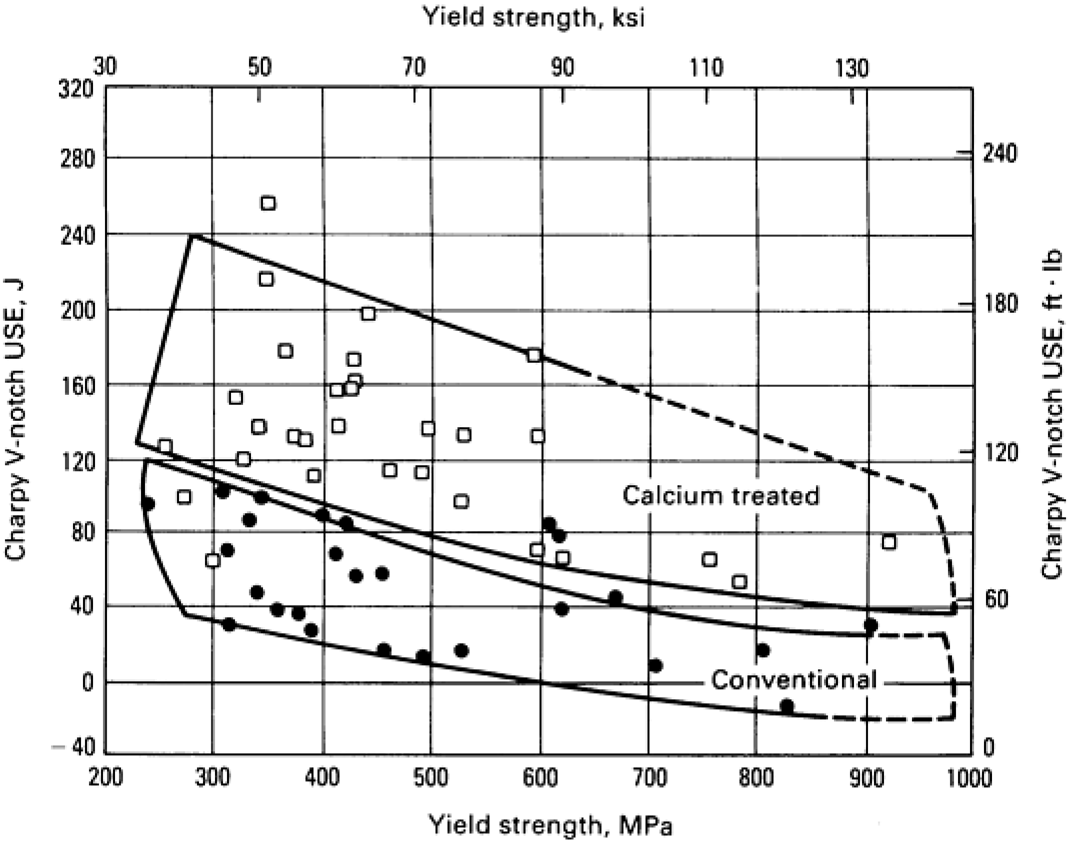

Fig. 6 Comparison of Charpy V-notch upper shelf energies (USEs) for several grades and thicknesses of untreated and calcium treated steel. Source: Ref 9.

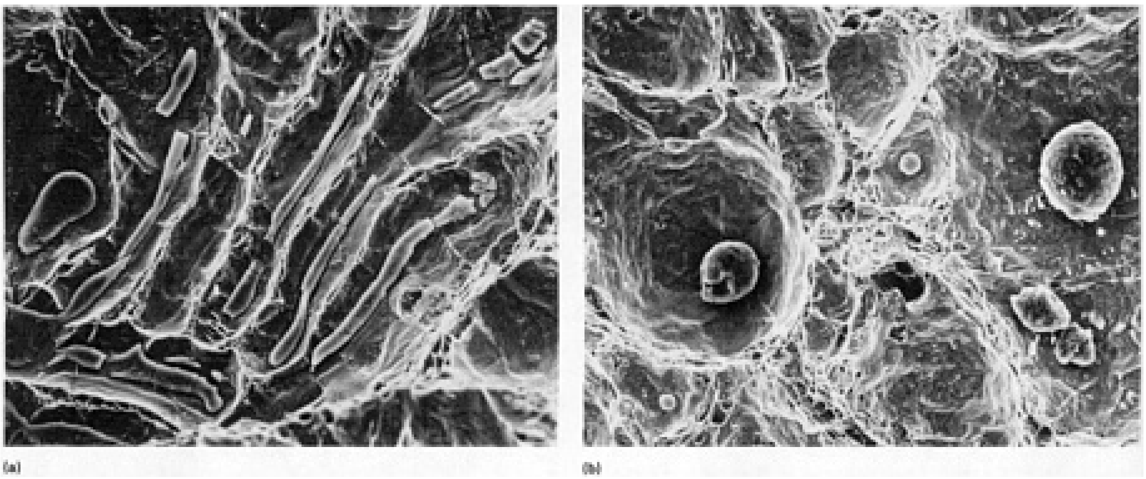

Fig. 7 SEM fractographs showing the effect of calcium treatment on the fracture morphology of ASTM A633C steel impact specimens. (a) Untreated steel with type II manganese sulfide inclusions showing evidence of brittle fracture. (b) Calcium treated steel with spherical inclusions; the fracture is ductile. Courtesy of A.D. Wilson, Lukens Steel Company.

This would then suggest that if inclusions are to occur and cannot be completely removed, a spherical shape is the least detrimental. Inclusion shape control, therefore, is a useful technique that is often applied to more demanding casting applications in which added processing costs can be justified. The principle is a control of surface energy between the inclusion and the metal--normally through suitable chemistry modification of the metal. By analogy, the technique may not be unlike the addition of magnesium to cast iron to change the graphite shape from flakes to nodules.

Inclusions in Ferrous Alloys

Some applications for inclusion minimization or shape control are immediately obvious. For example, proprietary addition agents are available for modifying the viscosity of slag or dross, thus facilitating their ease of removal. On the other hand, treatment of steels and cast irons is likely to be different, and a few examples, along with the application of appropriate physical chemistry, are given below.

Steels

Oxides. The amount of carbon in iron controls the amount of dissolved oxygen (Fig. 8). The curve has been calculated from thermochemical data with variable CO/CO_2 ratios. Experimental points would generally lie above the theoretical curve, but the relationship between carbon and oxygen would be the same. Low carbon in solution, as in many cast steels, results in higher dissolved oxygen.

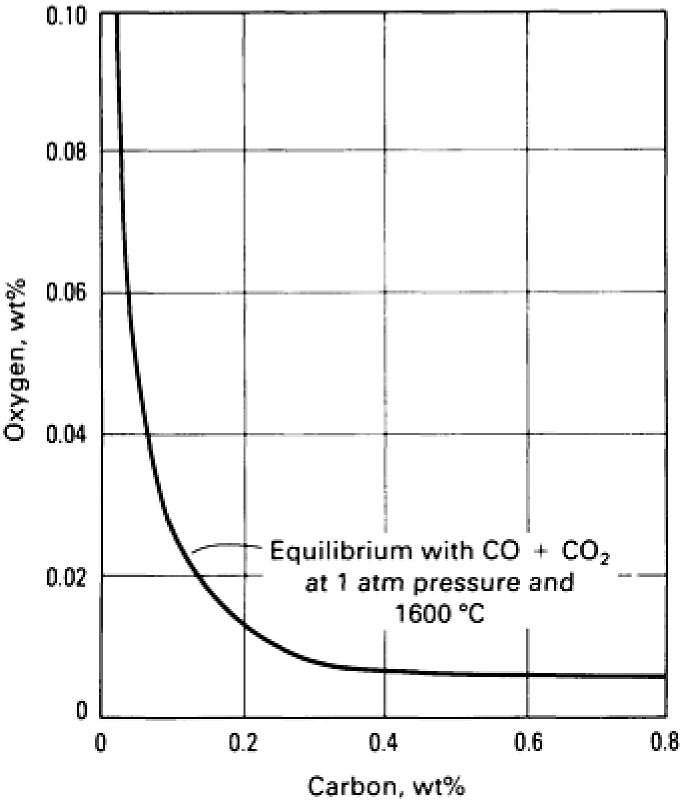

Fig. 8 Carbon-oxygen equilibrium at 1600 °C (2910 °F). Source: Ref 10.

The solid solubility of oxygen in iron is low, and during solidification, oxygen is rejected to the remaining liquid, where it can react with carbon to form CO and result in gas porosity. Although this is allowed to occur in steel ingots (induced porosity that is "healed" during subsequent processing), the amount of dissolved oxygen in steel castings is reduced by additions of aluminum or silicon. The resultant oxides are insoluble and form inclusions.

Because Al_2O_3 has a lower free energy of formation than SiO_2, aluminum is a more effective deoxidizer than silicon (Fig. 9). The FeO content is an index of the amount of dissolved oxygen in the steel where the oxygen can also be reduced by carbon, as shown in Fig. 8. At a given carbon content, the oxygen can then be reduced by aluminum or silicon to still lower levels, because the free energies for SiO_2 and Al_2O_3 are lower than those for CO or CO_2 at the reaction temperature.

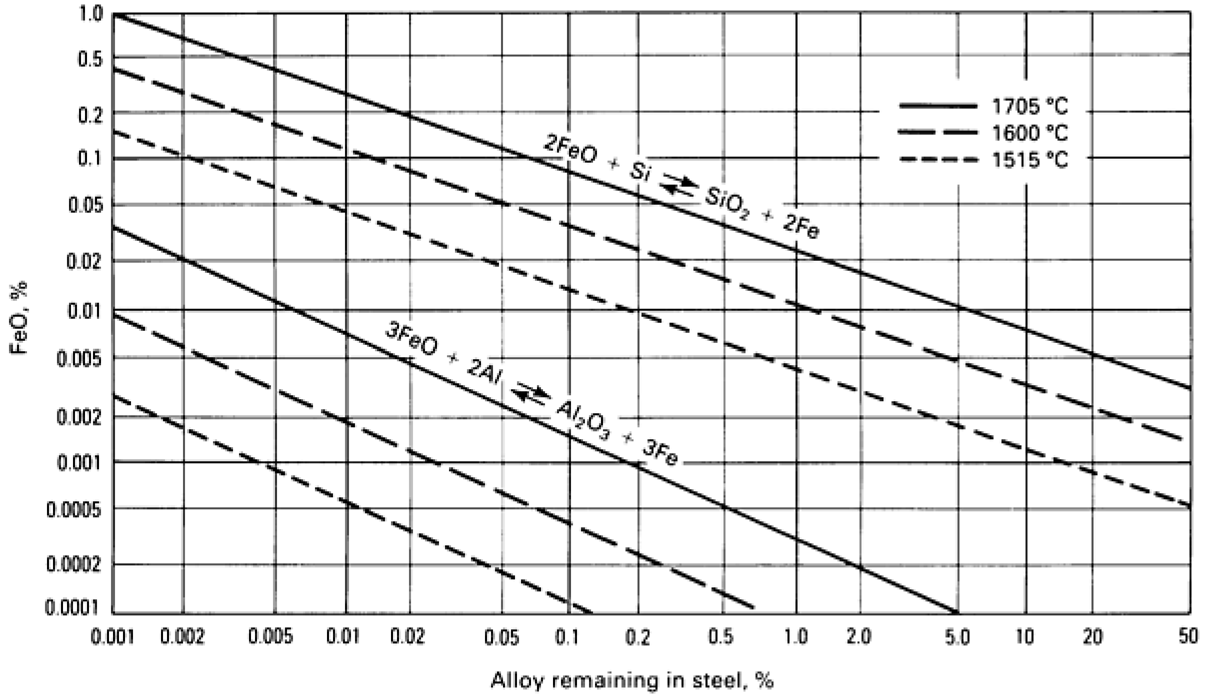

Fig. 9 Equilibrium between FeO and dissolved aluminum and silicon. Source: Ref 11.

Once the oxide forms, the inclusion removal rate depends on the nucleation of particles, their growth, ultimate agglomeration, and rise to the surface. Although there is a significant difference in density between the solid particles and

the liquid metal, a simple application of Stoke's law is difficult. The problem is dynamic and is influenced by the presence of other indigenous or exogenous inclusion species. Furthermore, gravitational effects are different while holding the treated metal in the ladle, pouring though air with an opportunity for the metal to reoxidize, and during solidification with the associated thermal convective currents. Therefore, it should not be surprising that oxide inclusions can become trapped in the final casting.

Sulfides. Sulfur is also often present in steels and is controlled by the nature of the slag-refining processes in the furnace. In general, as the process becomes more reducing (that is, the oxygen content of the metal is lower) and the slag more basic, lower sulfur will be present. Because the sulfur content is not reduced to zero, manganese is always present in steels to produce the more desirable manganese sulfide (MnS) inclusions rather than FeS inclusions with lower melting point.

The resulting inclusions, although usually identified as manganese sulfides, may have several distributions and shapes, depending on the presence of other elements and the deoxidation procedure.

Complex Inclusions. The various elements compete to form compounds with oxygen and sulfur. Furthermore, alloying elements in excess of those necessary to form compounds will modify the surface energy of the resultant inclusions. The shape and distribution of the inclusions will then also vary, depending on the variables discussed at the beginning of this article.

Historically, inclusions have been classified into three general types, as shown in Fig. 10. Of these, Type II has been demonstrated as particularly damaging to mechanical properties. The argument has been that sulfur, oxygen, and deoxidizer play a combined role in the inclusion type. Figure 11 shows this effect and the resulting decrease in structure-sensitive properties such as ductility and impact strength. The minimum in the curves is attributed to the formation of Type II inclusions.

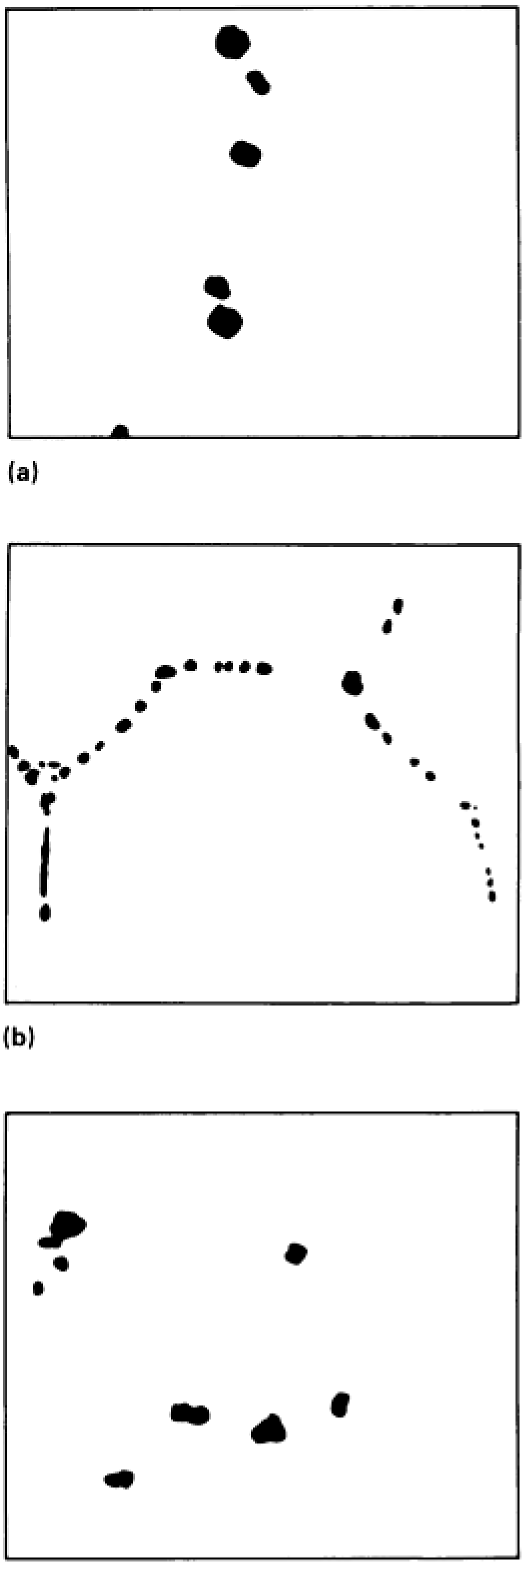

Fig. 10 Illustrations of common inclusion shapes and distributions found in steel. (a) Type I: globular silicates and oxides (no aluminum deoxidizer). (b) Type II: continuous eutectic sulfides and Al_2O_3 at grain boundaries (low aluminum addition). (c) Type III: duplex irregularly shaped sulfides and Al_2O_3 (large aluminum additions). Source: Ref 12, 13.

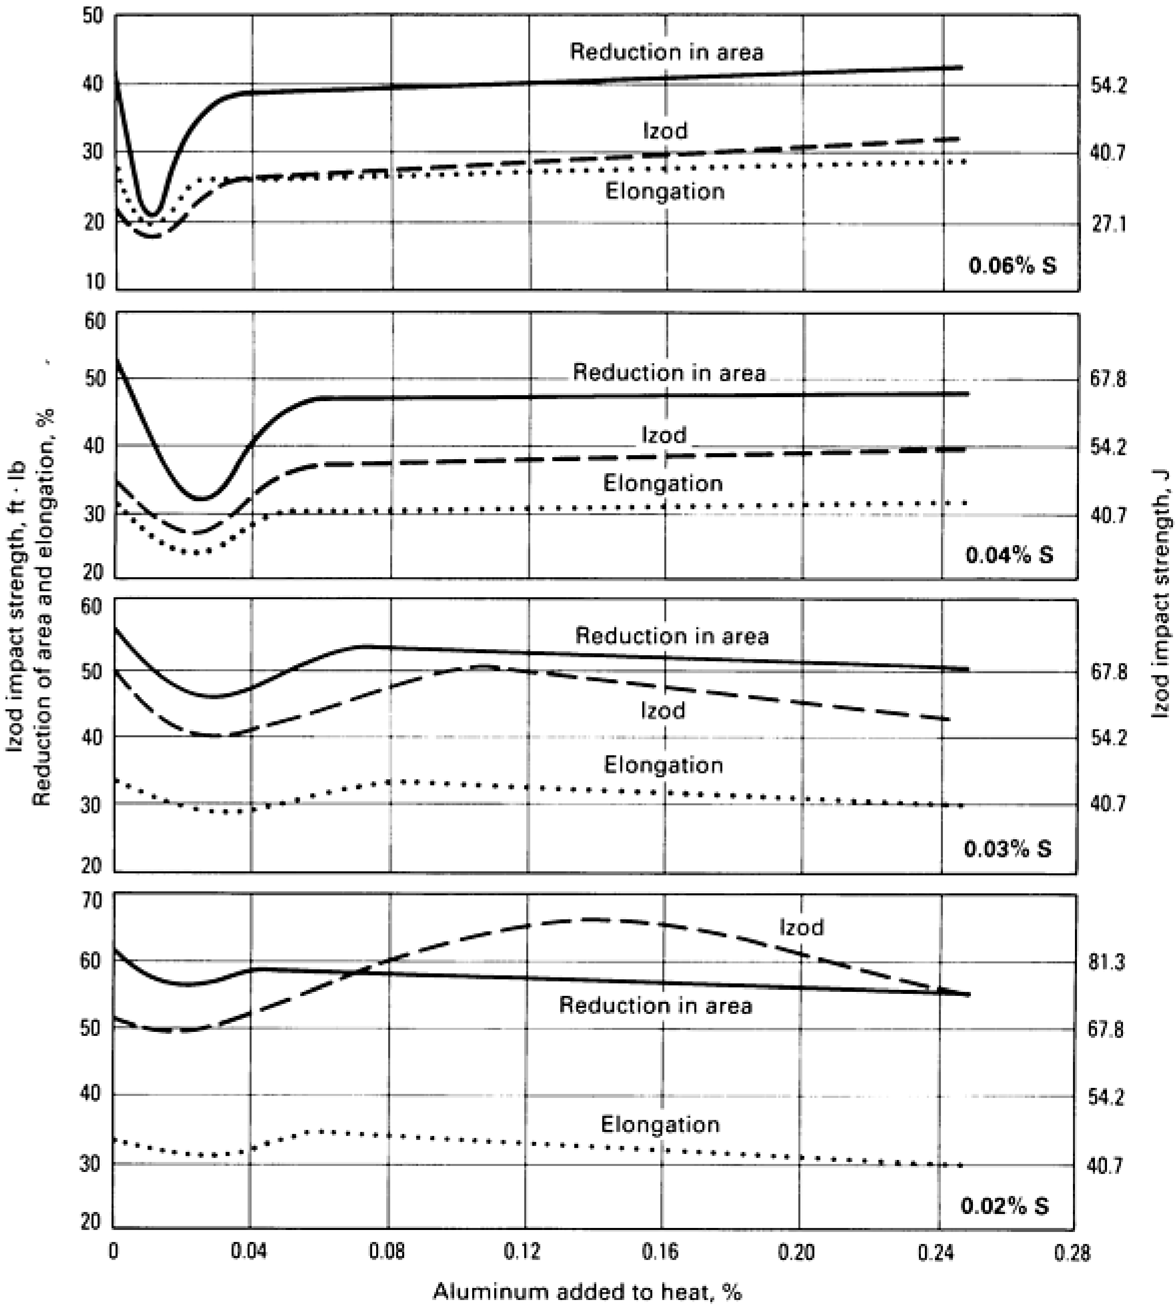

Fig. 11 Combined effect of aluminum and sulfur on the ductility and impact strength of cast and normalized medium-carbon steel. Source: Ref 11, 12, and 13.

The role of aluminum in the modification of inclusion shape and distribution also depends on the oxygen-sulfur equilibrium shift when the aluminum is added. Therefore, complex inclusions such as oxy-sulfides may be present in a cast steel, but can be controlled by the quantity of oxide-sulfide forming elements. A more complete discussion of oxide inclusion formation mechanisms and the relationship to mechanical properties is given in Ref 14.

Inclusion shape control become a consideration especially if fracture toughness, impact strength, or fatigue resistance must be optimized. Magnesium and calcium addition can be successfully used for shape control, that is, to produce more spherical shapes (Ref 15). It is noteworthy that both magnesium and calcium form stable sulfides and oxides as indexed by the free energy of formation of the compounds.

Several production methods have been employed for calcium or magnesium additions, either as the metallic elements or as compounds. Because of the high vapor pressure of the pure metals and to a lesser extent the compounds at the addition

temperatures, special procedures have evolved, including injection at the bottom of a filled ladle. In this case, the ferrostatic head provides a pressure that suppresses the boiling action and gives a longer reaction dwell time.

Rare earth elements added in conjunction with calcium, magnesium, and aluminum have been reported to enhance the spheroidization and fineness of the inclusions by breaking up the Al_2O_3 galaxies (Ref 16, 17).

Nitrides. Just as there are elements that preferentially form oxides or sulfides, there are differences in the free energy of formation of the nitrides. These elements control the amount of nitrogen that can be dissolved in both the solid and liquid states. For example, vanadium and manganese increase nitrogen solubility, while carbon and phosphorus decrease nitrogen solubility (Ref 12).

The effect of aluminum on nitrogen solubility has been extensively studied, and criteria that result in the precipitation of aluminum nitrides have been developed (Fig. 12).

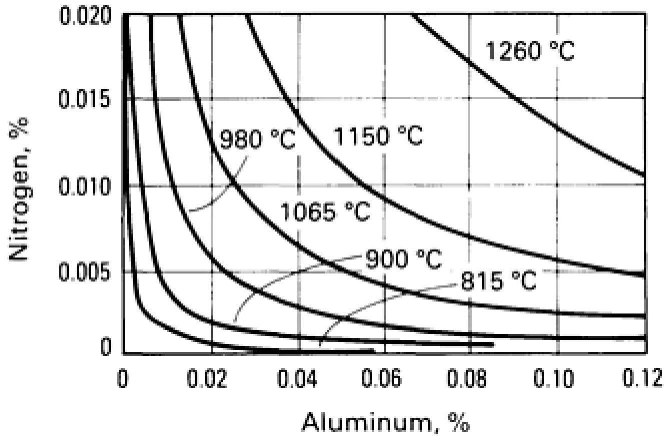

Fig. 12 Isothermal precipitation of aluminum nitride. Compositions to the right or above each isotherm cause precipitation. Source: Ref 12.

Other nitride-forming elements, such as titanium, zirconium, and vanadium, would show similar but numerically different results.

It is not uncommon to consider these nitride inclusions to be beneficial; they peg austenite grain boundaries, and this results in grain refinement. On the other hand, brittleness results when the nitrides become more or less continuous.

Exogenous Inclusions. Numerous examples of inclusions occur because of the reaction between the molten steel and the adjacent environment. A few of these are considered below.

When a steel is killed with aluminum, residual aluminum remains in solution. If the metal contacts a refractory that contains free SiO_2, the aluminum can reduce the SiO_2 because of the lower free energy of formation of the Al_2O_3. The eroded or partially dissolved refractory becomes a source of inclusions, as does the Al_2O_3 that is produced. Careful control of refractory chemistry and good pouring practice minimize this problem.

Similar reactions can occur at the mold/metal interface, where the first equilibrium of importance is iron-oxygen-silicon. When conditions are oxidizing, FeO is present, and the corresponding form for silicon is SiO_2. The FeO-SiO_2 phase diagram is shown in Fig. 13. The most significant observation here is the formation of lower-melting liquid phases as the amount of FeO is increased.

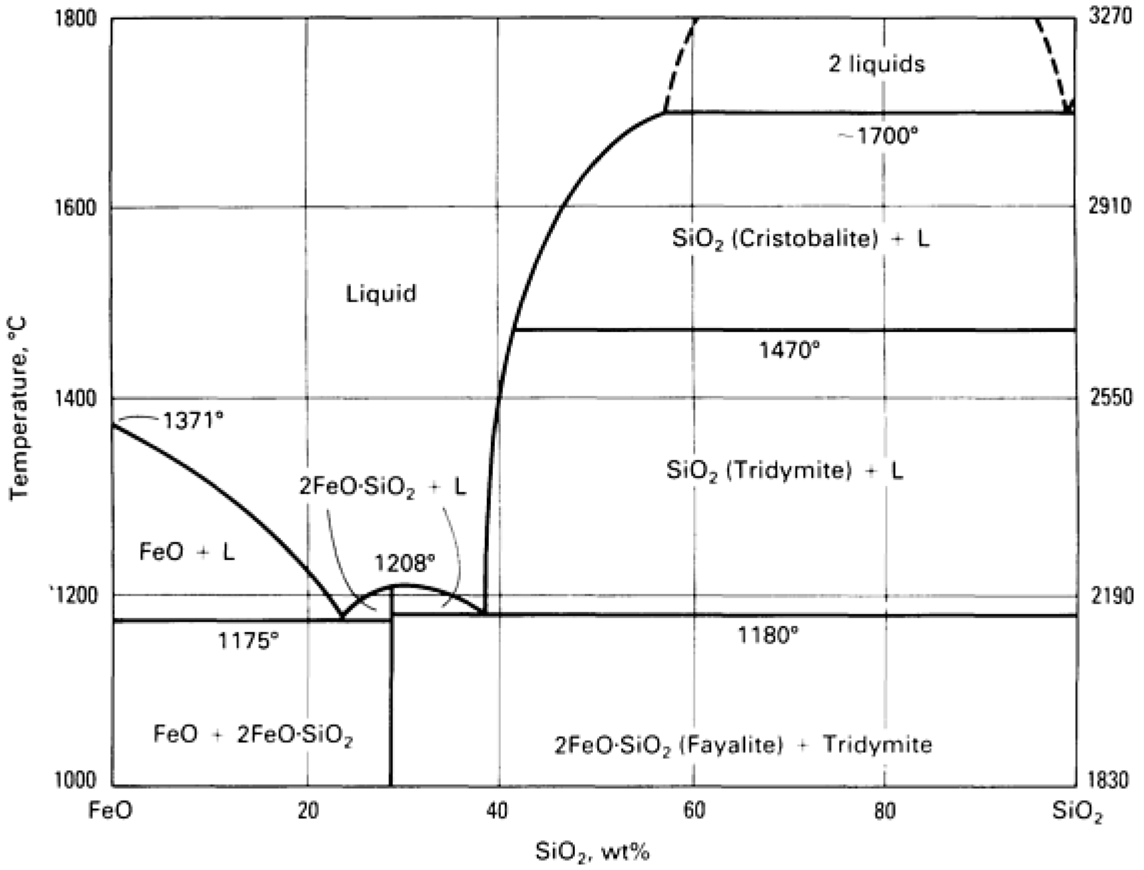

Fig. 13 FeO-SiO_2 phase diagram. Source: Ref 10.

With minimal oxidation, burned-on sand and metal penetration will occur. However, when the oxidation level increases, local macroinclusions may form, especially if poor pouring practice, segregated bentonite, nonuniform mold ramming, and excessive mold moisture exist. A number of the problems and solutions association with exogenous inclusions in steel have been summarized in Ref 18.

Cast Irons

Gray Cast Iron. The earlier discussion of the carbon-oxygen equilibrium (Fig. 8) suggests that dissolved oxygen should not be a problem in cast irons because of their high carbon contents. Therefore, oxide inclusions should not occur in gray cast iron. However, because the silicon content of this material is also significant, the carbon-silicon-oxygen equilibrium is of interest.

The temperature dependencies of the free energies of formation for SiO_2 and CO are different for the two species. At temperatures above approximately 1535 °C (2795 °F), CO is the more stable compound; below this temperature, SiO_2 is more stable. This can be observed on the surface of a cast iron melt that appears clean at high temperatures and yet develops a slag covering at lower temperatures.

The significance of the equilibrium shift is that skimming the slag from a melt surface may be unnecessary at high temperatures, because little may exist. Inclusions are then found in the casting because of pouring at lower temperatures and exposure of the metal to reoxidation during pouring. These inclusions are often silicates derived from the normal equilibrium change with temperature. Once the molten iron is in the mold cavity, there is less opportunity to form the silicates because conditions are usually less oxidizing.

Nitride and sulfide inclusions also exist in gray cast iron, but are not as severe a problem as in steel because of the inherently lower dissolved oxygen content of the cast iron. Special gray cast iron chemistries containing alloying elements

with an affinity for nitrogen, oxygen, or sulfur may result in inclusions by further reaction with the refractories, mold, or atmosphere. the remedies are usually similar to those given for steel.

Ductile Cast Iron. A number of foundries erroneously assumed that ductile (nodular) cast iron would be as easy to process as gray cast iron because the major difference was merely a lower sulfur plus a modest magnesium addition. Although many characteristics were found to be different, one of the more perplexing was the formation of dross usually not found in gray cast iron. The result was the so-called cope-side defect that was very prevalent in early ductile iron castings.

Magnesium forms a very stable oxide and can therefore reduce oxides of lower stability as determined by their free energy of formation. Furthermore, the alloys used to produce the nodular graphite found in ductile iron contain considerable amounts of silicon and are low in density, which allows them to float on ladle surfaces rather than reacting completely. These observations help to explain how dross particles form and can become entrapped in castings.

In general, there are three types of dross inclusions in ductile cast iron (Ref 19). Type I consists of large dross particles generally derived from oxidation of the silicon and magnesium used in the nodularizing alloys. The dross particles are present on the treated liquid-metal surface and can be removed by skimming. Silica does not exist in the pure form; rather, magnesia (MgO) and forsterite (Mg_2SiO_4) are the predominant species. This suggests a driving force from the high-MgO end of the phase diagram shown in Fig. 14. Under some circumstances, especially after a late silicon inoculation the dross also contains fayalite ($2FeO{\cdot}SiO_2$) (see Fig. 13). Fayalite and forsterite form a complete series of solid solutions known as the olivines and are used as molding materials.

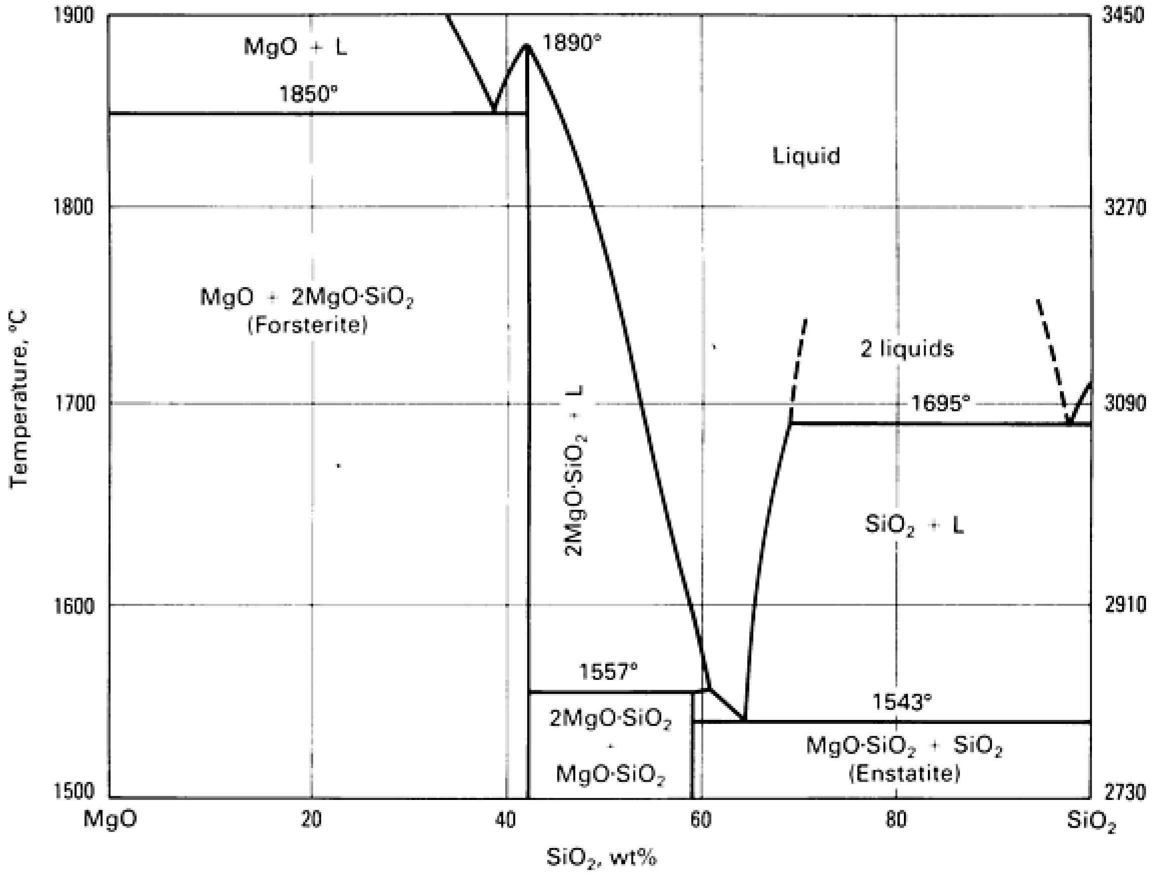

Fig. 14 $MgO-SiO_2$ phase diagram. Source: Ref 10.

Type II inclusions are in a more or less stringlike configuration in conjunction with decayed graphite shapes. Chemically, they are predominantly MgO with some iron and silicon atom replacement for the magnesium in the MgO lattice. Reaction with the oxidizing components in the mold material is one source for this type of inclusion, as is an excess of

nodularizing agent. Their position is usually just beneath the casting surface. Control of the mold atmosphere and the amount of nodularizer usually minimizes the defect.

Type III inclusions are fine dispersions of MgO and MgS, occasionally mixed with Mg_2Si. These components would normally be expected only if the oxygen content in the immediate vicinity is very low. Their normal uniform distribution does not usually detract from the overall performance of the casting. However, undissolved nodularizer may be a source of Type III inclusions because Mg_2Si is the active magnesium source in the nodularizing agent.

Finally, the examples provided in this section are not intended to represent all of the inclusions to be anticipated in every ferrous alloy. On the other hand, they are sufficiently representative so that analogies for occurrence and remedy can be derived for the alloys not discussed.

Inclusions in Nonferrous Alloys

Several important cases are given below for aluminum, copper, and magnesium alloys. The principles discussed in this section can be extended to include other alloy systems. In the alloys discussed, both nonmetallic and intermetallic compounds will be considered deleterious.

Aluminum Alloys

Oxides. It is nearly impossible to prevent dross formation in the melting of aluminum alloys. The most common form of dross contains large quantities of Al_2O_3 and, when agglomerated, can be removed from the melt surface by skimming. Pouring operations should employ skimming ladles to prevent larger dross particles from entering the mold. Furthermore, a gating practice must be used that minimizes Al_2O_3 formation during mold filling.

The fact that Al_2O_3 forms is not surprising, because the free energy of formation of Al_2O_3 is very low. Furthermore, the specific gravity of Al_2O_3 is not greatly different from that of the molten aluminum alloys. Although more dense, Al_2O_3 forms at an outside surface first if the melt is exposed to the atmosphere. The tenacious skin will float unless it is broken up into small particles, and it can become quite thick when melts are held for extended periods in the furnace.

When small oxide particles are formed, they may not sink, but may become suspended in the melt. In high-quality castings, these particles must be removed; ceramic filters have been used to remove the particles, as mentioned earlier in this article (Ref 3).

The degradation of mechanical properties also depends on the size and distribution of oxide inclusions. Therefore, solidification rate is very important for minimizing property loss. When the casting solidifies rapidly, as in thin sections or in permanent molds, the oxide inclusions are smaller and more uniformly dispersed. This observation is consistent with the general constraints of nucleation and growth where less time during solidification not only creates smaller particles but also prevents their agglomeration and growth.

Complex Oxides. Other elements in the aluminum alloys may react with oxygen sources and produce complex oxides with Al_2O_3 as one of the components. This is the case in magnesium-containing alloys, in which the spinel $MgAl_2O_4$ may form (Fig. 15). Here MgO has a lower free energy of formation than Al_2O_3; the spinel results when they form together.

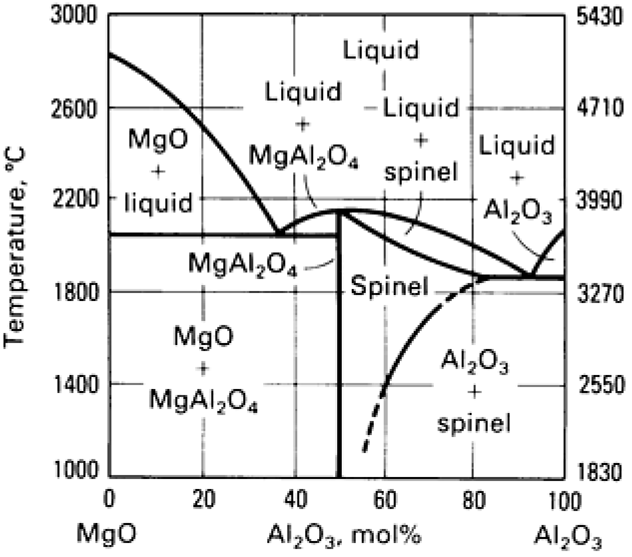

Fig. 15 MgO-Al_2O_3 phase diagram. Source: Ref 2.

Again, precautions in pouring, gating, and minimizing the reoxidation of the metal are important in inclusion control. The use of filtering systems is also advantageous, especially in high-strength castings in which fracture toughness characteristics are important.

Other Inclusion Types. Inclusions in aluminum alloys can occur from grain-refining operations in which the grain-refining additions may not be adequately controlled. Titanium, vanadium, and boron are used in various combinations to produce grain refinement, and the diborides can become undesirable inclusions. Again, the fact that a small addition is beneficial does not mean that larger additions will provide greater rewards.

Many of the commercial aluminum alloy compositions have been developed to exploit their age-hardening characteristics in conjunction with an alloyed matrix. They then become susceptible to the presence of seemingly minor elements such that undesirable intermetallic particles can be formed during cooling. In those cases of precipitation during solidification, the particles are placed in the category of inclusions.

The intermetallic inclusions are particularly troublesome in aluminum alloys containing large quantities of zinc or magnesium. Complexes can be formed with the transition elements.

These observations suggest that the remedy is close control of the metal chemistry. There are many examples in which control is inadequate and the problem is not identified until mechanical properties are marginally out of specification. Even aluminum carbide and iron-aluminum compounds have degraded properties by the formation of inclusions. Although the solubilities are low, the problem is additive in that scrap/revert procedures can cause a gradual increase in the impurity levels, and inclusion problems become more severe. The hazards associated with recycling then become apparent, especially when the final product is sensitive to the elements present and when strict mechanical property specifications are imposed.

Copper Alloys

A portion of the copper-oxygen system is shown in Fig. 16. The eutectic shows that the last liquid to solidify may contain 0.39% O even though the initial melt may contain 0.01% O. Therefore Cu_2O inclusions may be more predominant internal to the casting (liquid enrichment in oxygen due to slow diffusion) and may also be present at grain boundaries. The key to control is to add elements that combine with dissolved oxygen (that is, to form oxides with free energies lower than that of Cu_2O).

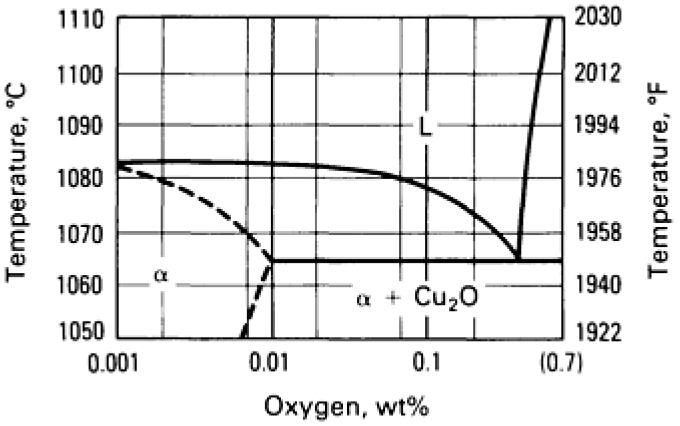

Fig. 16 A portion of the copper-oxygen equilibrium diagram. Source: Ref 20.

Examples are lithium, boron, magnesium, or phosphorus, where control of the excess addition becomes important to modification of the electrical conductivity in the high-copper alloys. The excess deoxidizer goes into solid solution. A more thorough discussion of gas solubility is available in Ref 20 (see also the article "Gases in Metals" in this Volume).

A number of the copper alloys are susceptible to dross formation, and the normal precautions in pouring and gating are absolutely necessary to minimize exogenous inclusions. The drosses are usually complex oxides of copper, zinc, tin, lead, or aluminum in the aluminum bronze family.

Iron is added as both a dispersion strengthener and as a grain refiner in aluminum and manganese bronzes. However, iron can become an undesirable inclusion in the other copper alloys. When a foundry pours several different alloy chemistries, scrap segregation becomes important to inclusion control. Consideration can also be given to alternative grain-refining agents such as zirconium.

In some cases, the intermetallic inclusions are rich only in iron, and complexes are formed. This is especially true when alloys are high in zinc, such as the high-strength yellow brasses. The problem becomes more severe when a melt is held close to its liquidus for extended periods. In this case, the solubility of the complex intermetallics is lower, and their formation is enhanced.

High-zinc alloys offer fewer problems with dissolved oxygen because of the vaporization of zinc and the purging action of the melt. Oxides as inclusions are then a lesser problem. However, zinc oxide (ZnO) can react with refractories and mold materials to produce inclusions during pouring.

In addition to careful pouring and gating practices, oxogenous inclusions can be removed by filtering processes. However, the practice has not been as well received for copper alloys as for aluminum alloys.

Although not strictly an inclusion from the previous definition, lead in many of the copper alloys can form oxides that will react with mold bonding agents such as bentonite. These lead complexes can become leachable in standard tests, and waste sand streams that contain lead compounds may be classified as toxic with the attendant difficulty in disposal (Ref 21).

Magnesium Alloys

Of the nonferrous alloys considered in this section, magnesium has the lowest free energy of formation for its oxide. Therefore, the complete prevention of oxide inclusions is impossible, and a number of methods have been developed to minimize oxide inclusion formation. Agents that evolve gas to partially insulate the melt from the atmosphere and fluxes that agglomerate the oxide (plus other impurities that are to be removed) are two examples of control of the melting practice.

Again, great care must be exercised in gating to minimize reoxidation. The magnesium alloys are light in weight, and many of the potential exogenous inclusions are collected as sludge in the bottom of the furnace and ladle. Desludging operations are then necessary. The use of filtering systems, whether metallic or ceramic, is common to all of the higher-quality magnesium castings. As with aluminum alloys, excess grain-refining agents can result in undesirable inclusions that can have complex chemistries because of secondary reactions.

The fluxes themselves must be reactive in order to perform their intended function. Excess flux can then react with the atmosphere, refractories, or the mold materials to produce inclusions. On the other hand, insufficient flux causes metal reaction with the atmosphere to produce oxides and nitrides that may be difficult to remove if not in an agglomerated form. Temperature, time at temperature, alloy composition, pouring practice, and gating procedures dictate the optimum fluxing process.

So-called fluxless melting has been suggested for magnesium alloys in order to overcome the environmental and metallurgical problems associated with fluxes (Ref 22). Fluxless melting uses nonreactive gaseous atmospheres above the melt. The most effective protective atmosphere is CO_2 plus the addition of trace inhibitors such as SO_2 and SF_6.

Nucleation Kinetics

J.H. Perepezko, University of Wisconsin--Madison

Introduction

NUCLEATION PROCESSES play a key role in the solidification of castings by controlling to a large extent the initial structure type, size scale, and spatial distribution of the product phases. During many solidification processes, the size scale of critical nucleation events is too small and the rate of their occurrence too rapid for accurate observation by direct methods. Nonetheless, nucleation effects in the solidification microstructure exert a strong influence on the grain size and morphology as well as the compositional homogeneity. The final microstructure is also modified by the crystal growth, fluid flow, and structural coarsening processes that are important in the later stages of ingot freezing.

In large bulk castings, the solidification temperature corresponding to the onset of freezing is often close to but slightly less than the melting point or equilibrium liquidus temperature. The offset of the solidification temperature with respect to the equilibrium temperature is called the undercooling or supercooling, ΔT, and it plays a vital role in the overall description of the initial stage of the solidification that is controlled by nucleation. The level of melt undercooling at the onset of solidification is important to consider in developing an understanding of the variety of structural modifications and grain-refining practices in common casting alloys and is the basis of more recent solidification processing technologies using rapid solidification methods. In this article, selected highlights of thermodynamic relationships during solidification and nucleation kinetics behavior will be discussed in connection with the basis of nucleation treatments, such as grain refinement and inoculation, to provide a summary of nucleation phenomena during casting.

Thermodynamics of Solidification

Macroscopic Solids. Throughout the analysis of solidification, thermodynamics is used to judge the alloy phase constitution, to describe the solidification path and composition changes in terms of partition coefficients and the slopes of the liquidus and solidus phase boundaries, and to account for the free energy changes involved in various crystallization processes. In most castings, a full global equilibrium associated with a uniform phase composition does not occur throughout the ingot. However, it is often valid to take the liquid and solid compositions at the solidification front to be represented by the liquidus and solidus compositions determined by the tie line end points at a given temperature on the phase diagram. This concept is called local interfacial equilibrium, and it has been successfully applied to the description of casting processes in which the rate of diffusion, particularly in the solid, is too sluggish to achieve uniform phase compositions (Ref 1).

The consideration of nucleation and the level of melt undercooling introduce another type of departure from full equilibrium that is known as metastable equilibrium. At full equilibrium, thermodynamics predicts that solidification is not possible. Only when there is a departure from full liquid-solid equilibrium will solidification be possible. For solidification to occur, this departure brings the liquid into an undercooled state in which it is metastable because of the absence of one or more stable solid phases. The change from a stable to a metastable state occurs in a continuous manner without an abrupt change in the physical properties, such as molar volume or heat capacity. Therefore, metastable states can exhibit a true reversible equilibrium.

The thermodynamic description of solidification can be quantified by recalling that for a pure metal at the equilibrium temperature, T_f, the free energy change is:

$$G_S - G_L = (H_S - H_L) - T_f\,(S_S - S_L) = 0$$

or

$$\Delta G_f = \Delta H_f - T_f\,\Delta S_f = 0 \qquad \textbf{(Eq 1)}$$

so that:

$$\Delta S_f = (\Delta H_f)/T_f \quad \textbf{(Eq 2)}$$

where G_S and G_L, H_S and H_L and S_S and S_L are the molar free energy, enthalpy, and entropy for the solid and liquid, respectively.

At T, a temperature other than T_f, $\Delta G_f \neq 0$, and Eq 1 and 2 can be combined to yield:

$$\Delta G_f = \frac{\Delta H_f (T_f - T)}{T_f} = \frac{\Delta H_f \Delta T}{T_f} \quad \textbf{(Eq 3)}$$

when the small correction due to heat capacity terms is neglected. Based on Eq 3, there is a direct relationship between ΔG_f and the undercooling ΔT. The relationship in Eq 3 is represented in Fig. 1, in which the relative stability of the two phases (stable α and metastable β) that form from the liquid without composition change is shown as a function of temperature. The behavior is also approximately followed for stable and metastable eutectics such as Al/Al_3Fe and Al/Al_6Fe and Fe/C and Fe/Fe_3C (Ref 2). An important feature illustrated in Fig. 1 is that the melting of a metastable phase always occurs at a lower temperature than the stable-phase melting.

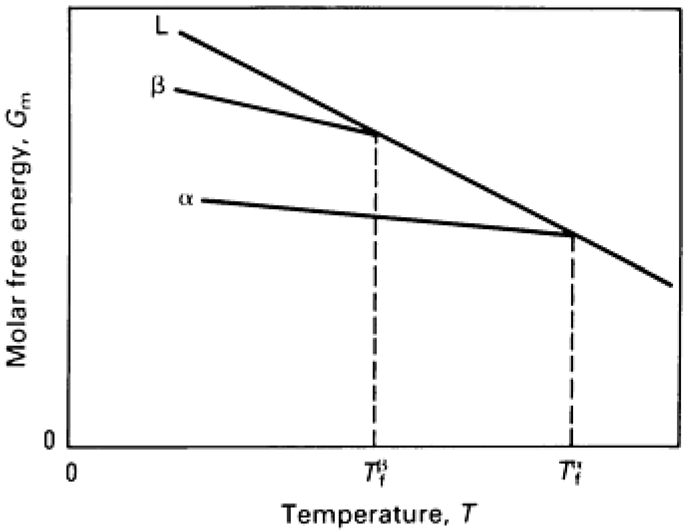

Fig. 1 Molar free energy versus temperature curves for a single component with a stable α phase and a metastable β phase, both at equilibrium temperature T_f. $T_f^b < T_f^a$ in every case.

For alloys, the free energy of a phase is a function of both temperature and composition. When components are mixed together to form an alloy, the molar free energy change, ΔG_m, can be estimated from thermodynamic solution models (Ref 3). The simplest approach is to assume that the heat of mixing, ΔH_m, is zero and that the entropy change upon mixing, ΔS_m, is given by the ideal entropy of mixing. This is the description of an ideal solution, and it is often a useful approximation for dilute alloys. For an ideal solution of composition C_B:

$$\begin{aligned} \Delta G_m &= \Delta H_m - T\,\Delta S_m \\ &= RT\,[C_B \ln C_B + (1 - C_B) \ln (1 - C_B)] \end{aligned} \quad \textbf{(Eq 4)}$$

With more concentrated alloys, a regular solution model is often applied in which the heat of mixing is given by the symmetrical term $\Omega C_B(1 - C_B)$, where Ω reflects the net interatomic interaction. For regular solutions, ΔS_m is taken as the ideal solution term in Eq 4.

The description of equilibrium between solid and liquid phases over a range of alloy composition and temperature is represented in terms of the component chemical potentials μ_A and μ_B for each phase. The chemical potential is related to the molar free energy at a given composition by the standard thermodynamic definition (Ref 3):

$$m_A = G_m - G_B \left(\frac{\partial G_m}{\partial G_B} \right)_{T,P} \qquad \textbf{(Eq 5a)}$$

$$m_B = G_m + (1 - G_B) \left(\frac{\partial G_m}{\partial G_B} \right)_{T,P} \qquad \textbf{(Eq 5b)}$$

As illustrated in Fig. 2(a), the definitions in Eq 5a and 5b indicate that a tangent to a molar free energy curve at composition C_o intersects the pure component axes at μ_A and μ_B. With this description, alloy phase equilibrium is represented by an equality of chemical potentials for each of the components in the equilibrated phases so that $m_A^L = m_A^S$ and $m_B^L = m_B^S$, as shown in Fig. 2(b). The geometric interpretation of alloy phase equilibrium is expressed in terms of the common tangent construction, which is also shown in Fig. 2(b). The molar free energy of the liquid or the solid phase is also related to the chemical potential by the expression:

$$G_m = (1 - C_B)\, \mu_A + C_B\, \mu_B \qquad \textbf{(Eq 6)}$$

and provides a useful form in representing the free energy changes involved in the formation of solid phases from an alloy liquid solution.

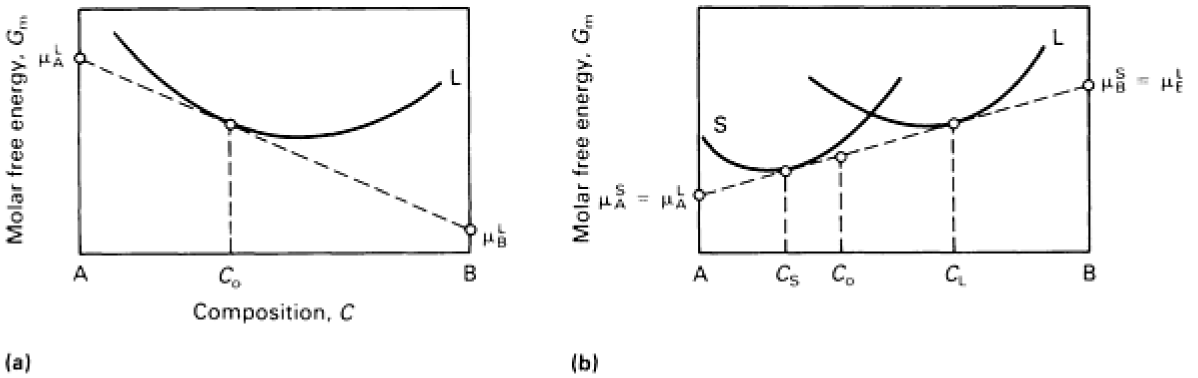

Fig. 2 Alloy phase equilibrium diagrams showing the chemical potentials of the liquid and solid components. (a) Variation of the molar free energy of mixing with composition for a liquid alloy solution. The chemical potentials, m_A^L and m_B^L, for the solution at composition C_o are given by the intercepts on the pure component axes. (b) Molar free energy versus composition diagram for two-phase liquid-solid equilibrium in an alloy of composition C_o. Solid of composition C_S is in equilibrium with liquid of composition C_L, and the chemical potentials of A and B are equal in the solid and liquid.

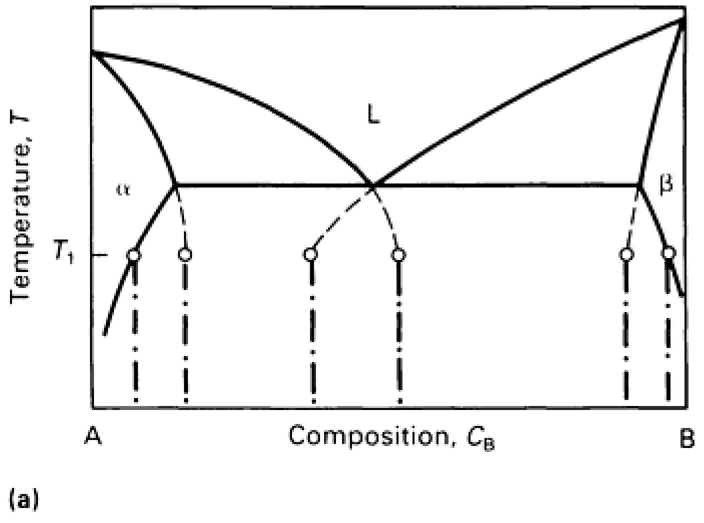
Free energy versus composition diagrams provide a useful method of analyzing the free energy relationships for alloy solidification reactions. Some of the relationships are shown in Fig. 3 for a temperature below the eutectic. For temperatures below the eutectic, the (α + L) and (β + L) equilibria are metastable with respect to the stable (α + β) phase mixture. In the phase diagram, the metastable two-phase conditions can be examined in terms of an extension of the respective solidus and liquidus phase boundaries below the eutectic, as noted in Fig. 3. For large excursions below the eutectic, the phase boundary extrapolations may not follow a simple linear extension. The relationships illustrated in Fig. 3 also show the common characteristic for a metastable phase to exhibit a higher solubility for solute than the equilibrium stable-phase solution. Similar behavior is found for the cases of peritectic and monotectic solidification reactions (Ref 2).



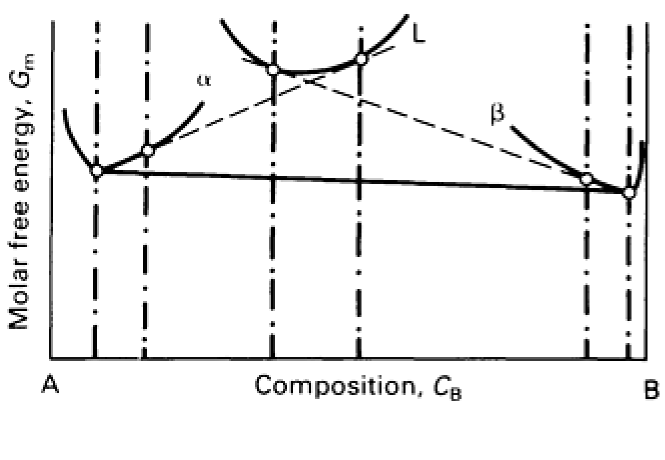


Fig. 3 Eutectic phase diagram (a) illustrating the metastable extensions of the liquidus and solidus phase boundaries to a temperature T_1 below the eutectic. (b) The molar free energy versus composition diagram at T_1 shows the metastable (α + L) and (β + L) equilibria by dashed common tangents and the stable (α + β) equilibrium the solid common tangent.

When one or both of the stable solid phases in a eutectic or peritectic reaction are suppressed, metastable solid phases may develop and yield metastable eutectics and peritectics (Ref 2). Figure 4 shows the modified phase diagram for a metastable peritectic. The stable Al/Al_3Ti and metastable Al/Al_xTi peritectic reactions may be relevant to the operation of grain refining in aluminum alloys (Ref 4, 5).

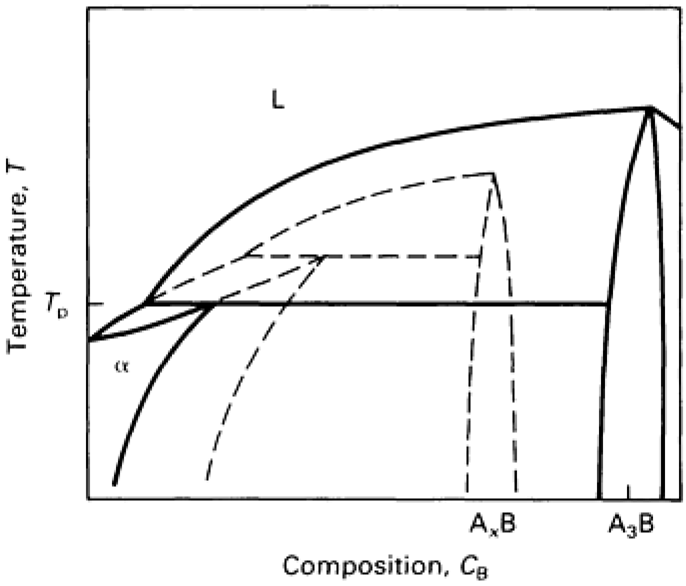

Fig. 4 Modified phase diagram for a metastable peritectic. When a stable A_3B phase is suppressed, the stable peritectic reaction involving A and A_3B may be replaced by a metastable peritectic reaction between A and A_xB. The peritectic temperature T_p and α phase solubility for the metastable peritectic are higher than for the stable peritectic case.

To provide a description of compositional segregation plus the influence of constitutional supercooling and solute redistribution during two-phase eutectic growth, phase diagram information such as the partition coefficient, *k*, or the liquidus slope, m_L, is often used in alloy solidification analysis (Ref 6, 7). For dilute solutions, the Vant'Hoff relation for liquid-solid equilibrium holds and relates *k* and m_L as:

$$k = 1 - \frac{m_L \Delta H_f^A}{R(T_f^A)^2} \qquad \textbf{(Eq 7)}$$

where ΔH_f^A and T_f^A are the latent heat and melting point, respectively, of pure solvent, A. The partition coefficient can be evaluated separately for a dilute solution by:

$$k = \exp\left[\frac{\Delta H_f^B}{R}\left(\frac{1}{T_f^B} - \frac{1}{T_f^A}\right)\right] \qquad \textbf{(Eq 8)}$$

where ΔH_f^B and T_f^B are the latent heat and melting point, respectively, of component B.

Microscopic Solids. The preceding discussion of solidification thermodynamics applies to cases in which the solid phases are of macroscopic size. There are several important situations during nucleation, dendritic solidification, or eutectic growth at high velocity in which the solid is of microscopic size or exhibits a sharply curved boundary with the liquid. The free energy of a small particle increases inversely with its size or radius of curvature. The increased free energy for the microscopic solid compared to the macroscopic solid results in a decrease in melting temperature, as expected for metastable equilibrium behavior. For a pure component, the free energy increment due to curvature K is given by:

$$\Delta G_k = \sigma K V_m \qquad \textbf{(Eq 9)}$$

where V_m is the molar volume and σ is the interfacial energy. For a sphere of radius, *r*, K = 2/*r*. In terms of Eq 9, the melting of a microscopic particle of pure component with radius *r*, $T_f(r)$, is depressed from the melting point of a macroscopic particle by:

$$T_f(r) = T_f - \frac{2s\,V_m}{(r\Delta S_f)} \quad \textbf{(Eq 10)}$$

For alloys, the influence of curvature can be treated by including a term based on Eq 9 to the chemical potential for the solid (Eq 6). This will shift the liquidus and solidus phase boundaries, but in a manner that results in a negligible change in *k* and m_L (Ref 6).

Nucleation Phenomena

Nucleation during solidification is a thermally activated process involving a fluctuational growth in the sizes of clusters of solids (Ref 8). Changes in cluster size are considered to occur by a single atom addition or by removal exchange between the cluster and the surrounding undercooled liquid. At small cluster sizes, the energetics of cluster formation reveal that the interfacial energy is dominant, as can be observed by noting that the ratio of surface area to volume of a sphere is 3/*r.* For the smallest sizes, clusters are called embryos; these are more likely to dissolve than grow to macroscopic crystals. In fact, the excess interfacial energy due to the curvature of small clusters is the main contribution to the activation barrier for solid nucleation. This accounts for the kinetic resistance of liquids to crystallization and is manifested in the frequent observation of undercooling effects during solidification (Ref 9, 10).

Homogeneous Nucleation

The principal features of nucleation phenomena and the kinetics of the rate process during solidification can be illustrated in the simplest terms by using the capillarity model to evaluate the kinetic factors (Ref 8). With this approach, it is useful to examine first the case of homogeneous nucleation in which solid formation occurs without the involvement of any extraneous impurity atoms or other surface sites in contact with the melt. As a further simplification, only the case of isotropic interfacial energy is treated, but it should be recognized that anisotropic behavior can yield faceted cluster shapes. The energetics of cluster formation for a spherical geometry can be expressed in terms of a surface and a volume contribution as:

$$\Delta G(r) = 4\,\pi r^2\sigma + \frac{4}{3}\pi r^3\,\Delta G_V \quad \textbf{(Eq 11)}$$

where $\Delta G(r)$ is the free energy change to form a cluster of size *r* and $\Delta G_V = \Delta H_f\,\Delta T/T_f V_m$. The relationship in Eq 11 is characterized in Fig. 5, in which the activation barrier for nucleation, ΔG_{cr}, is reached at a critical size r_{cr} (that is, $d\Delta G(r)/dr = 0$), as given by:

$$r_{cr} = -\frac{2s}{\Delta G_v} = -\frac{2s\,T_f V_m}{\Delta H_f \Delta T} \quad \textbf{(Eq 12)}$$

and

$$\Delta G_{cr} = \frac{16ps^3}{3\Delta G_v^2} = \frac{16ps^3 T_f^2 V_m^2}{3\Delta H_f^2 \Delta T^2} \quad \textbf{(Eq 13)}$$

At increasing values of undercooling, r_{cr} is reduced ($r_{cr} \propto \Delta T^{-1}$) and G_{cr} is reduced more rapidly ($\Delta G_{cr} \propto \Delta T^{-2}$). A cluster is often considered to reach the stage of a nucleus capable of continued growth with a decreasing free energy when the size r_{cr} is achieved, but in fact stable nucleus growth ensues when the cluster size exceeds r_{cr} by an amount corresponding to (ΔG_{cr} - kT) in Fig. 5 (Ref 8). The relationship between cluster size and the number of atoms in a cluster, n_{cr}, is expressed by ($n_{cr}V_a$) = $\frac{4}{3}\pi r_{cr}^3$ /3, where V_a is the atomic volume.

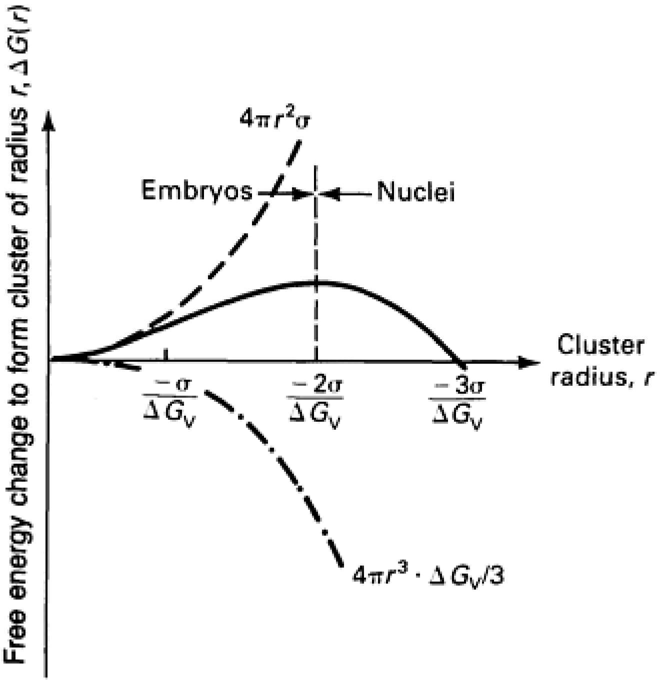

Fig. 5 Free energy change for cluster formation as a function of cluster size. The surface contribution to $\Delta G(r)$ is $4\pi r^2\sigma$, and the volume contribution is $4\pi r^3 \cdot \Delta G_v/3$; r_{cr} occurs at $-2\sigma/\Delta G_v$.

To relate cluster energetics and fluctuational growth to the rate of nucleation, it is necessary to describe the cluster population distribution. Because the mixture of clusters in an undercooled melt is a dilute solution, the entropy can be described in terms of an ideal solution. The metastable equilibrium concentration of clusters of a given size, $C(n)$, is then given by (Ref 8):

$$C(n) = C_l \exp\left(\frac{-\Delta G(n)}{kT}\right) \quad \textbf{(Eq 14)}$$

where C_l is the number of atoms per cubic meter in the liquid and $\Delta G(n)$ is given by Eq 11 when r is converted to n, as noted above.

If solid nucleation is regarded as the growth of clusters past the critical size, then the resulting cluster flux or the nucleation rate I (in $m^3 \cdot s^{-1}$) can be represented kinetically by the product:

$$I = \nu_{SL}\, S_{cr}\, C(n_{cr}) \qquad \textbf{(Eq 15)}$$

where ν_{SL} is the jump frequency associated with atom jumps from the liquid to join the cluster and can be estimated from the liquid diffusivity, D_L, and jump distance, a, as in (D_L/a^2); S_{cr} is the number of atoms surrounding a cluster that is roughly $(4p\, r_{cr}^2 / a^2)$; and $C(n_{cr})$ is the concentration of critical clusters. The full expression for the steady-state nucleation rate is then:

$$I = \left(\frac{D_L}{a^2}\right)\left(\frac{4p\, r_{cr}^2}{a^2}\right) c_1 \exp\left(\frac{-\Delta G_{cr}}{kT}\right) \qquad \textbf{(Eq 16)}$$

For typical metals, $C\mathbf{l}$ ~10^{28} m^{-3}, D_L ~10^{-9} m^2/s, and a_o ~0.3×10^{-9} m so that:

$$I\ ;\ 10^{40} \exp\left(-\frac{16 p s^3 T_f^2 V_m^2}{3k \Delta H_f^2 T \Delta T^2}\right) \qquad \textbf{(Eq 17)}$$

and shows a rather steep temperature dependence, as illustrated in Fig. 6. At high temperature, the temperature dependence of I is dominated by the driving free energy term, which is contained within the exponential dependence on the activation barrier, and I can vary by about a factor of five per degree Celsius. Equation 16 or 17 indicates that the maximum nucleation rate occurs at $(\frac{1}{3})T_f$. Over a wide temperature range, the liquid diffusivity cannot be taken as constant, but can instead be represented as an Arrhenius function, $D_L = D_o \exp(-Q/kT)$, where D_o is a constant and Q is the activation energy for liquid diffusion. At large undercooling or low temperatures, and especially for glass-forming alloys, the diffusivity is often obtained from the viscosity in the form $D_L = (kT/3\pi a\, n_o) \exp - [A/(T - T_o)]$, where n_o, A, and T_o are constants. In evaluating nucleation rates, accurate values for the activation barrier are important because of the exponential dependence of I on ΔG_{cr}. The evaluation of ΔG_V is based on thermodynamic data or reasonably accurate models (Ref 11). However, separate, independent measurements of liquid-solid interfacial energy, σ_{LS}, at the nucleation temperature are not available, and calculations based on model-dependent estimates of σ_{LS} are of uncertain accuracy.

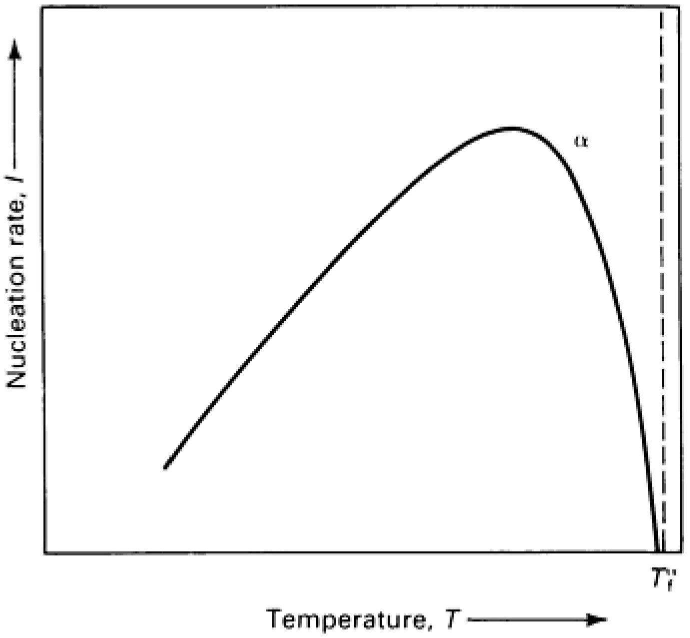

Fig. 6 Steady-state nucleation rate as a function of undercooling below the melting point. At low undercooling, the nucleation rate is primarily controlled by driving free energy; at high undercooling, nucleation is limited by diffusional mobility.

Heterogeneous Nucleation

Homogeneous nucleation is the most difficult kinetic path to crystal formation because of the relatively large activation barrier for nucleus development (ΔG_{cr}). To overcome this barrier, classical theory predicts that large undercooling values are required, but in practice an undercooling of only a few degrees or less is the common observation with most castings. This behavior is accounted for by the operation of heterogeneous nucleation in which foreign bodies such as impurity inclusions, oxide films, or crucible walls act to promote crystallization by lowering ΔG_{cr}. Because only a single nucleation event is required for the freezing of a liquid volume, the likelihood of finding a heterogeneous nucleation site in contact with a bulk liquid is great. Indeed, it has been estimated that even in a sample of high-purity liquid metal there is a nucleant particle concentration of the order of about 10^{12} m^{-3} (Ref 9). Only by using special sample preparation methods to isolate the melt from internal and external nucleation sites by subdivision into a fine droplet dispersion has it been possible to achieve undercoolings in the range of 0.3 to 0.4 T_f (Ref 10).

The action of heterogeneous nucleation in promoting crystallization can be visualized in terms of the nucleus volume that is substituted by the existing nucleant, as illustrated schematically in Fig. 7. For a nucleus that wets a heterogeneous nucleation site with a contact angle θ, the degree of wetting can be assessed in terms of $\cos\theta = (\sigma_{nL} - \sigma_{nS})/\sigma_{LS}$, where the interfacial energies are defined in Fig. 7. As θ approaches 0, complete wetting develops; as θ approaches 180°, there is no wetting between the nucleus and the nucleant (which is inert), and the conditions approach homogeneous nucleation.

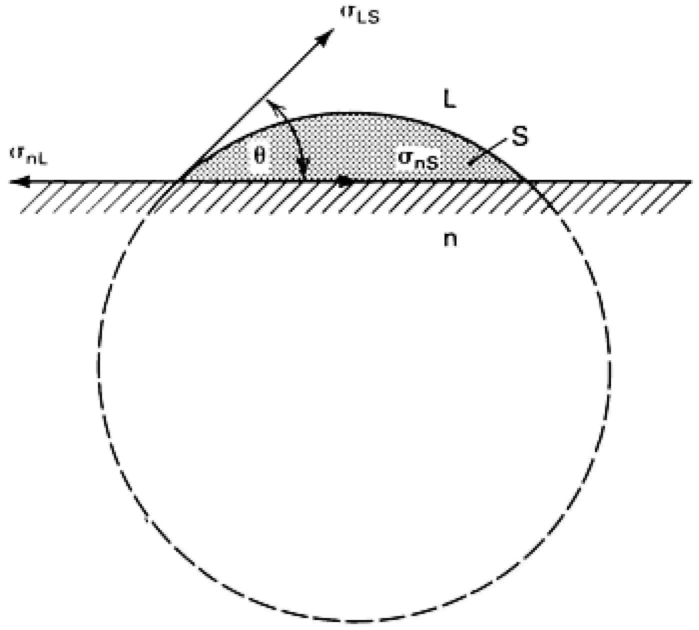

Fig. 7 The interfacial energy, σ, relationships among a planar nucleant substrate (n), a spherical sector solid (S), and the liquid (L). The interfacial regions are designated by the subscripts LS (liquid-solid), nL (nucleant-liquid), and nS (nucleant-solid).

The energetics of heterogeneous nucleation can be described by a modification of Eq 11 to account for the different interfaces and the modified cluster volume involved in nucleus formation. In terms of the cluster formation shown in Fig. 7, the free energy change during heterogeneous nucleation is expressed by:

$$\Delta G(r)_{het} = V_{SC}\,\Delta G_V + A_{SL}\,\sigma_{SL} + A_{nS}\,\sigma_{nS} - A_{nL}\,\sigma_{nL} \qquad \textbf{(Eq 18)}$$

where V_{SC} is the spherical cap volume and A_{SL}, A_{nS}, and A_{nL}, are the solid-liquid, nucleant-solid, and nucleant-liquid interfacial areas, respectively. When the volume and relevant interfacial areas are expressed in terms of the geometry of Fig. 7, the evaluation of ΔG_{cr} for heterogeneous nucleation yields:

$$\Delta G_{cr}(het) = \frac{16ps^{3}_{LS}}{3\Delta_V^2}\left[\frac{2-3\cos q+\cos^3 q}{4}\right] = \Delta G_{cr}(\text{hom})[f(q)] \qquad \textbf{(Eq 19)}$$

so that the barrier for homogeneous nucleation is modified by $f(\theta)$, the shape factor, during heterogeneous nucleation. Over the variation in θ ranging from complete wetting (θ = 0°) to nonwetting (θ = 180°) $f(\theta)$ or [ΔG_{cr}(het)/ΔG_{cr}(hom)] varies from 0 to 1.0, as illustrated in Fig. 8. It is important to note that the value of r_{cr} for the curvature of the critical nucleus does not change in the classical analysis of heterogeneous nucleation, but the reduction in the activation barrier shown in Fig. 8 has a significant influence on the nucleation rate. This feature is also described in Fig. 8, in which the spherical cap size as measured by the ratio (h/*r*) is plotted as a function of θ. The dimension h is the height above the substrate.

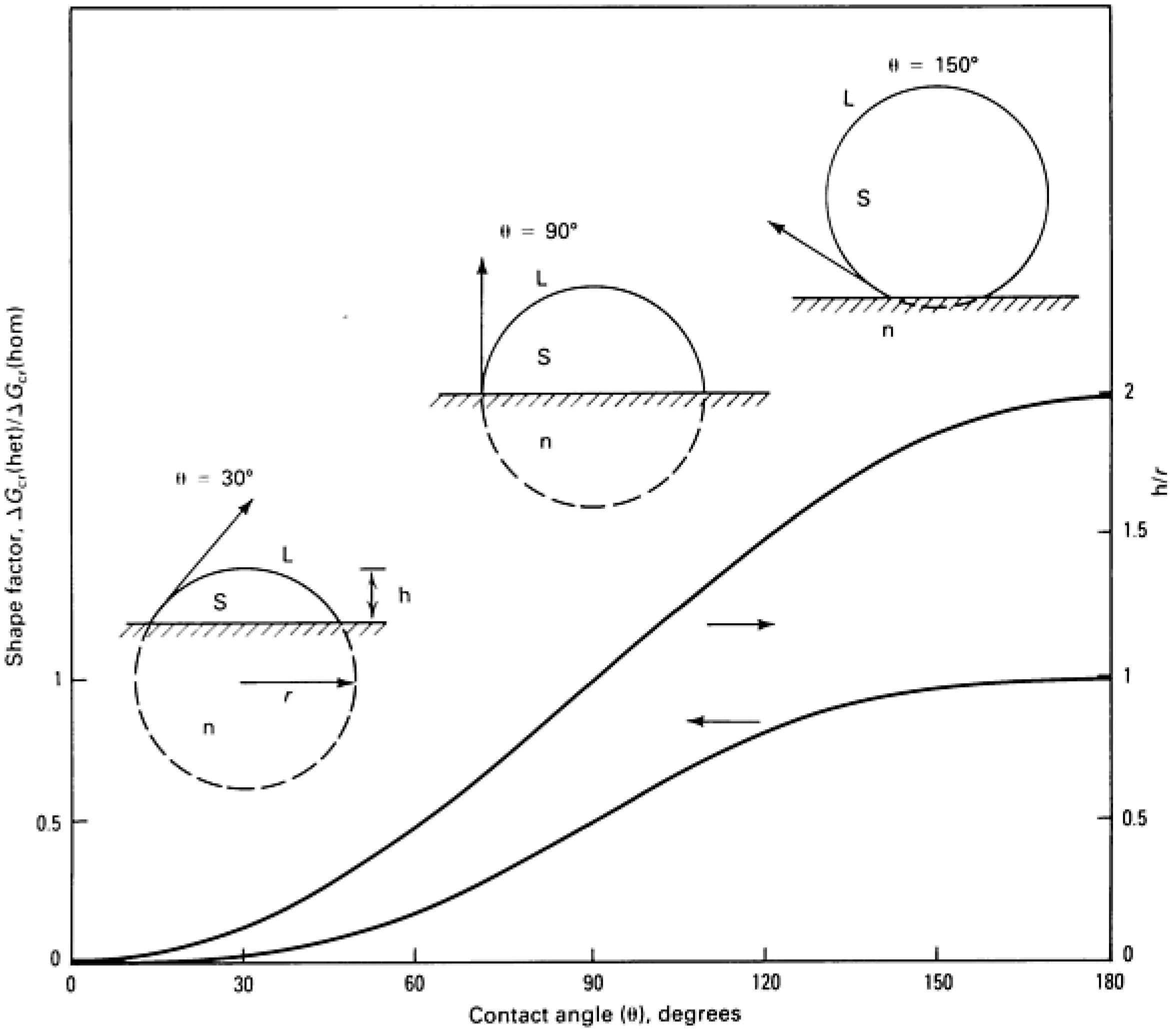

Fig. 8 The variation in shape factor $f(\theta)$ or [ΔG_{cr}(het)/ΔG_{cr}(hom)] and spherical cap size, h/*r*, as a function of the contact angle, θ.

Following an analysis similar to that developed for homogeneous nucleation based on Eq 15, an expression can be obtained for the rate of heterogeneous nucleation. In this case, the value of the surface area, S_{cr}, for a spherical cap geometry is estimated by [$2p\,r_{cr}^2$ (1 - cos θ)/a^2]. In addition, the concentration of critical clusters is represented in terms of

the number of surface atoms of the nucleation site per unit volume of liquid, C_a, which is of the order of 10^{20} m^{-3}. The heterogeneous nucleation rate expression I_{het} ($m^{-3} \cdot s^{-1}$) is given by:

$$I_{het} = \left(\frac{D_L}{a^2}\right)\left(\frac{2\pi r_{cr}^2(1-\cos\theta)}{a^2}\right)c_a \exp\left[\left(-\frac{\Delta G_{cr}(\text{hom})}{KT}\right)f(\theta)\right] \qquad \textbf{(Eq 20)}$$

or for typical metals:

$$I_{het} \approx 10^{30} \exp\left(-\frac{16\pi\sigma_{LS}^3 T_f^2 V_m^2 f(\theta)}{3k\Delta H_f^2 T \Delta T^2}\right) \qquad \textbf{(Eq 21)}$$

The comparison between heterogeneous and homogeneous nucleation kinetics is illustrated in Fig. 9 by a schematic time-temperature transformation diagram. Although only a single transformation curve (that is, C-curve) is shown in Fig. 9 for heterogeneous nucleation, in reality there will be as many curves as the number of heterogeneous nucleation sites. Each curve for heterogeneous nucleation will be distinguished by a catalytic potency, that is, $f(\theta)$, and a site density (Ref 10). To attain homogeneous nucleation conditions, it is clear that all heterogeneous nucleation sites must be removed or bypassed kinetically.

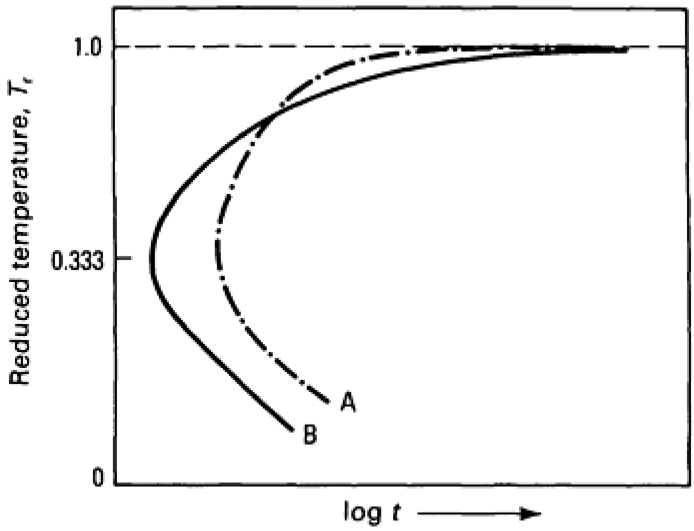

Fig. 9 Comparison between heterogeneous nucleation (A) and homogeneous nucleation (B) in terms of the relative transformation kinetics below the melting point. The reduced temperature T_r = T/T_f and time $t \propto I^{-1}$.

Inoculation Practice

There is a wide commercial application of cast alloy treatments that modify the initial solidification characteristics to provide a means for effective control of grain size and morphology. Inoculation is the common approach to grain refinement, and it involves the introduction of nucleating agents to a melt either externally in the form of a fine dispersion or through internal means by phase or chemical reactions that result in the formation of a solid reaction product. Although the success of this approach is established, an understanding of the actual mechanism by which inoculating agents operate still remains somewhat uncertain. There is widespread experience with inoculation, and several models have been developed for the process, primarily (but not exclusively) in connection with aluminum alloy melts (Ref 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24). It is not possible to discuss all of this work in this article; instead, the key features of inoculation will be treated in relation to specific features of nucleation during solidification.

In commercial practice, inoculants are used as additions to numerous molten alloys to yield fine grain sizes in castings. In cast iron, ferrosilicon is added to nucleate graphite; zirconium or carbon can be added to magnesium alloys; iron, cobalt, or zirconium is added to copper-base alloys; phosphorus is introduced to aluminum-silicon alloys to refine the silicon phase size; arsenic or tellurium can be added to lead alloys; and titanium is added to zinc-base systems. Other additives, such as sodium in aluminum-silicon alloys, are used to modify the growth morphology. In addition, there is a large body of experience on the grain refinement of aluminum-base alloys by aluminum-titanium and aluminum-titanium-boron melt additions. To illustrate the principal features of inoculation and the physical mechanisms that have been developed to account for the effectiveness of inoculating agents, some of the experience with aluminum alloys will be used as a basis for discussion. The basic features of inoculation in other alloy systems follow the pattern that appears to apply to aluminum alloys.

The basic requirements for an efficient nucleant can be assessed from consideration of nucleation theory (Ref 25, 26, 27). To promote the formation of crystals on a nucleant, the interface between the nucleant and the liquid should be of higher energy than that between the nucleant and the crystal solid. A means of maximizing this condition is to provide a nucleant crystal relationship that is associated with a good crystallographic fit between the respective crystal lattices. In fact, the potency of a given catalyst is believed to be increased for decreasing values of relative lattice disregistry, with the degree of undercooling decreasing with a lowering of lattice disregistry. In addition to the basic requirement of lattice compatibility, the melt should tend to wet the surface of the nucleant, and for a uniform refining, the solid nucleant should remain widely dispersed in the liquid.

As an ancillary condition, the onset of nucleation should not be followed by a rapid and an isotropic crystal growth, because this will permit the full effect of the potential nucleants to be realized. In alloys, the growth restriction can be achieved as a consequence of solute segregation during freezing, which allows for nucleants throughout the melt to become effective and favors an equiaxed fine grain structure (Ref 27). At the onset, it should be noted that the theoretical description of an efficient nucleant should serve as a basis for predicting useful inoculants. However, in practice, this approach has not been successful; instead, nucleation theory has been primarily used to rationalize the identification of a useful grain refiner.

Within the general requirements for effective nucleants, there appear to be two general classes of compounds that are effective in aluminum-base alloys. Similar compound particle types apply to other common casting alloys. The first group includes Al_3Ti, Al_3Zr, and Al_7Cr and can be considered to be associated with a peritectic reaction. The second group comprises compounds such as TiC, TiB_2, and AlB_2, which are added either intentionally or which result from a chemical reaction in the melt with residual impurities. It is useful to note that the undercooling required to activate solidification is usually less than about 5 °C (9 °F). Despite the rather extensive discussion concerning the mechanism of action and the activity of these proposed nucleants, the strongest evidence for the operation of compound nucleant is derived from the observed orientation relationships.

Table 1 lists disregistry calculations along two directions, *a* and *b*, that are normal to each other and are located in the plane in which nucleation is considered to initiate, as illustrated in Fig. 10. For the most part, the crystallographic relationships that have been observed involve planes of relatively close packing between the nucleant and aluminum with disregistries of usually less than about 10%. The issue of specific nucleant identity is not insignificant considering that in commercial melts the rather broad spectrum of background catalysts may often result in solidification at undercoolings of about 5 °C (9 °F). Indeed, only about 1 to 2% of all potential nucleant particles in a master alloy addition result in the formation of grains. Furthermore, it has not been clearly established that these proposed nucleants operate singly or in association with each other or with background nucleants in the melt.

Table 1 Observed characteristics of potential nucleant compounds

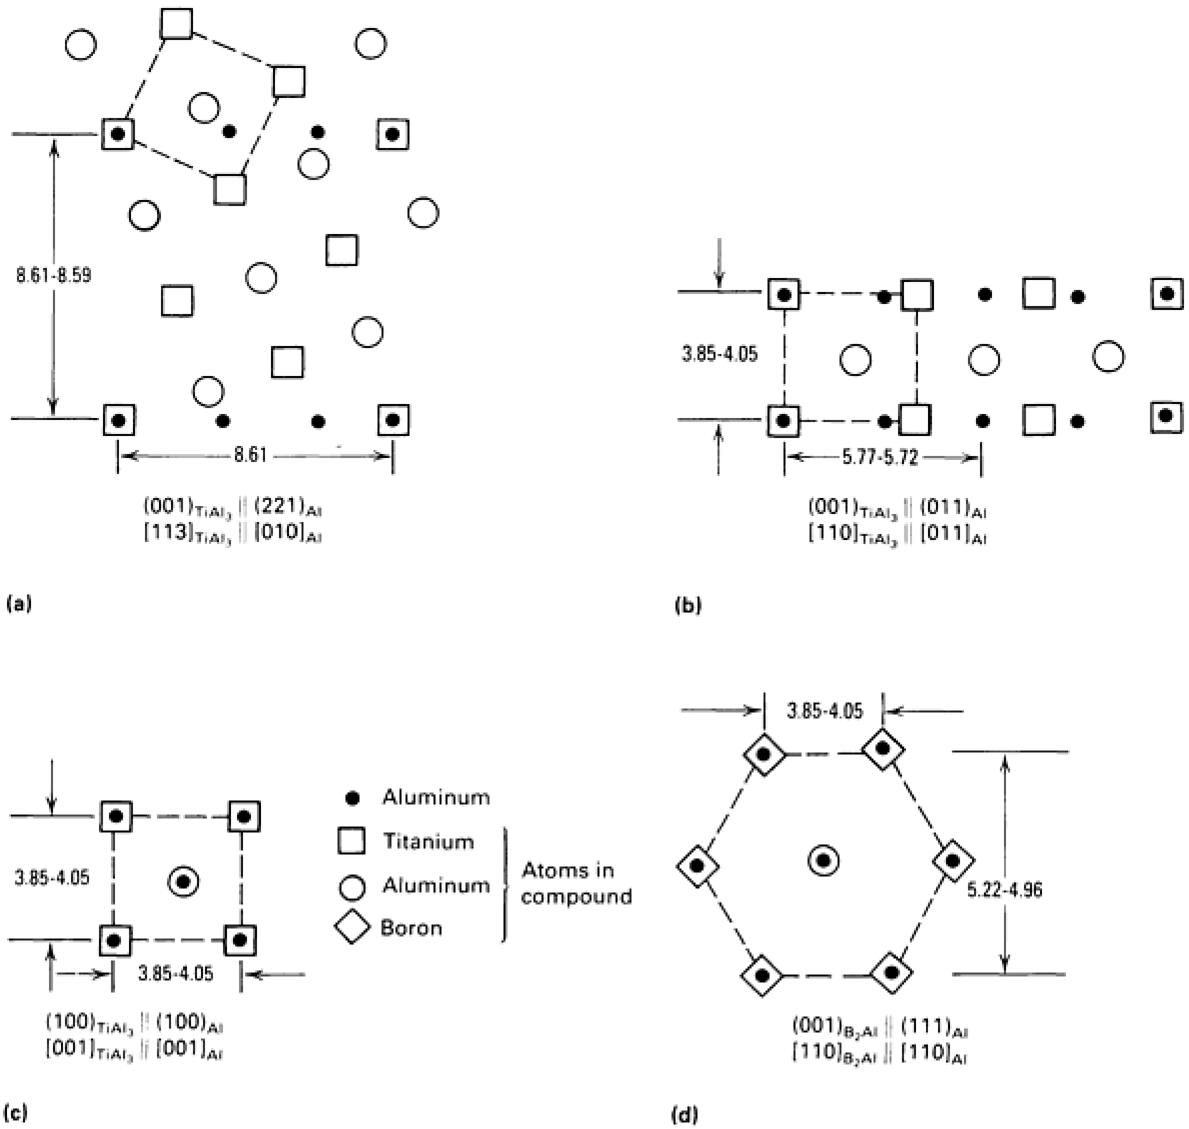

Fig. 10 Orientation relationships found among some potential nucleants and aluminum. The dashed lines delineate the compound nucleant lattice. Lattice dimensions given in angstroms.

Among the nucleant-forming elements listed in Table 1, titanium and, in particular, titanium associated with boron in the master alloy form with a typical composition (Al-5Ti-1B); this is the most effective grain refinement addition in use for aluminum. In the commercial application of grain-refining agents involving titanium and boron, it is well known that an optimum contact time (that is, the holding time necessary after the addition of refining agents to obtain maximum grain refinement) can vary considerably among different master alloy compositions. As shown in Fig. 11, this feature is generally observed to occur where the optimum contact time interval (period A-B) for minimum grain size is followed by contact time intervals that yield large grain sizes during the interval B-C, which is called a fading process.

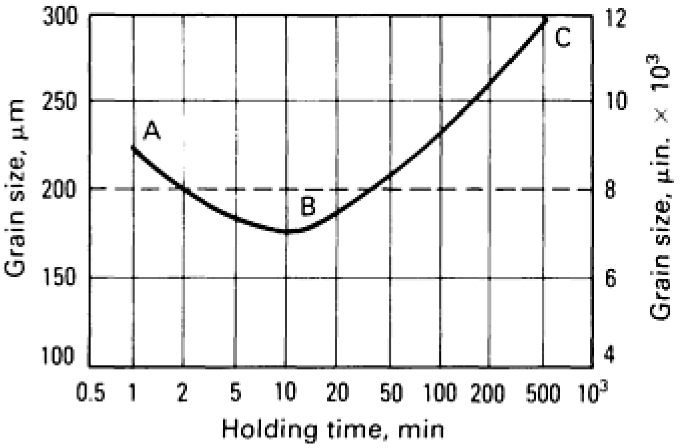

Fig. 11 The influence of holding time after the introduction of a grain-refiner master alloy on the degree of grain refinement. The period A-B represents the contact time, and the period B-C refers to a fading process.

Grain Refinement Models

It is generally viewed that Al_3Ti crystals are mainly responsible for grain refinement at alloy compositions above 0.15% Ti, that is, within the peritectic range. For compositions outside the peritectic range, where the Al_3Ti phase is not stable under equilibrium conditions, there are basically two interpretations of the grain refinement effect: the carbide-boride view and the peritectic reaction theory.

The carbide-boride model suggests that a compound such as AlB_2, TiB_2, or TiC is responsible for the nucleation of aluminum crystals, because the Al_3Ti particles that are introduced into the master alloy are expected to dissolve rapidly. The borides are hexagonal structures, and the carbide is a cubic structure with a relatively close correspondence (Table 1) with the aluminum lattice. Although it is considered that a boride or a carbide is the site of nucleation, the Al_3Ti particles do play a role in the overall grain refinement process. The dissolution of Al_3Ti is required, for example, to provide a constitutional deterrent (that is, excess titanium) to rapid crystal growth. Within this viewpoint, the establishment of an optimum contact time can be related to the initial dissolution of Al_3Ti and to the possible conditioning of the nucleant surface. The subsequent fading reaction is related to the agglomeration and settling of nucleant particles (Ref 15).

Although there is evidence for the stability of boride or carbide particles in aluminum melts and reports of observations of these particles in ingots, other observations have indicated a number of problems in attributing nucleation solely to the action of the boride or carbide particles. For example, a consistent orientation relationship between Al_3Ti and aluminum can be found; however, no consistent relationship between TiB_2 and aluminum has been detected even though the orientation indicated in Table 1 for AlB_2 would be expected to develop for TiB_2 with a lattice disregistry of -5.9 and -5.8%, respectively, in the *a* and *b* directions. In addition, boride particles have often been observed to be located at grain boundaries rather than within grain centers, indicating that the borides were present as insoluble material and inactive particles for nucleation during freezing (Ref 14).

Peritectic Reaction Theory. There is an alternate viewpoint of the nucleation behavior during grain refinement that was originally developed on the basis of a peritectic reaction, but this viewpoint has subsequently evolved into a model with more general scope (Ref 13). Although many types of particles are believed to be active in the nucleation of aluminum crystals at undercoolings less than about 5 °C (9 °F), the presence of Al_3Ti is believed to offer a more active catalyst requiring little or no under-cooling. Thus, Al_3Ti crystals, when present, will predominate in the grain refinement nucleation. For peritectic alloys such as the one illustrated by the solid lines in Fig. 4, it is clear that Al_3Ti can form upon cooling below the liquidus and can promote the formation of aluminum crystals at the peritectic temperature T_p. At alloy compositions below the peritectic range, a grain refinement effect is expected to be reduced by the loss of Al_3Ti particles, which are added externally in master alloy form. Indeed, independent Al_3Ti particles in liquid aluminum that is not saturated with titanium dissolve within several minutes.

On the other hand, boride particles, that is, TiB_2 or $(Al,Ti)B_2$, are observed to be reasonably stable in melts and offer a fine particulate dispersion. To account for the beneficial effect of incorporating boron into the master alloy compositions and also the observation of the interaction between TiB_2 and Al_3Ti, it appears likely that TiB_2 particles may provide an effective substrate for the nucleation of Al_3Ti for compositions spanning the peritectic reaction. During cooling of the melt or holding (that is, the contact time period), the TiB_2 particles will react slowly with liquid aluminum to form an $(Al,Ti)B_2$ solution and to liberate excess titanium locally to provide for the formation of a sheath of Al_3Ti as a coating on the $(Al,Ti)B_2$ particles (Ref 19). In this way, the boride particle is believed to act as a substrate for the formation of Al_3Ti particles at low titanium levels, that is, even in alloys with compositions below the peritectic range. Of course, this process is a transitory one, and with time a full equilibrium will develop and accompany the loss of the Al_3Ti coating as required to account for a fading effect. With this viewpoint, the presence of boride enhancement of grain refinement is attributed to the effect of the boride and TiB_2 in retarding the dissolution of Al_3Ti in the melt, but the actual mechanism for this process may be complex.

Master Alloy Processing

Another important aspect of the grain refinement reaction that has not received much consideration relates to the influence of preparation conditions during master alloy processing and structural differences on the effectiveness of nucleant particles (Ref 19, 20). This feature has taken on new significance with the observation that Al_3Ti particles may appear with different morphologies (Fig. 12) and may exhibit several possible crystallographic orientation relationships with aluminum crystals. The degree of refinement is observed to be dependent on the Al_3Ti crystal morphology.

Essentially, two types of Al_3 Ti crystals are observed to be present: a flake type exposing (001) planes to the melt that forms at high preparation temperatures (>760 °C, or 1400 °F) and a blocky form that tends to form at low temperatures. Each particle morphology is found to differ in nucleating potency.

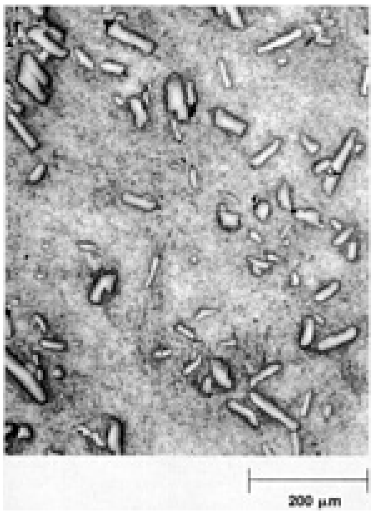

Fig. 12 Photomicrograph of an Al-6Ti master alloy illustrating the range of size and shape of Al_3Ti particles.

The blocklike crystals expose (011) planes to the melt, as indicated in Fig. 13, for a [(011)Al_3Ti P (012) Al] relationship with aluminum. For flake-type crystals, the crystallographic axes of Al_3Ti and aluminum are closely parallel, that is, (001)Al_3Ti P $(00\bar{1})$Al. Although the latter relationship also gives a relatively small disregistry, the (011) Al_3Ti surface as indicated in Fig. 13 is occupied by three successive layers of aluminum atoms, which can be viewed as somewhat distorted (012) aluminum lattice planes. The formation of aluminum crystals on such a surface merely requires a growth (that is, epitaxy) of this existing distorted lattice at little or no undercooling below the peritectic temperature T_p. The (001) Al_3Ti surface, on the other hand, contains titanium atoms so that a simple growth of the existing surface is not sufficient to generate an aluminum crystal, and a lower nucleating potency may be expected and is observed. In addition, the observation of different morphologies and twinning for Al_3Ti crystals may account for the variety of orientation relationships that have been observed between Al_3Ti and aluminum. Other particles, such as TiB_2, TiC, TiN, ZrB_2, and TaB_2, have been examined, but the undercooling required to initiate solidification was minimized when Al_3Ti particles were present.

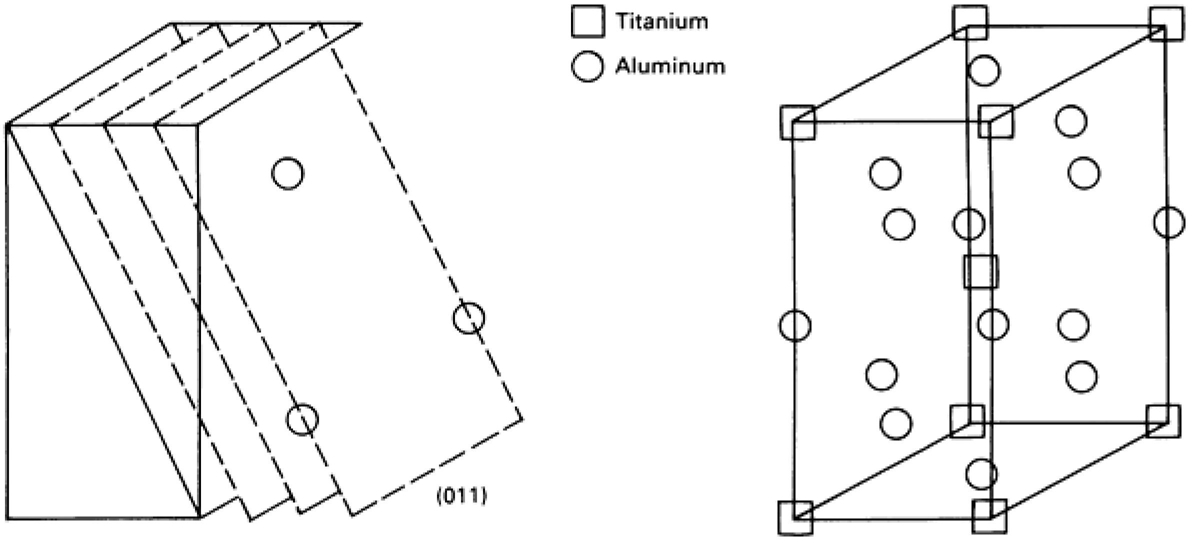

Fig. 13 The Al_3Ti structure and the arrangement of the (011) planes. Three successive (011) planes identified by dashed lines contain only aluminum atoms and offer a low disregistry to the atom arrangement on (012) planes of aluminum.

Thermal Analysis Techniques. Grain-refining characteristics can also be conveniently assessed through thermal analysis techniques. In examining cooling curves after master alloy dilution, three main groups of characteristic curves are often observed, as shown in Fig. 14. The characteristic curve A in Fig. 14 is detected for a high degree of grain refinement and is related to a large number of aluminum crystals that form on surviving Al_3Ti particles at T_p. With continued cooling upon reaching the growth temperature, T_G, the aluminum crystals can grow, consuming the liquid and raising the temperature to the equilibrium liquidus temperature, T_L. This reaction creates a peritectic hump, which is an indication that Al_3Ti crystals are present in the melt. The type A cooling curve in Fig. 14 was detected with blocky Al_3Ti crystals following a short holding time but also with flake-type Al_3Ti after a long contact time of 1 h or more. With a

cooling curve of the type B configuration in Fig. 14, relatively few Al_3Ti crystals remain; therefore, poor grain refinement occurs. A cooling curve of the type C configuration in Fig. 14 represents an intermediate case in which there are a sufficient number of Al_3Ti crystals, but the local titanium concentration is not sufficient to allow for growth at high temperatures, a condition that yields poor grain refinement.

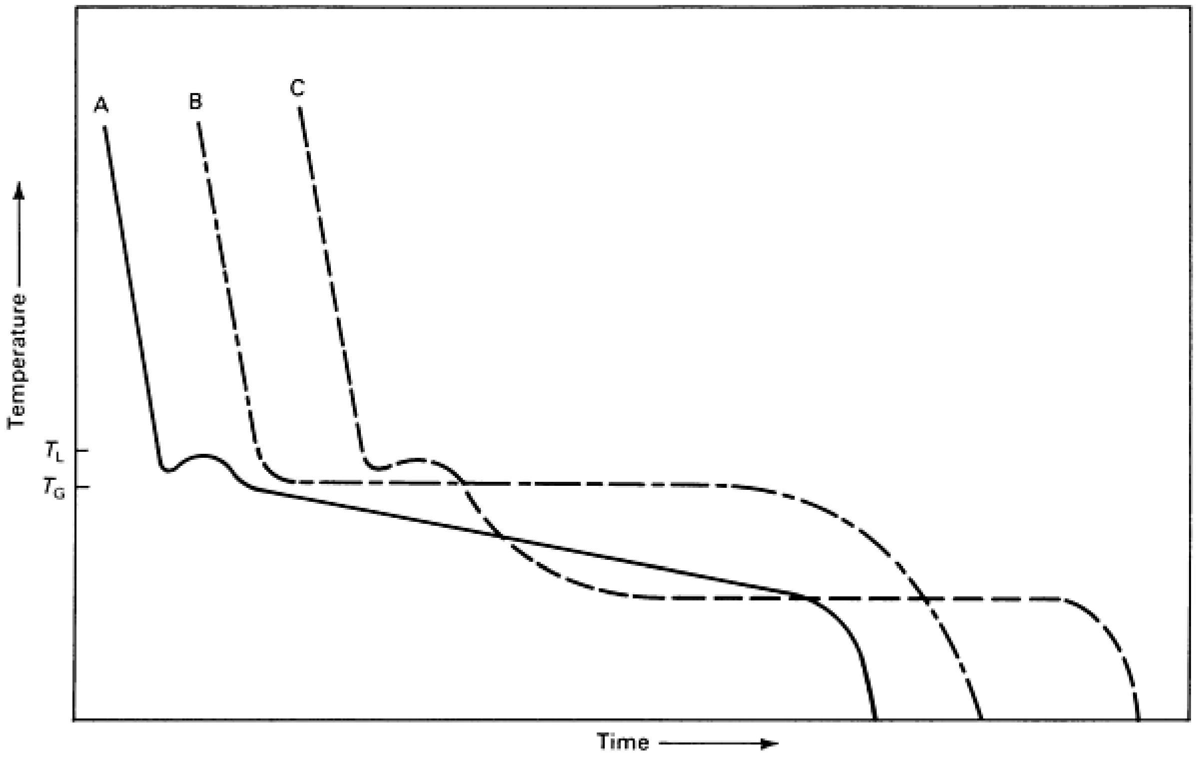

Fig. 14 Representative types of cooling curves for an aluminum melt treated with different master alloys to yield varying levels of grain refinement. A, high degree of grain refinement coincides with Al_3Ti crystals present in melt; B, poor grain refinement due to few Al_3Ti crystals in melt; C, intermediate case in which there are a sufficient number of Al_3Ti crystals but an insufficient local titanium concentration to promote grain refinement. The characteristic peritectic hump for all three curves lies between the growth temperature, T_G, and the equilibrium liquidus temperature, T_L Source: Ref 18.

In addition to these factors, new observations concerning the possible effect of metastable phases produced in Al-Ti and Al-Zr systems on grain refinement have been reported (Ref 4, 5, 28). In aluminum-titanium and aluminum-zirconium alloys cooled at relatively high rates (1 °C/s, or 1.8 °F/s), a reaction has been reported above the peritectic isotherm in which a metastable phase forms and can be associated with existing intermetallic particles, that is, Al_3Ti or Al_3Zr. During holding of the liquid, the metastable phase decomposes, but the time periods involved are of the same order of magnitude as those obtained in grain refinement.

Although the results of recent work represent a significant improvement in the description of grain refinement and in the improved characterization of grain refinement agents and their effectiveness, the overall understanding of the grain refinement of aluminum or other metallic melts by compound particles remains incomplete. Most examinations have focused on the study of one particular particle, but it is clear that in commercial purity alloys several different particles or alloying elements can be present and can interact to obscure the actual nucleant identity. This is sometimes observed in terms of the poisoning of a grain refiner (Ref 23). In addition, the interaction among processing parameters is an unresolved point, but is likely to be significant.

Introduction

CRYSTAL GROWTH AND SOLIDIFICATION in metal castings is largely a function of atomic mobility. Thermal and kinetic factors must be considered when determining whether crystal growth will be inhibited or accelerated. Whether spherical or needle-like in configuration, the metal particles behave differently depending on their location within the composition: in the liquid, at the liquid/solid interface, or in the solid. In addition, metals such as aluminum and copper have only one structure (face-centered cubic, fcc); on the other hand, metals such as iron and cobalt can have different crystal structures at different temperatures (for example, iron can be fcc and body-centered cubic, bcc).

Liquid and Solid State

Atomic Mobility. The solidification of metals results in an enormous and abrupt decrease in atomic mobility. The dynamic viscosity η of pure liquid metals near their melting temperature T_f is comparable to that of water at room temperature, that is, of the order of 10^{-3} Pa · s (10^{-2} P), as shown in both Table 1 and Fig. 1. On the other hand, the following observations can be made:

- In the solid state, metals and alloys have a high tensile strength
- Pure metals resist stresses of the order of 10^4 Pa (1.5 psi) near the melting point
- The decrease in ductility of commercial alloys several hundred degrees below the solidus temperature is due to the presence of liquid films in the segregated zones

Table 1 Physical properties of pure metals relevant to solidification

Property	Iron (δ)	Copper	Aluminum
Dynamic viscosity η of liquid at T_f, 10^{-3} Pa · s	5.03	3.05	1.235
Melting point, T_f, K	1809	1356	933
Enthalpy of fusion per mole, J/mol	13,807	13,263	10,711
Enthalpy of fusion per volume, J/m^3 · 10^9	1.93	1.62	0.95
Heat capacity C_P of liquid at T_f, J/K · m^3 · 10^6	5.74	3.96	2.58
Heat capacity C_P of solid at T_f, J/K · m^3 · 10^6	5.73	3.63	3.0
Thermal conductivity of liquid K_L at T_f, W/m · K	35	166	95
Thermal conductivity of solid K_S at T_f, W/m · K	33	244	210
Thermal diffusivity of liquid α_L at T_f, m^2/s · 10^{-6}	6.1	42	37

Thermal diffusivity of solid α_S at T_f, $m^2/s \cdot 10^{-6}$	5.8	67	70
Density of liquid ρ_L at T_f, g/cm^3	7.024	7.937	2.368
Density of solid ρ_S at T_f, g/cm^3	7.265	8.350	2.548
Solidification shrinkage $(V^{l} - V^{s})/V^{s}$, %	3.55	5.20	7.59
Solid/liquid interfacial tension σ, MJ/m^2	251	237	158
Faceting factor F for the most dense planes	1.78	1.96	2.19
Molar volume of the solid V_m, cm^3/mol	7.69	7.61	10.59
Entropy of fusion per mole ΔS_f, $J/K \cdot mol$	7.63	9.78	11.48

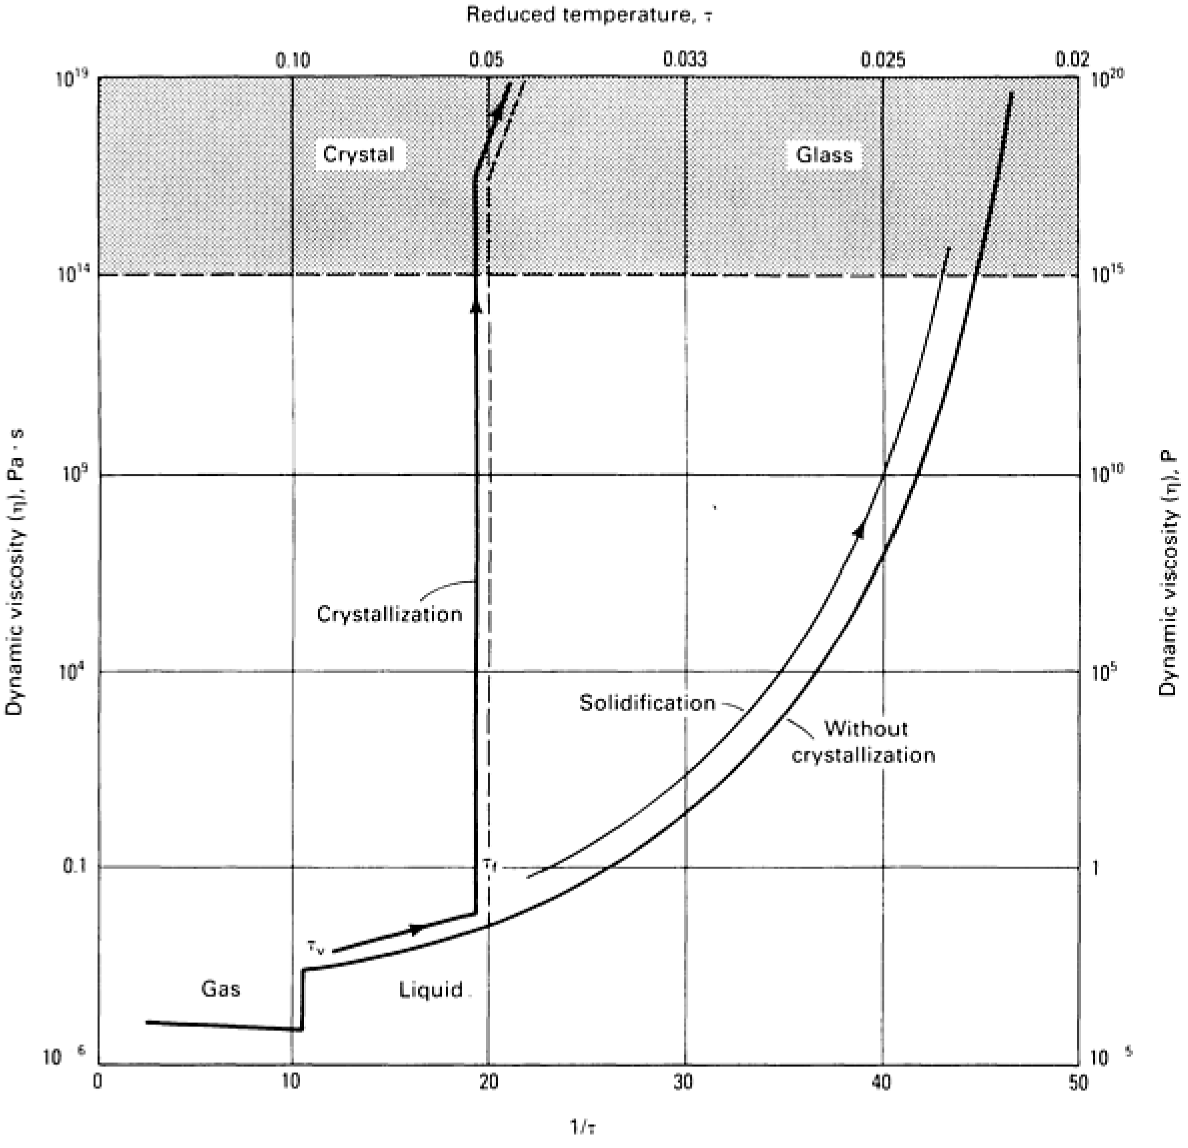

Fig. 1 Dynamic viscosity of metals as a function of reduced temperature $t = R \cdot T/\Delta H_v$, where ΔH_v is the enthalpy of vaporization per mole. The melting point corresponds to t_f. Source: Ref 1

The self-diffusion and chemical diffusion of alloying elements and impurities are much slower in the solid than in the liquid, as shown in Table 2 for both iron- and aluminum-base alloys. In liquid iron for example, diffusion coefficients range from 10^{-9} m^2/s (1.1×10^{-8} ft^2/s) for the slowest solutes to 10^{-7} m^2/s (1.1×10^{-6} ft^2/s) for hydrogen. The diffusion coefficient range between the slowest solutes and hydrogen is larger in ferrite and is maximum in austenite.

Table 2 Physical properties of alloys relevant to solidification

Base metal	**Diffusion coefficient at T_f, m^2/s**				
	Iron			**Aluminum**	
	Liquid	**δ**	**γ[(a)]**	**Liquid**	**Solid**
Self-diffusion	1.4×10^{-8}	2.3×10^{-11}	6.5×10^{-13}	. . .	1.2×10^{-12}
Diffusion of solutes					
Carbon	2.32×10^{-8}	5.72×10^{-9}	5.53×10^{-10}	. . .	. . .
Manganese	3.83×10^{-9}	2.57×10^{-11}	5.02×10^{-13}	. . .	. . .
Nickel	5.47×10^{-9}	2.65×10^{-11}	2.47×10^{-13}	. . .	. . .
Copper	. . .	. . .	. . .	4.9×10^{-9}	1.95×10^{-12}
Silicon	. . .	. . .	. . .	4×10^{-9}	5×10^{-12}

Dilute alloys	**Partition ratio *k* and liquidus slope m_L**			
	***k* in δ iron**	**$-m_L$, K for δ iron**	***k***	**$-m_L$, K**
Hydrogen	0.3	70,700[(a)]	. . .	. . .
Carbon	0.11	8000	. . .	. . .
Manganese	0.73	500	0.7-0.9	100
Silicon	0.77	1300	0.13	600

Copper	0.70	. . .	0.14	260

Interface	Interfacial tension, σ, of graphite/iron interface[b], MJ/m^2	
	Without $\underline{O}$ and $\underline{S}$	With $\underline{O}$ and $\underline{S}$
Basal plane	1460	1270
Prismatic plane	1720	845

(a) Extrapolated, not measured, values to compare magnitude.

(b) Change of partial molar volume of carbon during solution of graphite: 70%

Heat release during solidification is large--approximately 270 MJ/tonne (116 Btu/lb) for steel. The higher the melting point of the metal, the larger the latent heat of fusion (Table 1). Therefore, solidification processing is initially a matter of extracting large quantities of heat quickly.

Table 1 also lists heat capacities C_P, thermal conductivities K, and thermal diffusivities α in solid (α_S) and liquid (α_L) at the melting temperature for iron, aluminum, and copper. Even in the liquid, thermal diffusivities are more than 100 times larger than coefficients of chemical diffusion. Moreover, relative differences in thermal diffusivity between liquid and solid are small compared to the related differences in chemical diffusion coefficients.

Solidification Shrinkage. Most metals shrink when they solidify. Solidification shrinkage ranges from 3 to 8% for pure metals (Table 1). It may result in the formation of voids (microporosity and shrinkage) during solidification. Thermal contraction of the solid during subsequent cooling may increase the risk of shrinkage if care is not exercised in casting of the metal.

Several commercial foundry alloys, based on simple eutectic alloys, form nonmetallic phases during solidification that are atomically less dense than the melt--for example, graphite in iron-carbon alloys or silicon in aluminum-silicon alloys. In the case of gray cast iron, the precipitation of austenite from the melt is associated with shrinkage, while the growth of graphite from the same melt is associated with volume expansion (Table 2). The sign of the resultant volume change is uncertain; the alloy may shrink or expand upon solidification, depending on the composition of the melt.

Solubility. When the heterogeneous thermodynamic equilibrium between liquid and solid is achieved, most crystalline solid solutions contain a smaller amount of each solute than the related liquid solutions. This difference in composition, combined with slow solid-state diffusion, results in various segregation patterns in cast alloys. Table 2 lists the values of the equilibrium partition coefficient (or ratio) k, which is defined as follows:

$$k = \frac{C_S^*}{C_L^*} \quad \textbf{(Eq 1)}$$

where C^*_S and C^*_L are the solid and liquid concentrations, respectively, in mutual equilibrium across a plane solid/liquid interface. Tabulated values are valid only for very dilute binary alloys.

Adding solutes in a metallic melt usually decreases the liquidus temperature T_L, that is, the temperature at which the alloy begins to solidify. Table 2 lists values of the liquidus slope m_L for some very dilute iron- and aluminum-base alloys. The liquidus slope is defined as follows:

$$m_L = \frac{dT_L}{dC_L}$$ **(Eq 2)**

Solid/Liquid Interface

The first models to describe the solid/liquid interface and its motion at the atomic scale were strongly influenced by the physical models that successfully describe the behavior of the crystal/vapor surfaces. Crystal growth from the vapor can proceed either by two-dimensional nucleation or by lateral motion in steps of atomic height around screw dislocations emerging at the surface. This is because these surfaces are atomically sharp. In this case, the average thermal energy available for the surface atoms to escape from the crystal (that is, $R \cdot T$, where R is the gas constant) is too small compared to the difference in cohesive energy between crystal and vapor (that is, the enthalpy of sublimation per mole ΔH_s). Physicists relate the sharpness of the crystal/vapor surfaces to the high value of the ratio $\Delta H_s/R \cdot T$ (Ref 2).

The solid/liquid interface is a region between two condensed phases in which interatomic cohesive energies are comparable. Interactions between solid and liquid atoms across the interface must be taken into account to describe this interface properly at the atomic scale; enthalpy of fusion is not a proper quantity for this condition. Physicists successfully correlate the sharpness of the solid/liquid interfaces of pure substances to a faceting factor *F,* which is defined as follows (Ref 3):

$$F = \frac{Z^*}{1-Z^*} . \frac{A_m s}{R.T_f}$$ **(Eq 3)**

where z^* is the ratio between the number of near-neighbor atoms in the plane of the interface and the total number of near-neighbor atoms in the bulk (z^* = 0.5 for dense planes of fcc crystals), A_m is the area occupied by 1 mol at the interface, σ is the solid/liquid interfacial tension, and T_f is the melting temperature. Pure metals are expected to grow from their own melts with a diffuse interface as opposed to a sharp interface, because their faceting factors are approximately equal to the critical value of 2 (Table 1).

Interface Equilibrium. The solid/liquid interfacial tension can be considered excess energy associated with any area of the solid/liquid interface. It causes the change in equilibrium melting point, often called Gibbs-Thomson undercooling, when the interface is curved. For pure substances, this curvature undercooling ΔT_K is given by:

$$\Delta T_K = T_f - Tf_k = \Gamma \cdot K$$ **(Eq 4)**

where Tf_k is the equilibrium temperature between liquid and solid across an interface whose curvature is K and where Γ is the Gibbs-Thomson coefficient. The curvature can be expressed as:

$$k = \frac{1}{r_1} + \frac{1}{r_2}$$ **(Eq 5)**

where r_1 and r_2 are the principal radii of curvature; K is defined such that a positive undercooling is associated with a portion of the solid/liquid interface that is convex toward the liquid.

The Gibbs-Thomson coefficient is given by:

$$\Gamma = \frac{s . V_m}{\Delta S_f}$$ **(Eq 6)**

where V_m is the molar volume of the solid and ΔS_f is the entropy of fusion per mole.

For most metals, Γ is of the order of 10^{-7} K · m. Therefore, the curvature undercooling might often appear negligible; it is of the order of 0.05 K for a spherical portion of the interface where the radius of curvature is equal to 10 μm. However, this undercooling is very important for describing the nucleation stage and the morphological stability of growth shapes (dendritic and eutectic structures). Table 1 lists σ for pure iron, aluminum, and copper; it can be assumed to be isotropic for estimating the undercooling. Table 1 also lists T_f, V_m, and ΔS_f.

Equation 4 can also be used to estimate the effect of the curvature on the liquidus temperature of an alloy with a given composition. Conversely, it can be used to calculate the change in equilibrium composition of both liquid and solid solutions in mutual contact at a fixed temperature across a curved interface. The changes in liquid and solid solubilities are then given by:

$$\Delta C_{L.K} = C_{L(TK)} - C_{L(T,k=x)} = \frac{K\Gamma}{m_L} \quad \textbf{(Eq 7a)}$$

$$\Delta C_{S.K} = C_{S(T,K)} - C_{S(T,k=x)} = \frac{K\Gamma}{m_L} \quad \textbf{(Eq 7b)}$$

where m_S is the solidus slope.

Some nonmetallic eutectic phases, such as graphite or silicon in foundry alloys, exhibit strong anisotropies of interfacial tension in contact with the melted alloy. In this case, surface-active solutes or impurities can significantly modify the interfacial tensions and their degree of anisotropy (Table 2) (Ref 4).

Interface Kinetics. Solidification can be described as a succession of atomic events that occur in series; it includes heterogeneous chemical reactions at the interface. At a diffuse interface, as for pure metals, liquid atoms can become solid atoms at almost every lattice site. The interface then moves more or less continuously, and the growth is said to be continuous. The kinetics of continuous growth have been described by using the rate theory of classical chemistry (Ref 5). This theory leads to the following estimate for the kinetic undercooling ΔT_k in the case of pure substances:

$$\Delta T_k = T_{f_k} - T^* = \left(\frac{a}{D_L}\right)\left(\frac{R.T_f}{\Delta S_f}\right)v \quad \textbf{(Eq 8)}$$

where Tf_K is the equilibrium temperature defined by Eq 4, T^* is the actual temperature of the moving interface, D_L is the liquid diffusivity, a is the atomic distance between the crystallographic planes parallel to the interface, and v is the velocity of the interface.

For most metals, the proportionality coefficient between the kinetic undercooling and the velocity is of the order of 1 K · s/cm, according to Eq 8. For most usual solidification conditions, velocities do not exceed the order of 10^{-4} m/s (3.3×10^{-4} ft/s) or 0.36 m/h (1.18 ft/h), and the kinetic undercooling does not exceed 10^{-2} K. Therefore, unlike other major contributions, kinetic undercooling is often neglected. This simplification is probably invalid in the case of rapid solidification, even for pure metals.

Kinetic undercooling might be much higher than that predicted by Eq 8 in the case of crystals growing from a dilute solution such that the interface is atomically sharp. This might occur for graphite growing from iron melts or for silicon growing from aluminum-silicon melts.

Although the mean value of the kinetic undercooling is often negligible, the anisotropy of the faceting factor predicted by Eq 3 and the related anisotropy of the kinetics of the growth of metallic crystals from the melt are observable. For a given driving force, the growth velocity of the interfaces parallel to atomically dense planes is smaller than any other growth velocity. For an fcc crystal, for example, the dense {111} planes will tend to spread laterally more or less rapidly and form pyramids that have fourfold symmetry axes, that is, <100> axes. The vertex of each pyramid will then move along a

<100> axis during growth. Therefore, the well-known fact that dendrites of cubic metals exhibit <100> axes and branches is probably related to their slight growth anisotropies.

Departure from interface equilibrium during growth results not only in a kinetic undercooling but also a dependence of the partition coefficient on velocity. The following functional form has been proposed to describe the effect of velocity on k_v where $k < 1$ (Ref 6):

$$K_v = \frac{C_S^*}{C_L^*} = \frac{k + (a_o/D_L).v}{1 + (a_o/D_L).v} \qquad \textbf{(Eq 9)}$$

where a_o is a length scale related to the interatomic distance; its value is estimated to be 0.5 to 5.0 nm (5 to 50 Å). Figure 2 shows how the partition coefficient changes monotonically from its equilibrium value to unity as growth velocity increases according to Eq 9.

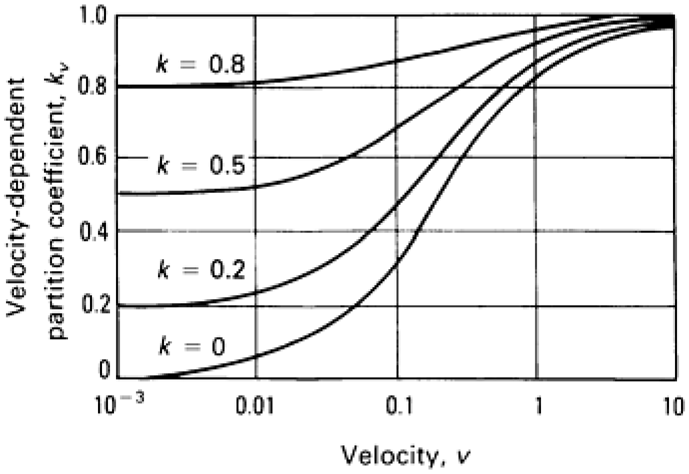

Fig. 2 Dependence of k_v on v according to Eq 9 when a_o = 5 nm and D_L = 10^{-9} m^2/s.

Mass and Heat Transport

Basic Phenomena. Solidification typically involves heat and mass transport phenomena on the micro- and macroscopic levels. Because this Section is devoted to the formation of microstructures in cast metals, this discussion will focus on the problems of microscopic heat and mass transfer near the interface.

From the viewpoint of mass transfer, it is useful to distinguish among the zones of plane front solidification illustrated in Fig. 3(a) and 3(b):

- The solid, where only diffusion is effective, although it is usually very slow
- The interface, where heterogeneous chemical reactions occur
- A boundary layer of thickness δ_i in the liquid, where diffusion is the only mechanism effective for solute *i* to move perpendicular to the interface
- The bulk liquid, where convection is also effective

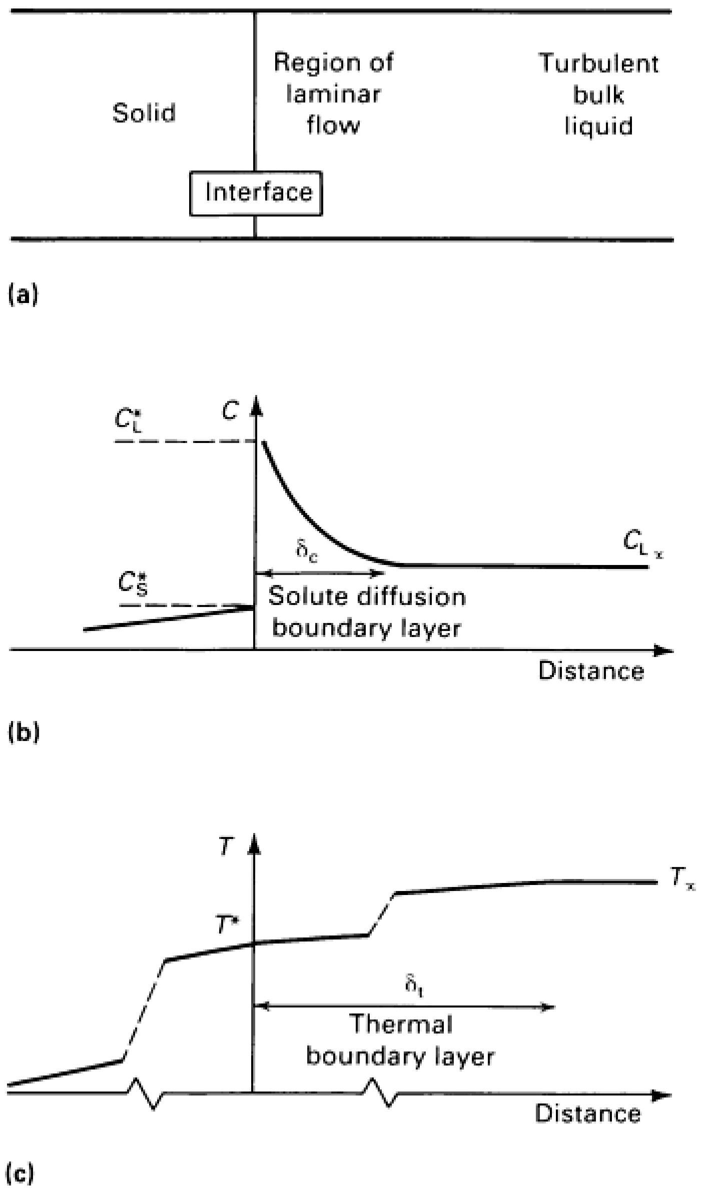

Fig. 3 Constrained growth during plane front solidification (a) and schematic profiles of solute concentration (b) and temperature (c)

For metallic alloys, solid and liquid can usually be assumed to be in mutual equilibrium locally across the interface, except for rapid solidification (Fig. 1 and 2). Therefore, for a given interface temperature, the partition of solute between liquid and solid will be calculated by taking into account the equilibrium phase diagram and the curvature effect (Eq. 7a and 7b).

In the case of plane front solidification, the thickness of the diffusion boundary layer, when controlled by turbulent convection, can be estimated as follows (in SI units):

$$d_i = 5.6\ x\ 10^{-3}.L^{0.1}.\left(\frac{h}{r_L}\right)^{0.57}.D_{Li}^{0.33}U^{-0.9} \qquad \textbf{(Eq 10)}$$

where L is a characteristic length for the convective flow parallel to the interface, η is the dynamic viscosity of liquid, ρ_L is the density of liquid, and U is the mean liquid velocity parallel to the interface.

When the thickness δ_i is large enough, the solute builds up ahead of the interface (if $k < 1$), while a uniform level Ci_∞ of the solute exists at a sufficiently large distance from the interface. The thickness of the region where solute i is built up is scaled by the characteristic diffusion length $l_i = D_{L,i}/v$ when smaller than δ_i.

From the viewpoint of heat transfer, one can discern three separate zones; the solid, the thermal boundary layer in the liquid, and the bulk liquid. The thickness of the thermal boundary layer δ_t can be calculated as for δ_i by substituting α_L for D_L in Eq 10. Because thermal diffusivities $\alpha$are much larger than chemical diffusion coefficients for metals, the thermal boundary layer is always thicker (by a factor of 10) than the diffusion boundary layer.

When the thickness δ_t is large enough, the thickness of the region close to the interface where the release of latent heat is detectable can be measured by the characteristic conduction length $l_t = \alpha/v$. Then, because of the large difference in orders of magnitude between D_L, and α_L, the temperature profile approaches linear characteristics (Fig. 3c), while the composition profile approaches an exponential curve (Fig. 3b) when both are plotted against the distance from the interface.

Regardless of the shape of the interface, the rejection of the solute always triggers changes in the liquid composition and the interface temperature. Therefore, it is useful to define the dimensionless solutal supersaturation at the interface Ω_c as the ratio of the change in liquid concentration at the interface C^*_L - CL_∞ to the equilibrium concentration difference C^*_L - C^*_S at the temperature of the interface (Ref 7):

$$\Omega_c = \frac{C_L^* - C_{Lx}}{C_L^* - C_S^*} \qquad \textbf{(Eq 11)}$$

It is instructive to compare supersaturations in various growth conditions.

Plane Front Solidification. In terms of heat transfer, plane front solidification requires a high positive temperature gradient. The case in which heat flow is opposite to the direction of growth is often referred to as constrained growth.

When the bulk liquid is at rest, the thickness of the diffusion boundary layer is infinite. Moreover, when a stationary state is achieved, the solid formed approaches the composition of the liquid far ahead of the interface. Then, supersaturation simply equals unity:

$$\Omega_c = 1 \qquad \textbf{(Eq 12)}$$

When the bulk liquid is stirred, the thickness of the diffusion boundary layer δ_c can be of the order of the diffusion length, l_c (Fig. 3). In this case, the solute content of the solid formed is lower than that of bulk liquid. It is then useful to define an effective partition coefficient k_{ef}:

$$k_{ef} = \frac{C_S^*}{C_{Lx}} \qquad \textbf{(Eq 13)}$$

The supersaturation becomes:

$$\Omega_c = \frac{1-(k/k_{ef})}{1-k} \quad \textbf{(Eq 14)}$$

When a quasi-stationary state is achieved, the effective partition coefficient is related to the solidification and stirring conditions (Ref 8):

$$k_{ef} = \frac{k}{k+(1-k).\exp(-d_c/l_c)} \quad \textbf{(Eq 15)}$$

It changes monotonically from the equilibrium value k to unity as the ratio $\sigma_c l_c$ (or the product $v \cdot \delta_c$) increases from 0 to infinity. At the same time, supersaturation increases from 0 to unity. Therefore, stirring can greatly decrease supersaturation by reducing δ_c, and it increases segregation in the solid.

Growth of a Sphere. Figure 4 shows a schematic illustration of a crystal growing from a melt. This situation, often referred to as free growth, requires the crystal to be hotter than the surrounding liquid and the radial heat flux to have the same direction as that of the growth.

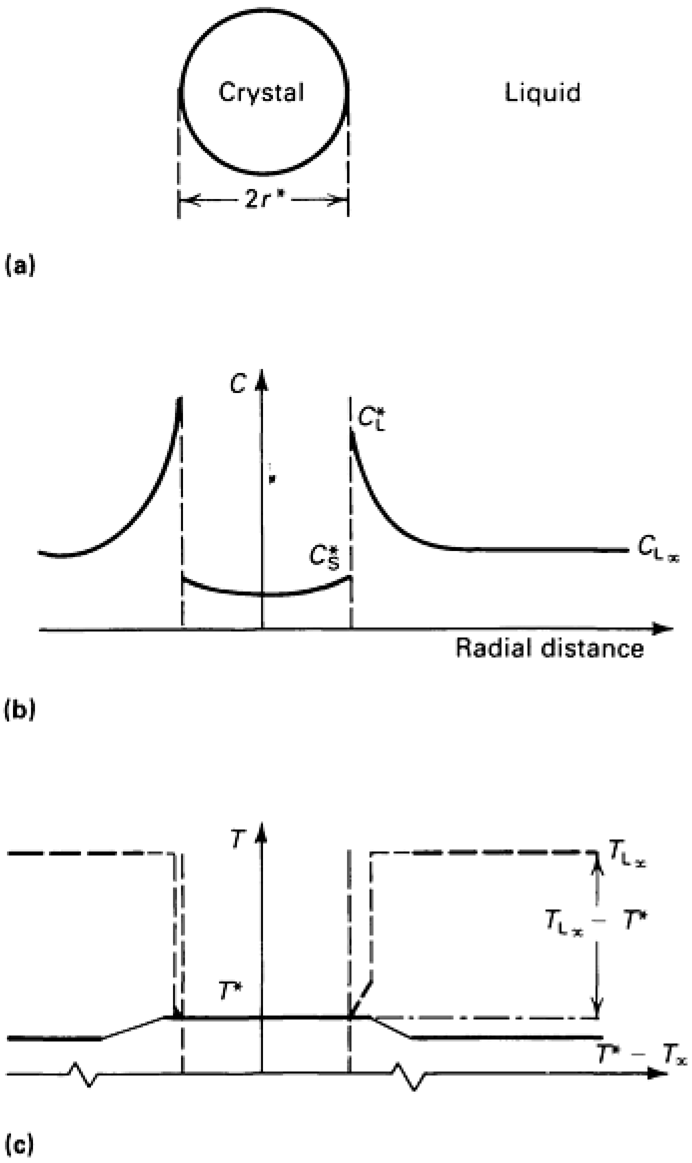

Fig. 4 Free growth of a spherical crystal (a) and schematic profiles of solute concentration (b) and both liquidus

temperature T_L (dashed line) and actual temperature T (full line) (c)

If a quasi-stationary growth could be achieved under such conditions, solute mass transfer by liquid diffusion would only impose the following supersaturation:

$$\Omega_c = 2 \cdot P_c \qquad \textbf{(Eq 16)}$$

where P_c is the solute Péclet number associated with the spherical crystal of radius r^*:

$$P_c = \frac{r^* . dr^* / dt}{2 . D_L} \qquad \textbf{(Eq 17)}$$

Moreover, heat balance around a crystal that grows quasi-steadily makes the Péclet number P proportional to the actual undercooling of the bulk liquid TL_∞ - $T\infty$ provided (1 - k) · (T_f · $T\infty$) is not too small:

$$P_c ; \frac{1}{2.(1-k)} . \frac{T_{Lx} - T_\infty}{T_f - T_\infty} \qquad \textbf{(Eq 18)}$$

where TL_∞ is the liquidus temperature related to the bulk liquid concentration CL_∞, and $T\infty$ is the actual temperature of the bulk liquid. Thus, quasi-stationary growth of a spherical crystal, if achievable, should proceed with a constant solute supersaturation that should be proportional to the actual undercooling of the bulk liquid.

Growth of a Needle. The situations described previously are either difficult to achieve or transient. Plane front solidification is possible only for low imposed velocities, and the nondendritic growth of spherical crystals is possible only for low undercoolings and small radii. Otherwise, the interface will tend to form needles that are often described as paraboloids of revolution (Fig. 5).

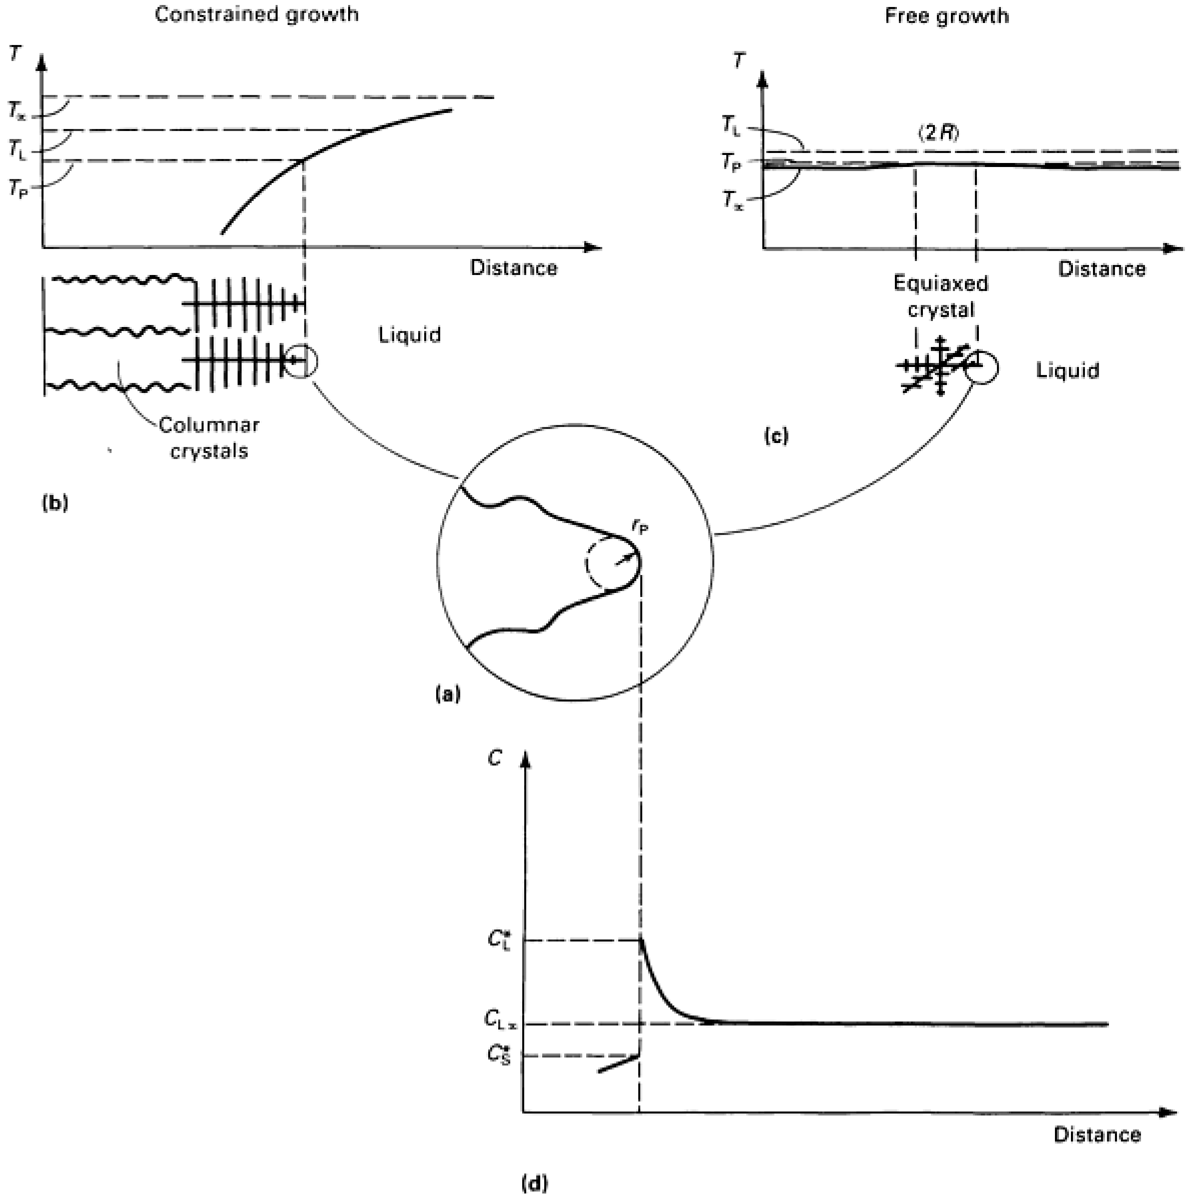

Fig. 5 Growth of a needle (a) and temperature profiles of constrained growth (b) and free growth (c). A profile of solute concentration in both cases is shown in (d).

The mathematical solution of the diffusion problem for a steady-state growing paraboloid was derived by Ivantsov, who deduced the following relationship among supersaturation, the paraboloid tip radius r_P, and the growth velocity (Ref 9):

$$\Omega_c = I(P_c) \qquad \textbf{(Eq 19a)}$$

where $I(P) = P \cdot \exp(P) \cdot E_1(P)$ is the Ivantsov function, $E_1(P) = \int (e^{-u}/u)du$ is the exponential integral function, and $P_c = v \cdot r_P/2D_L$ is the Péclet number associated with the moving tip of the paraboloid.

When simple analytical expressions are needed, the following estimate is useful in the range $P_c > 0.1$ (Fig. 6) (Ref 10):

$$\Omega_c \;;\; \frac{2.P_c}{2.P_c+1} = I_2 \qquad \textbf{(Eq 19b)}$$

For a given alloy composition and for a given growth velocity, the smaller the tip radius, the smaller the solute supersaturation at the tip of the needle. The needle can be either hotter or colder than its liquid surroundings depending on whether the growth is free or constrained (Fig. 5).

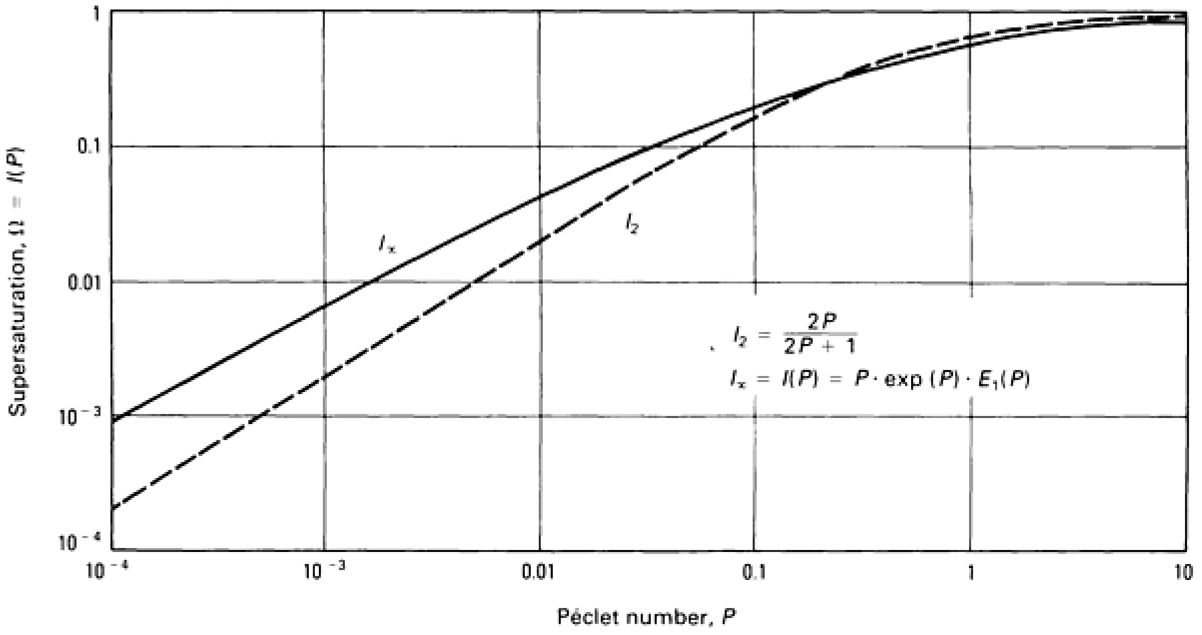

Fig. 6 Analytical approximation I_2 for $\Omega = I(P)$ according to Eq 19b. $I\infty$ is the exact solution. Source: Ref 7

Solidification of Single-Phase Alloys

R. Trivedi, Iowa State University; W. Kurz, Professor, Swiss Federal Institute of Technology, Switzerland

Introduction

The solidification process by which a liquid metal freezes in a mold plays a critical role in determining the properties of the as-cast alloy. Even when the final object is obtained by the mechanical forming of ingots, the solidification structures of ingots often influence the properties of the object. The influence of the solidification process on properties arises primarily because of the following effects:

- The initial uniform composition in liquid becomes nonuniform as the liquid transforms to solid
- Different solidification conditions give rise to different microstructures of the solid
- Many casting defects, such as porosity and shrinkage, depend on the manner in which the alloy is solidified in a mold

Two important factors that control solidification microstructures are the composition of the alloy and the heat flow conditions in the mold. These two factors will be described first, and their influence on the microstructure and the accompanying solute segregation profiles will then be discussed in this section. The solidification structures of ferrous, nonferrous, and superalloy single-crystal single-phase alloys are discussed in the other articles in this Section.

Alloy Composition

An alloy consists of a base metal to which other elements are added to give the desired properties. In this discussion, only binary alloys that solidify into a single-phase structure will be considered. When an element is added to the base metal, it significantly alters the solidification process. A pure metal has a specific melting point T_m, while an alloy freezes over a range of temperatures. This freezing range is generally represented by a phase diagram, as shown in Fig. 1. The liquidus line represents the temperature at which the liquid alloy begins to freeze, and the freezing process is complete when the solidus temperature is reached, if the solidification occurs close to equilibrium conditions or below the solidus under nonequilibrium conditions.

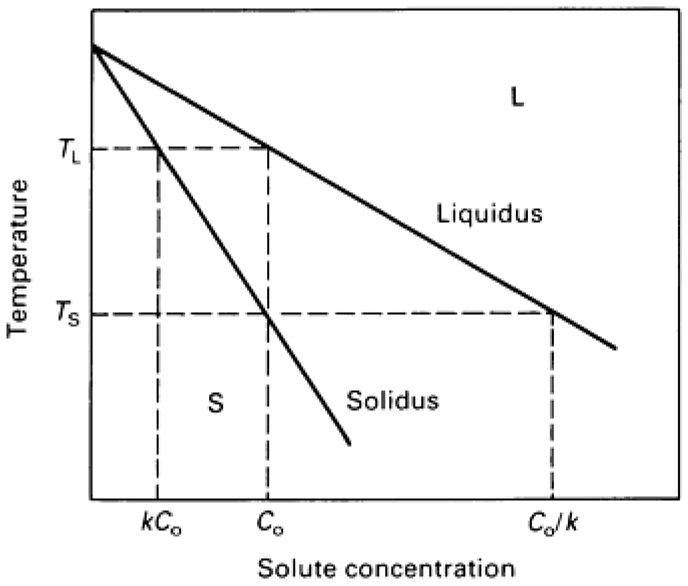

Fig. 1 A single-phase region of a phase diagram showing the liquidus and the solidus lines

When an alloy of uniform liquid composition C_o is cooled, it begins to solidify when the temperature of the liquid reaches the liquidus temperature T_L, if nucleation occurs readily. The composition of the solid that forms at T_L will be different from the composition of the liquid, and it is given by the composition on the solidus line at temperature T_L, as shown in Fig. 1. The ratio of the solid to liquid composition at a given temperature is called the solute distribution coefficient *k*. For dilute solutions, the solidus and the liquidus lines are generally assumed to be straight lines in which case *k* is a constant that does not depend on temperature. Figure 1 shows a phase diagram in which $k < 1$.

The first solid that forms at temperature T_L will have a composition kC_o, which is lower than the liquid composition C_o. Thus, the excess solute rejected by the solid will give rise to a solute-rich liquid layer at the interface. As the alloy is cooled further, the liquid composition increases. This increase in liquid composition, along with the lowering of temperature, gives rise to solute segregation patterns in the solid if the diffusion of solute in the solid is not very rapid (Ref 1).

The buildup of solute in liquid requires diffusion of solute in liquid for further growth. For efficient distribution of the solute in liquid, the interface may change its shape. Thus, the actual solute segregation pattern is dictated by the shape of the interface. In addition to the solute transfer, the interface shape is governed by the effective removal of the latent heat of fusion. This heat flow problem will be described below.

Heat Flow Conditions

The thermal field in a casting is very important in determining the microstructure of the cast alloy. Two distinctly different heat flow conditions may exist in a mold.

In the first case, the temperature gradients in the liquid and the solid are positive such that the latent heat generated at the interface is dissipated through the solid. Such a temperature field gives rise to directional solidification and results in the columnar zone in a casting.

In the second case, an equiaxed zone exists if the liquid surrounding the solid is undercooled so that a negative temperature gradient is present in the liquid at the solid/liquid interface. In this case, the latent heat of fusion is dissipated through the liquid. Such a thermal condition is generally present at the center of the mold.

A positive temperature gradient in the liquid at the interface gives rise to a planar solid/liquid interface for pure metals. However, for alloys, the shape of the interface is dictated by the relative magnitudes of the interface velocity and the temperature gradients in the solid and liquid at the interface. For given temperature gradients and composition, four different interface morphologies can exist, depending on the velocity (Fig. 2). Below some critical velocity v_{cr}, a planar solid/liquid interface will be present. However, above v_{cr}, the planar interface becomes unstable and forms a cellular, a cellular dendritic, or a dendritic interface. For the heat flow condition in which the solid grows in an undercooled melt, a dendritic structure is present, as shown in Fig. 3. Such equiaxed dendrites form for pure metals as well as for alloys.

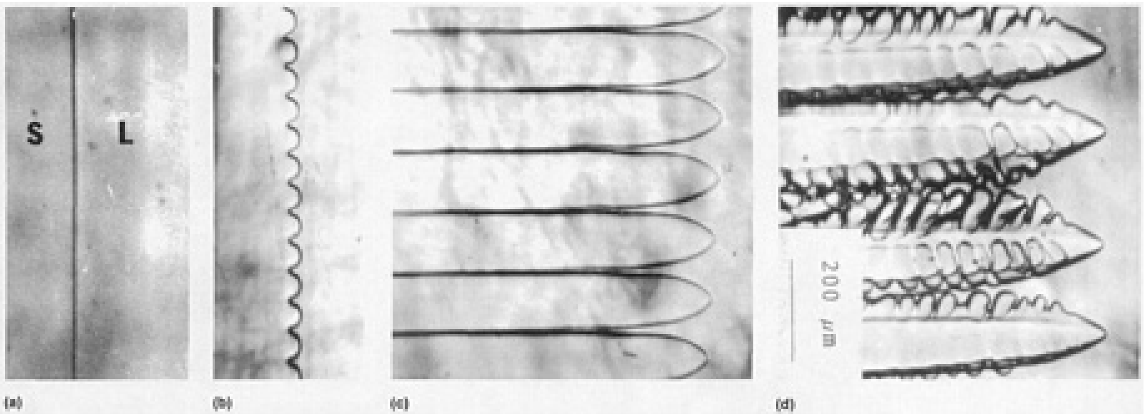

Fig. 2 Effect of increasing growth rate on the shape of the solid/liquid interface in a transparent organic system, pivalic acid-0.076 wt% ethanol, solidified directionally at$G$ = 2.98 K/mm (75.7 K/in.). (a) v = 0.2 μm/s (8 μin./s). (b) v = 1.0 μm/s (40 μin./s). (c) v = 3.0 μm/s (120 μin./s). (d) v = 7.0 μm/s (280 μin./s)

Interface Velocity Below Critical Velocity

Planar interface growth occurs only under directional solidification conditions and, for alloys, only under low growth rate or high-temperature gradient conditions. To describe quantitatively the condition under which a planar

interface growth can occur, consider an interface that is moving at a constant velocity *v*, with heat flowing from the liquid to the solid under temperature gradients G_L and G_S in liquid and solid, respectively, at the interface. Under steady-state growth conditions, the interface temperature corresponds to the solidus temperature T_S in Fig. 1. At this temperature, the interface composition in liquid is C_o/k, which is larger (for $k < 1$) than the liquid composition C_o far from the interface so that a solute-rich layer exists in the liquid ahead of the interface (Fig. 4). This liquid composition profile gives rise to a variation in the liquidus temperature with distance, as indicated by T_f in Fig. 4. If the actual liquid temperature lies below the liquidus profile, a region of supercooled liquid is present ahead of the interface. This supercooled region is indicated in Fig. 4.

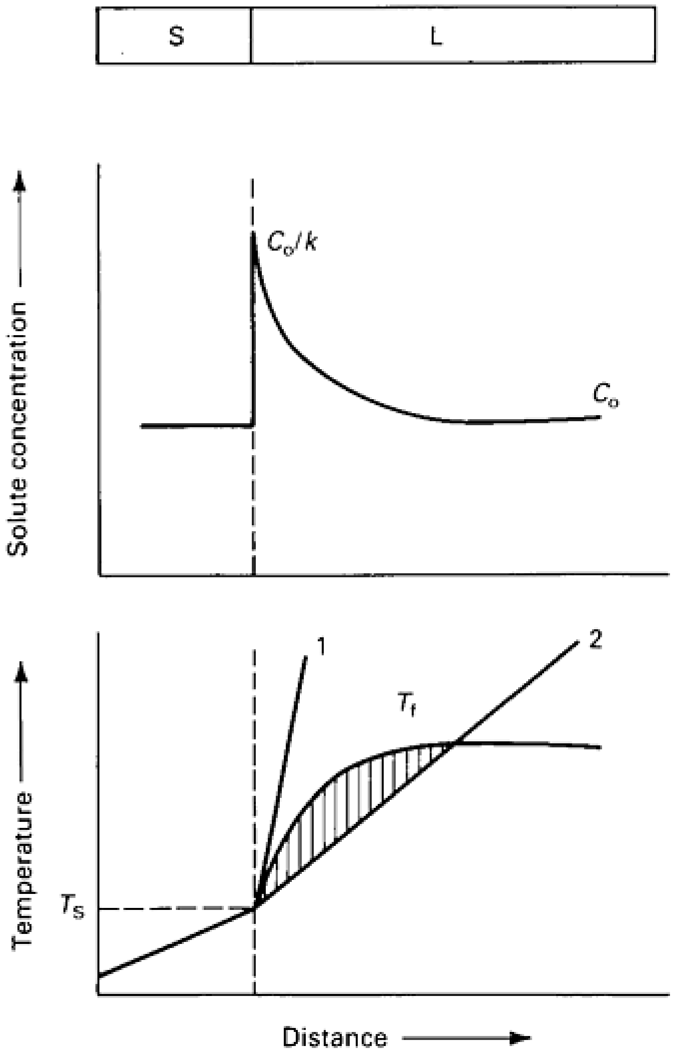

Fig. 4 Constitutional supercooling diagram. The solute concentration profile in the liquid gives rise to the variation in the equilibrium freezing temperature T_f of liquid near the interface. The actual temperature in liquid is given by line 1, and the slope of T_f at the interface is given by line 2. A supercooled liquid exists in the shaded region.

The stability of a planar interface can be determined by examining whether any small bump on the interface will grow or decay. If the supercooling ahead of the interface increases with distance, then any small bump will see a larger supercooling and may grow faster, which will make the planar interface unstable. To avoid supercooling ahead of the interface, the actual temperature gradient in the liquid (line 2, Fig. 4) must be equal to or larger than the gradient of the liquidus profile at the interface (line 1, Fig. 4). This condition for the planar interface stability, known as the constitutional supercooling criterion (Ref 2), is given by:

$$G_L \geq \frac{v\Delta T_o}{D} \qquad \textbf{(Eq 1)}$$

where D is the diffusion coefficient of solute in liquid and ΔT_o is the freezing range of the alloy, that is, $\Delta T_o = T_L - T_S$ in Fig. 1.

The above constitutional supercooling criterion does not take into account the effect of the temperature gradient in the solid. It also neglects the effect of interfacial energy, which may be significant because the formation of a bump is accompanied by an increase in the interfacial area. A more detailed model of the planar interface stability is given by a linear stability analysis (Ref 3). In such a model, a planar interface is perturbed infinitesimally, as shown in Fig. 5, and the change in amplitude of the perturbation with time is examined. If the amplitude decreases with time, the planar interface is stable. Thus, for the planar interface stability, the velocity at point A must be smaller than the velocity at point B. Such an analysis shows that a planar interface will be stable below a critical velocity v_{cr} and above a certain velocity v_a, where v_a, is known as the absolute velocity for the planar interface stability.

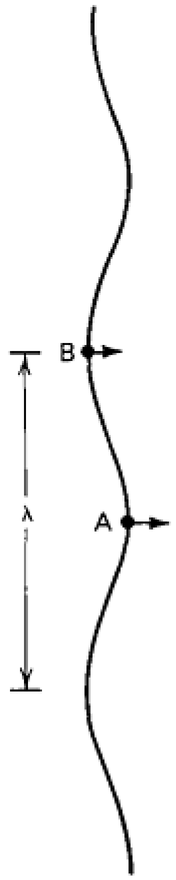

Fig. 5 Perturbed shape of the interface with wavelength λ. The linear stability analysis determines the condition when the velocity of point A is less than that of point B.

The velocity v_a is given by:

$$v_a = \frac{D\Delta T_o}{\Gamma k} \qquad \textbf{(Eq 2)}$$

where $\Gamma = \gamma/\Delta S$ is the capillarity constant in which γ is the interfacial energy and ΔS is the entropy of fusion per unit volume. For typical metallic systems with $D \approx 10^{-9}$ m²/s, $\Delta T_o = 5$ K, $\Gamma = 10^{-7}$ K · m, and $k = 0.2$, one obtains $v_a = 0.25$ m/s. This velocity is large, and it can be obtained by the laser or electron beam scanning technique (Ref 4). In casting, the

velocity is significantly smaller than v_a, so that the important planar interface stability criterion of interest is $v < v_{cr}$. The linear stability analysis gives v_{cr} as:

$$\mathrm{v}_{cr} = \frac{G.D}{\Delta T_o} + f(\Gamma, G, \Delta T_o, k) \quad \textbf{(Eq 3)}$$

The second term on the right-hand side of Eq 3 is generally less than 10% of the first term, so that the planar interface growth condition can be approximated as:

$$v < \frac{G.D}{\Delta T_o} \quad \textbf{(Eq 4)}$$

where G is the conductivity-weighted average temperature gradient at the interface:

$$\mathrm{G} = \frac{\mathrm{K_L}.G_\mathrm{L} + \mathrm{K_S}.G_\mathrm{S}}{\mathrm{K_L} + \mathrm{K_S}} \quad \textbf{(Eq 5)}$$

where K_S and K_L are the thermal conductivities of solid and liquid, respectively.

This stability criterion is similar to the constitutional supercooling criterion except that the proper temperature gradient is G rather than G_L. Under most casting conditions, G_L is very small compared to G_S. In addition, for metallic systems, $K_S > K_L$. Thus, the stability analysis, not the constitutional supercooling criterion, should be used to obtain the appropriate planar stability criterion for cast microstructures. For most metallic systems, the diffusion coefficient is about 10^{-9} m^2/s. Thus for $\Delta T_o = 5$ K and $G = 10^4$ K/m, the planar interface growth will occur only when the velocity is less than $2 \cdot 10^{-6}$ m/s. Because typical velocities in castings are larger than this value, most practical metallurgical alloys rarely solidify with a planar interface in a mold.

Interface Velocity Exceeding Critical Velocity

Cellular and Cellular Dendritic Structures. Under directional solidification conditions, a cellular or a cellular dendritic interface is observed when the interface velocity exceeds the critical velocity for the planar interface growth. For velocities just above v_{cr}, the cellular structures that form have two important characteristics. First, the length of the cell is small, and it is of the same order of magnitude as the cell spacing (Fig. 2b). Second, the tip region of the cell is broader, and the cell has a larger tip radius. At higher velocities, a cellular dendritic structure forms (Fig. 2c) in which the length of the cell is much larger than the cell spacing. Also, the cell tip assumes a sharper, nearly parabolic shape, which is similar to the dendrite tip shape so that the term cellular dendritic is used to characterize this structure (Ref 5, 6, 7).

The formation of cellular structures gives rise to solute segregation in the solid. The tip of the cell is at a higher temperature than the base of the cell. Thus, for $k < 1$, the solid that forms at the cell tip will have a lower composition than the solid that forms at the cell base. This microsegregation profile is approximately characterized by the normal freeze, or Scheil, equation:

$$C_S = k \cdot C_o (1 - f_S)^{k-1} \quad \textbf{(Eq 6)}$$

where f_S is the volume fraction of solid, which is 0 at the cell tip and 1 at the cell base. Equation 6 is derived under the assumptions that k is constant and that the composition of liquid is uniform in a small-volume element in the direction perpendicular to the growth direction. Equation 6 also assumes that the diffusion in the solid is negligible, so that it predicts C_S to be infinity at the base of the cell.

Equation 6 is useful for nonequilibrium solidification when the phase diagram shows the presence of a higher-composition second phase that can nucleate in the intercellular region. For example, for systems with eutectic phase diagrams, the maximum composition in the single phase corresponds to kC_E, where C_E is the eutectic composition. Thus,

once this composition is achieved, the intercellular liquid will freeze with a eutectic structure, as shown in Fig. 6. For this case, Eq 6 can be used to predict the volume fraction of the eutectic phase f_E:

$$f_E = \left(\frac{C_E}{C_o} \right)^{1/(k-1)} \quad \textbf{(Eq 7)}$$

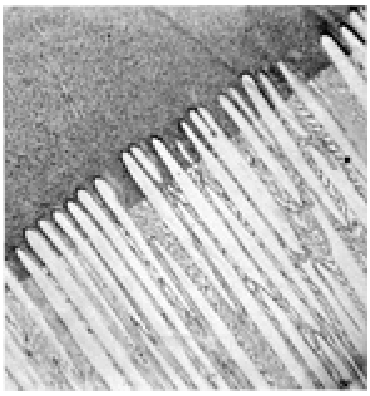

Fig. 6 Formation of cells with intercellular eutectic in the directionally solidified Sn-20Pb alloy. *G* = 31 K/mm (79 K/in.) and *v* = 1.2 μm/s (48 μin./s). The nearly flat eutectic interface is at the eutectic temperature.

For single-phase solidification in which the diffusion in the solid is important, it is preferable to describe microsegregation by the segregation ratio (*SR*). The segregation ratio is defined as the ratio of the maximum solid composition (at the cell base) to the minimum solid composition (at the cell tip). If **l** is the length of the cell, G_M the average temperature gradient in the two-phase region, and ΔT the cell tip undercooling, then:

$$SR = 1 + \frac{\mathbf{l}.G_M}{\Delta T} \quad \textbf{(Eq 8)}$$

As the cellular structure becomes cellular dendritic or dendritic, **l** increases sharply and ΔT decreases under normal solidification conditions. Thus, the segregation ratio will increase significantly upon the formation of cellular dendrites or dendrites.

Figure 2(b) shows that all cells have the same orientation; therefore, once the base of each individual cell solidifies, a single grain is obtained. This single grain, however, will have a microsegregation pattern that reflects the periodicity of the cells. This cell spacing λ is important because the time required to homogenize the solid depends on λ and is given by (Ref 8):

$$t = \frac{0.47 l^2}{D_S} \quad \textbf{(Eq 9)}$$

where *t* is the time required to homogenize to 1% of the original composition difference and D_S is the diffusion coefficient in the solid. The spacing λ decreases with velocity for both the cellular (Ref 9) and the cellular dendritic structures (Ref 6). However, λ increases sharply at the cellular-to-cellular-dendritic transition, as shown in Fig. 7.

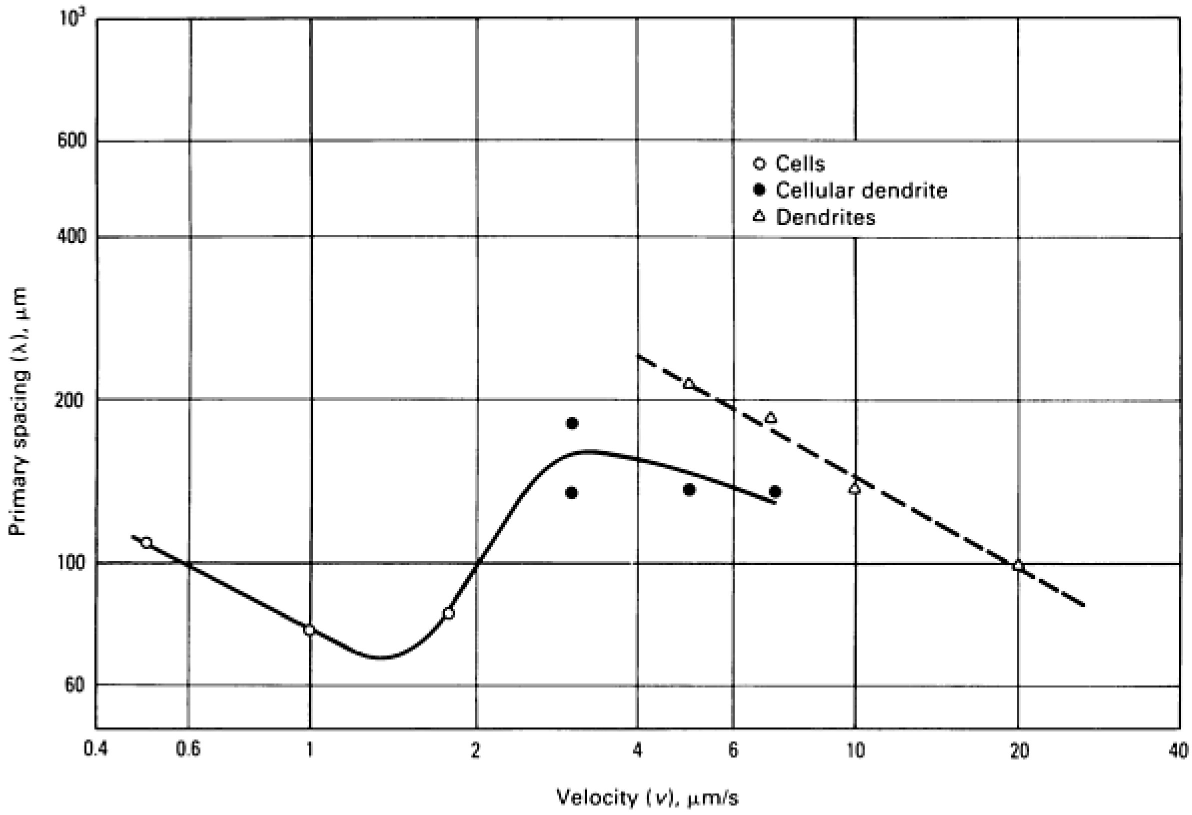

Fig. 7 The effect of velocity on cellular, cellular dendrite, and primary dendrite spacings in the pivalic acid-ethanol system. Source: Ref 6

Cellular structures are observed in castings only for heat flow conditions that produce directional solidification and for alloys with very small freezing ranges. Thus, cellular structures are important for very dilute alloys or for alloys that are close to the eutectic composition.

Dendritic Structures. A dendritic structure is formed when the interface velocity is increased beyond the cellular dendritic regime. Dendritic structures are characterized by the formation of sidebranches (Fig. 2d). These sidebranches, as well as the primary dendrite, grow in a preferred crystallographic direction, for example, <100> for cubic metals, so that cubic metals exhibit fourfold sidebranches. A three-dimensional view of dendrites in metals is difficult to observe because only parts of dendrites that intersect the plane of polish are visible. Figure 8 shows a three-dimensional view of cobalt dendrites in a cobalt-samarium-copper alloy in which the matrix is etched away. The cut surfaces in the foreground are those that are typically observed in a polished section of a solid alloy.

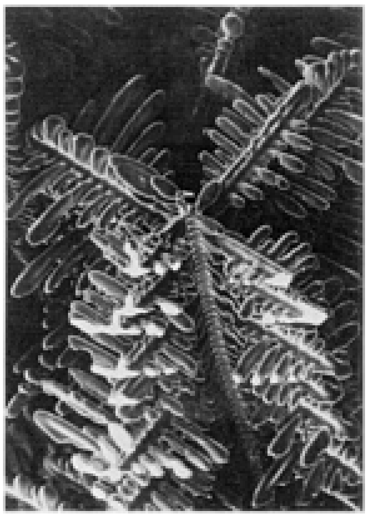

Fig. 8 Directionally solidified peritectic cobalt-samarium-copper alloy showing primary cobalt dendrites when the $Co_{17}Sm_2$ matrix is etched away. The cut surfaces in the foreground indicate the structure that would be observed on the plane of polish if the matrix were not etched away.

The formation of secondary dendrite arms is clearly seen for a dendritic structure in a transparent alloy (Fig. 9). The secondary arms form very close to the dendrite tip, and the first few sidebranches are uniformly spaced. However, the secondary arm spacing increases as the base of the dendrite is approached (Ref 10). Initial coarsening occurs by the competition in the growth process among secondary arms. However, once the diffusion fields of their tips interact with those of the neighboring dendrite, the growth of the secondary arms is reduced, and a coarsening process to reduce interfacial energy begins (Ref 10). The final secondary arm spacing near the dendrite base is significantly larger than that near the dendrite tip. This final secondary arm spacing controls the microsegregation profile in the solidified alloy. This microsegregation pattern is analogous to that discussed for the cellular structure, except that the periodicity of segregation is controlled by the final secondary arm spacing and not by the primary spacing.

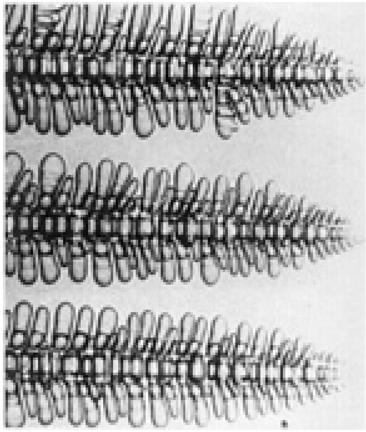

Fig. 9 Dendritic structure in a directionally solidified transparent organic system, succinonitrile-4.0 wt% acetone. G = 6.7 K/mm (170 K/in.) and v = 6.4 μm/s (260 μin./s). The secondary dendrite arm spacing increases with the distance behind the tip.

Because the secondary arm coarsening requires solute diffusion, the coarsening process is negligible once the interdendritic liquid has solidified. Thus, the final value of secondary spacing, λ_2 is determined by the total time that a given secondary branch spends in contact with the liquid because the diffusion coefficient of the solute is significantly larger in the liquid than in the solid. This total time spent by a secondary branch in the two-phase region is known as the

local solidification time, t_f. For directional solidification, $t_f = L/v$, where L is the length of the primary dendrite and v is the imposed velocity. The following relationship between λ_2 and t_f is predicted:

$$\lambda_2 = a t_f^{1/3} \qquad \textbf{(Eq 10)}$$

where a is a constant that depends on system parameters such as the diffusion coefficient in liquid, solid-liquid interfacial energy, and the equilibrium freezing range of the alloy (Ref 1, 7).

Another important microstructural parameter for dendritic structures is the length of the dendrite, which is given by the relationship:

$$L = \frac{T_L - T_b}{G_M} \qquad \textbf{(Eq 11)}$$

where T_L is the liquidus temperature of the alloy and T_b is the base temperature of the dendrite. Under most casting conditions, the dendrite tip undercooling is quite small, so that the tip temperature has been approximated as T_L.

For alloy systems that exhibit a eutectic phase transformation, a eutectic structure will form at the base of the dendrite, as shown in Fig. 10. Thus, in eutectic systems, with negligible solid diffusion, $T_b = T_E$. For dilute alloys, in which appreciable solid diffusion occurs, a single phase is observed in which T_b is between the solidus and the eutectic temperatures. For this case, a lower limit on dendrite length can be estimated by taking $T_b = T_S$, as has been verified in the iron-carbon system for low carbon steels. Thus, the dendrite length will be directly proportional to the equilibrium freezing range and inversely proportional to the average temperature gradient in the two-phase region. For a large freezing range alloy, with ΔT_o = 50 K, a temperature gradient of 0.5 K/mm (13 K/in.) will give a dendrite that is 100 mm (3.9 in.) long. Such long dendrites are more prone to breakup during growth and can influence the final microstructure of the casting.

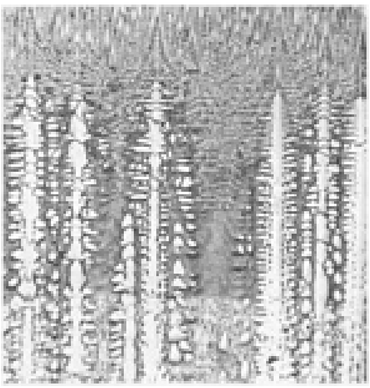

Fig. 10 Longitudinal section of Sn-20Pb alloy, directionally solidified at v = 11.8 μm/s (472 μin./s) under G = 31 K/mm (790 K/in.). A eutectic interface is observed between the dendrites.

Most practical metallurgical alloys solidify with a dendritic structure in a mold. Both columnar and equiaxed dendrites may be present in a casting (Fig. 11). As the liquid metal is poured into the mold, solid nuclei appear at the mold wall that give rise to an equiaxed chilled zone. Some of these crystals are then favorably oriented for growth under directional heat flow conditions. The actual mechanism by which this preferred growth occurs is illustrated in Fig. 12. The dendrites in region 1 are favorably oriented with respect to heat flow compared to those in region 2. As the growth proceeds, region 1 expands by creating new primary dendrites from the tertiary branches of the dendrite at the junction of regions 1 and 2. Region 2 will be eliminated if the dendrites below it are also favorably oriented. Because all of the dendrites in a given region have formed from the same initial crystal, they will give rise to one grain when the solidification is complete. These favorably oriented grains produce a columnar zone in a casting, and they exhibit [100] texture in cubic metals.

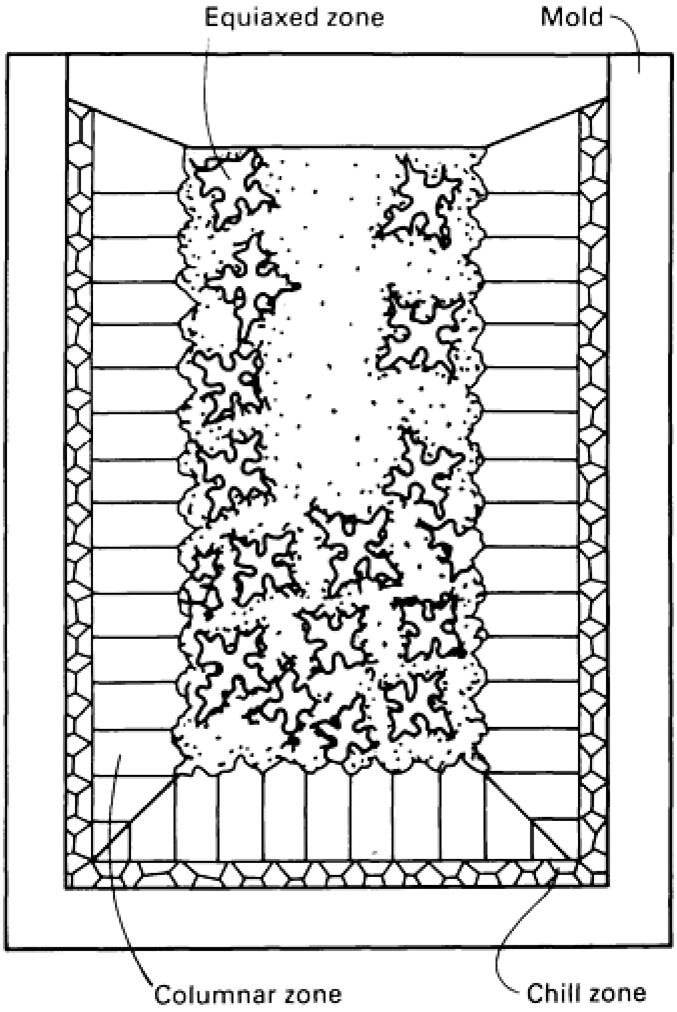

Fig. 11 Schematic of microstructure zone formation in castings. Directional solidification conditions give rise to a columnar zone, while an equiaxed zone is formed at the center where the liquid is undercooled.

Fig. 12 Mechanism of chill to columnar transition. Region 1, in which dendrites are favorably oriented, will expand by converting a tertiary branch into a new primary dendrite. Such expansion continues until region 2 is eliminated. All dendrites in region 1, after solidification, become a single grain.

For alloy solidification, equiaxed dendritic crystals are observed at the center of the mold (Fig. 11). This phenomenon can be explained in the following way: Because of the convection effects present in the melt, the temperature ahead of the columnar dendrite in the later stages of solidification is nearly constant, and it approaches the dendrite tip temperature. Because the columnar dendritic tip is slightly undercooled, a small undercooling also exists at the central melt region of the casting. Thus, if any crystals or efficient nuclei are present, they can grow in this undercooled liquid, creating equiaxed crystals. Observations in transparent alloys show that the nuclei for the equiaxed zone come from the detached dendrite arms that are carried to the center of the mold by convection currents (Fig. 13). The dendrite breakup occurs easily if the dendrites are thin and very long, as in the case of large freezing range alloys. In addition, if long dendrites are present in the columnar zone, the feeding problem becomes critical because the liquid must be transported from the tip region to the base region through a complex secondary branch structure. Consequently, it may not be possible to avoid small shrinkage voids or microporosity in alloys with very large freezing ranges.

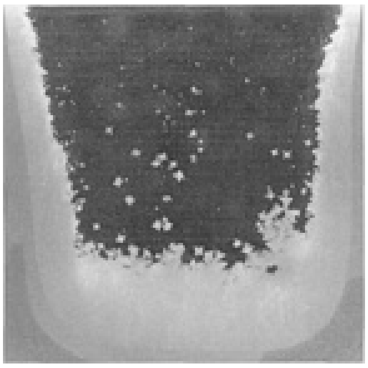

Fig. 13 A model experiment showing the microstructure formation during the freezing of an ammonium chloride-water system in a mold. The broken dendrite branches are transported to the center by convection in the liquid, where they form an equiaxed structure.

Solidification of Eutectics

P. Magnin and W. Kurz, Swiss Federal Institute of Technology, Switzerland

---

Introduction

Alloys of eutectic composition make up the bulk of cast metals. The reason for their widespread use can be found in the unique combination of good castability (comparable to that of pure metals), relatively low melting point (minimizing the energy required for production), and interesting behavior as "composite" materials.

Eutectic Morphologies

Eutectic structures are characterized by the simultaneous growth of two or more phases from the liquid. Three or even four phases are sometimes observed growing simultaneously from the melt. However, because most technologically useful eutectic alloys are composed of two phases, only this type will be discussed in this section. Eutectic alloys exhibit a wide variety of microstructures, which can be classified according to two criteria:

- Lamellar or fibrous morphology of the phases
- Regular or irregular growth

Lamellar and Fibrous Eutectics. When there are approximately equal volume fractions of the phases (nearly symmetrical phase diagram), eutectic alloys generally have a lamellar structure, for example, Al-Al_2Cu (Fig. 1). On the other hand, if one phase is present in a small volume fraction, this phase will in most cases tend to form fibers, for example molybdenum in NiAl-Mo (Fig. 2).

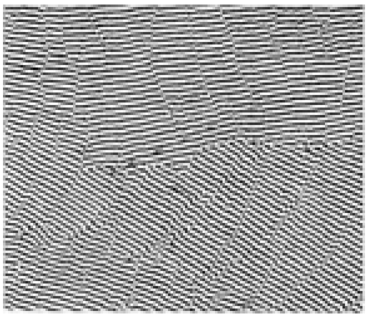

Fig. 1 Example of a lamellar eutectic microstructure (Al-Al_2Cu) with approximately equal volume fractions of the phases. Transverse section of a directionally solidified sample. As-polished.

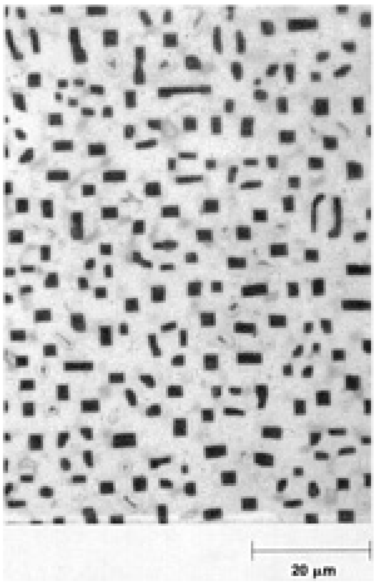

Fig. 2 Example of a fibrous eutectic microstructure with a small volume fraction of one phase (molybdenum fibers in NiAl matrix). Transverse section of a directionally solidified sample. As-polished. Courtesy of E. Blank.

In general, the microstructure obtained will usually be fibrous when the volume fraction of the minor phase is lower than 0.25, and it will be lamellar otherwise. This is because of the small separation of the eutectic phases (typically several microns) and the resulting large interfacial area (of the order of 1 m^2/cm^3) that exists between the two solid phases. The system will therefore tend to minimize its interfacial energy by choosing the morphology that leads to the lowest total interface area. For a given spacing (imposed by growth conditions), the interface area is smaller for fibers than for lamellae at volume fractions below 0.25. However, when the minor phase is faceted*, a lamellar structure may be formed even at a very low volume fraction, because the interfacial energy is then considerably lower along specific planes, along which the lamellae can be aligned. This is the case in gray cast iron, where the volume fraction of the graphite lamellae is 7.4% (Fig. 3).

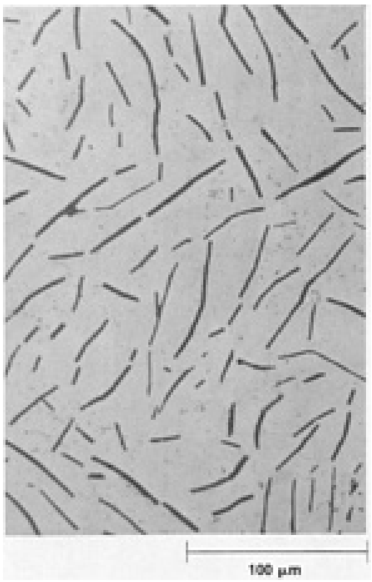

Fig. 3 Microstructure of a gray cast iron showing flake graphite. Transverse section etched with nital.

Many eutectic microstructures can be classified as lamellar or fibrous, but there is an important exception, namely, spheroidal graphite cast iron (Fig. 4). In this case, there is no cooperative eutecticlike growth of both phases; instead, there is separate growth of spheroidal graphite particles as a primary phase (at least during the initial stages), together with austenite dendrites. This special case of eutectic growth (divorced growth) is discussed further in the article "Ductile Iron" in this Volume. Cast iron often exhibits intermediate microstructural forms, such as vermicular or chunky graphite.

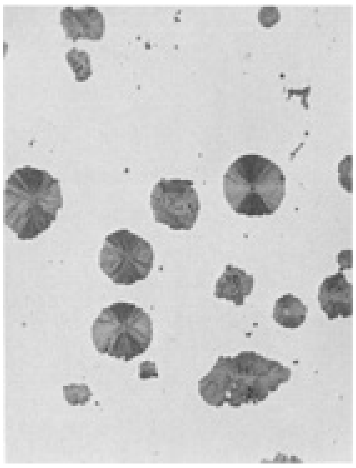

Fig. 4 Graphite in spheroidal cast iron, which results from the divorced growth of the phases. Etched with nital. 130×.

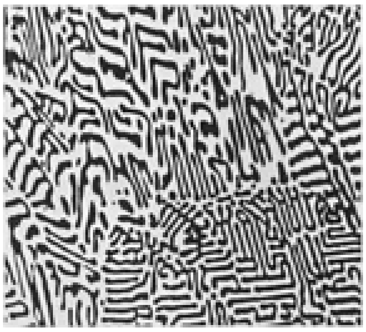

Fig. 5 Irregular "Chinese script" eutectic consisting of faceted Mg_2Sn phase (dark) in a magnesium matrix. Etched with glycol. 250×.

Regular and Irregular Eutectics. If both phases are nonfaceted (usually when both are metallic), the eutectic will exhibit a regular morphology. The microstructure is then made up of lamellae or fibers having a high degree of regularity and periodicity, particularly in unidirectionally solidified specimens (Fig. 1).

On the other hand, if one phase is faceted, the eutectic morphology often becomes irregular (Fig. 3 and 5). This is because the faceted phase grows preferentially in a direction determined by specific atomic planes. Because the various faceted lamellae have no common crystal orientation, their growth directions are not parallel, and the formation of a regular microstructure becomes impossible. The two eutectic alloys of greatest practical importance--iron-carbon (cast iron) and aluminum-silicon--belong to this category.

Although the examination of metallographic sections of irregular eutectics seems to reveal many dispersed lamellae of the minor phase, these lamellae are generally interconnected in a complex three-dimensional arrangement. In the foundry literature, such eutectic grains are often referred to as eutectic cells. In the solidification literature, the term cell defines a certain interface morphology (see Fig. 13b in related discussion below); therefore, the term eutectic grain will be used throughout this section.

The regularity of some eutectic microstructures can be used to make *in situ* composites. By using a controlled heat flux to achieve slow directional solidification, it is possible to obtain an aligned microstructure throughout the entire casting. When one of the phases is particularly strong, as in the case of TaC fibers in the Ni-TaC eutectic, the mechanical properties of the alloy can be enhanced in the growth direction. In contrast, an equiaxed microstructure can be formed by inoculation, and there is no long-range orientation.

Interpretation of Eutectic Microstructures. Eutectic microstructures, as seen in metallographic section, are two-dimensional images of a three-dimensional arrangement of two (or more) phases. One must therefore be very careful in interpreting these metallographic sections. For example, Fig. 6 shows a longitudinal section of a directionally solidified lamellar eutectic (white cast iron) covering two different grains. Despite their different appearances, the two grains have the same lamellar spacing. However, the sectioning plane is perpendicular to the lamellae of one grain but is at a small angle with respect to the lamellae of the other grain. Therefore, in directionally solidified samples, the lamellar spacing of eutectic microstructures must always be measured perpendicular to the growth direction. In a casting containing equiaxed grains, only a mean spacing can be measured. Eutectic grains are often difficult to identify, as can be seen in Fig. 1.

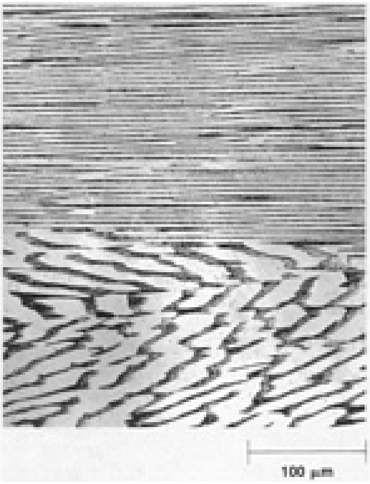

Fig. 6 Longitudinal section of directionally solidified white cast iron. The two grains in the micrograph have the same lamellar spacing but are oriented differently with regard to the plane of polish. Etched with nital.

Note cited in this section

* Growth of faceted phases occurs on well-defined atomic planes, thus creating planar, angular surfaces (facets). Faceted substances are generally characterized by an entropy of fusion (ratio of the molar entropy of fusion to the gas constant *R*) higher than 2.0. Typical examples of faceted phases are graphite, silicon, and intermetallic compounds. Additional information is available in Ref 1.

Solidification and Scale of Eutectic Structures

Figure 7 shows a schematic eutectic phase diagram. When a liquid L of eutectic composition C_E is frozen, the α and β solid phases solidify simultaneously when the temperature of the melt is below the eutectic temperature T_E. A variety of geometrical arrangements can be produced. For simplicity, the case of a lamellar microstructure is considered in this discussion; the solidification of fibers can be described in terms of similar mechanisms. Because eutectic growth is essentially solute diffusion controlled, there is no fundamental difference between equiaxed and directional solidification. Therefore, the mechanisms described are valid for both cases.

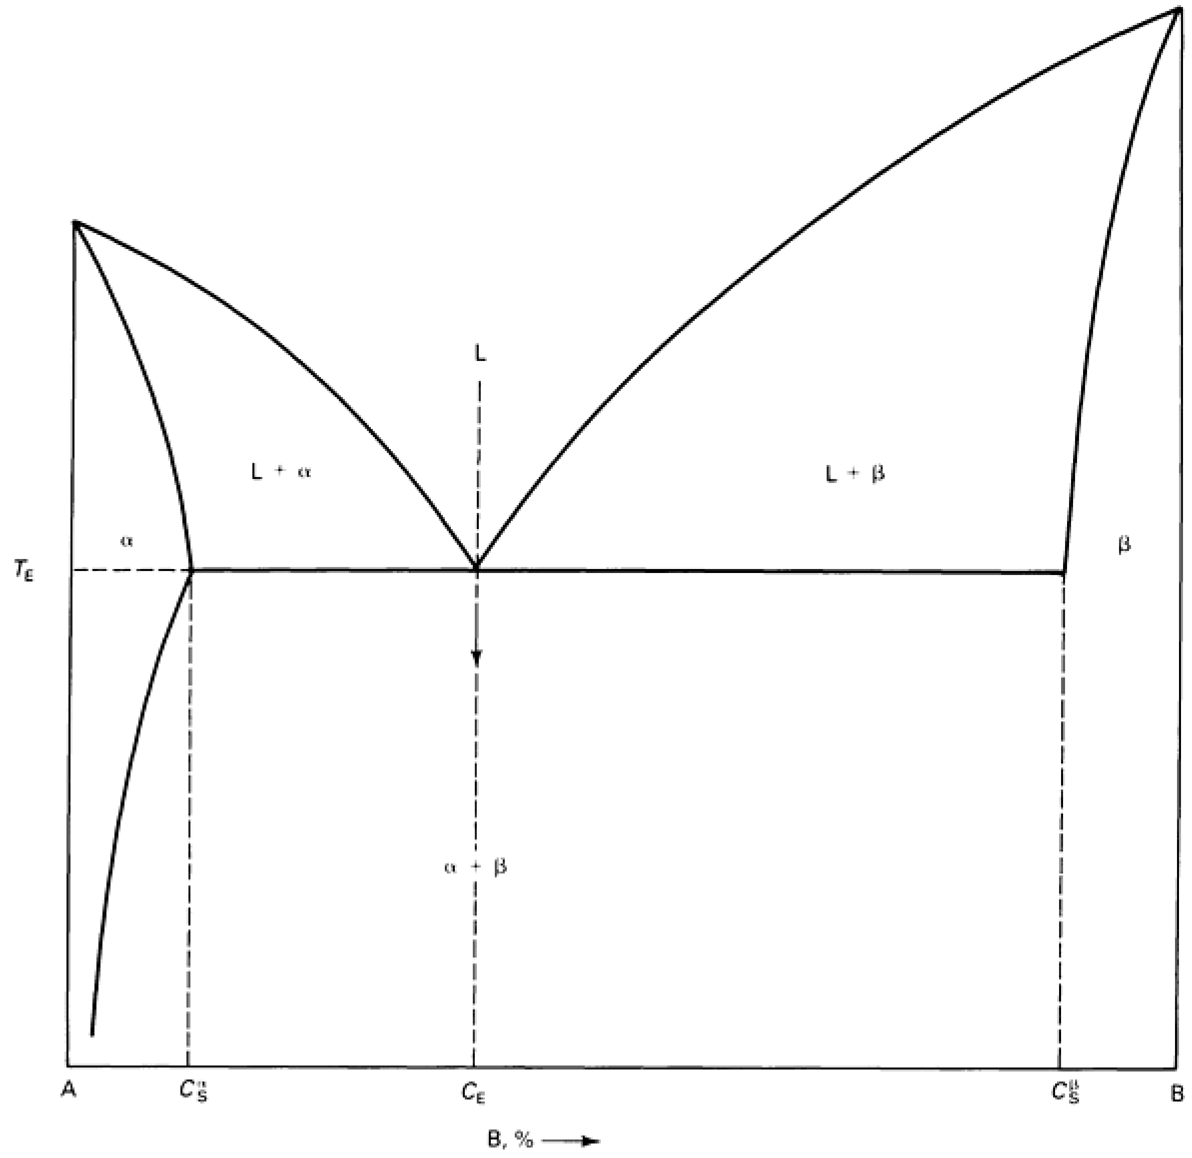

Fig. 7 Schematic eutectic phase diagram. See text for explanation.

Regular Eutectic Growth. During eutectic solidification, the growing α phase rejects B atoms into the liquid because of their lower solubility with respect to the liquid concentration. Conversely, the β phase rejects A atoms. If the α and β phases grow separately, solute rejection would occur only in the growth direction. This involves long-range diffusion. Therefore, a very large boundary layer would be created in the liquid ahead of the solid/liquid interface, as shown in Fig. 8(a).

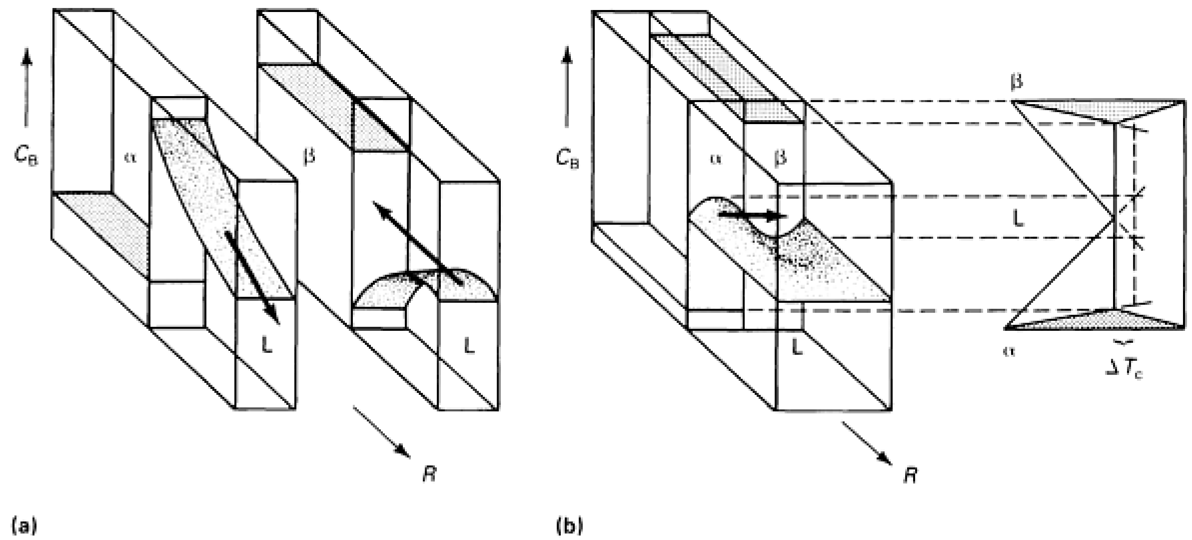

Fig. 8 Diffusion fields ahead of the growing α and β phases in isolated (a) and coupled (b) eutectic growth. The dark arrow represents the flux of B atoms. Source: Ref 1.

However, during eutectic solidification, the α and β phases grow side by side in a cooperative manner; the B atoms rejected by the α phase are needed for the growth of the β phase, and conversely. The solute then needs only to diffuse along the solid/liquid interface from one phase to the other (Fig. 8b). The solute buildup in the liquid ahead of the growing solid/liquid interface is considerably lowered by this sidewise diffusion (diffusion coupling), thus being thermodynamically favorable (see Appendix 1). This is the fundamental reason for the occurrence of eutectic growth. As can be seen in Fig. 8(b), the smaller the lamellar spacing λ, the smaller the solute buildup, if the driving force for diffusion provided by the concentration gradient remains constant.

On the other hand, at the three-phase junction α/β/L, the surface tensions must be balanced to ensure mechanical equilibrium (Fig. 9). This imposes fixed contact angles, leading to a curvature of the solid/liquid interface. This curvature is thermodynamically disadvantageous. Because the contact angles are material constants, this curvature is higher when the lamellar spacing is small.

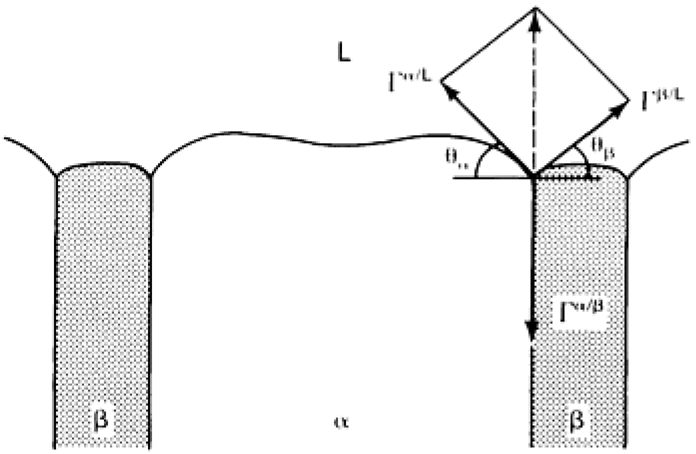

Fig. 9 Surface tension balance at the three-phase (α /β/L) junction, and the resulting curvature of the solid/liquid interface.

The scale of the eutectic structure is therefore determined by a compromise between two opposing factors:

- Solute diffusion, which tends to reduce the spacing
- Surface energy (interface curvature), which tends to increase the spacing

The lamellar spacing λ and the growth undercooling ΔT (defined as the difference between the eutectic temperature T_E and the actual interface temperature during growth) are given by (Ref 2, 3):

$$l = \frac{f k_1}{\sqrt{R}} \quad \textbf{(Eq 1)}$$

$$\Delta T = \frac{(f + 1/f)}{2} k_2 \sqrt{R} \quad \textbf{(Eq 2)}$$

where R is the solidification rate (velocity at which the solid/liquid interface advances), K_1 and K_2 are constants related to the material properties (see Appendix 1), and f is a regularity constant whose value is close to unity for regular eutectics. Figure 10 shows typical values for the $\lambda(R)$ relationship (Eq 1). It can be seen that regular eutectics have spacings between the coarse ones of irregular eutectics and the fine ones of eutectoids. In the latter, the effect of diffusion on spacing is more marked because it occurs in a solid phase.

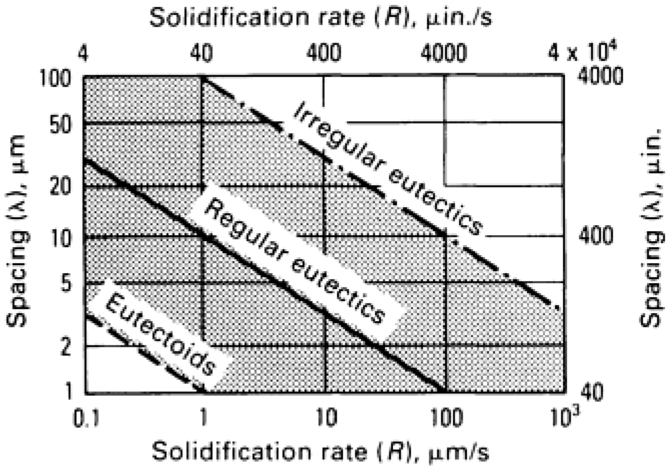

Fig. 10 Typical spacings of eutectics and eutectoids as a function of growth rate. Source: Ref 1.

The scale of the eutectic microstructure depends on the solidification rate, not directly on the cooling rate. The reason is that the thermal gradient has a negligible effect on the size of the eutectic microstructure (Ref 4). Because the cooling rate is the product of the solidification rate and the thermal gradient, two growth conditions characterized by the same cooling rate but with different thermal gradients lead to different solidification rates and therefore to different spacings. An important characteristic of regular eutectic growth is that the lamellae (or fibers) are parallel to the heat flow direction during solidification and perpendicular to the solid/liquid interface.

Irregular Eutectic Growth. Irregular eutectics grown under given growth conditions exhibit an entire range of spacings because the growth direction of the faceted phase (for example, graphite in cast iron or silicon in aluminum-silicon) is determined by specific atomic orientations and is not necessarily parallel to the heat flux. In this case, growth involves the following mechanism: When two lamellae converge, the growth of one simply ceases when λ becomes smaller than a critical spacing λ_{min} because the local interface energy becomes too large (Ref 5). Thus, the spacing is increased. This mechanism is illustrated in Fig. 11. Conversely, diverging lamellae can grow until another critical spacing, λ_{br}, is reached. When this occurs, one of the lamellae branches into two diverging lamellae, thus reducing the spacing. Growth of an irregular eutectic thus occurs within the range of interlamellar spacings between λ_{min} and λ_{br}.

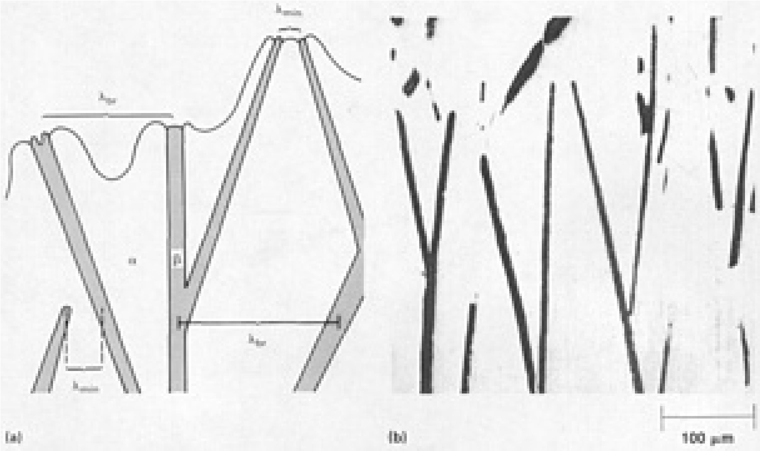

Fig. 11 Growth of irregular eutectics. (a) Schematic of branching of the faceted phase at λ_{br}, termination at λ_{min} and the corresponding shape of the solid/liquid interface. (b) Iron-carbon eutectic alloy directionally solidified at *R* = 0.017 μm/s. Branching was induced by a rapid tenfold increase in *R.* Longitudinal section. As-polished. Source: Ref 4.

It can be shown that the growth temperature of the region of small λ is higher than that in the large λ zones. The solid/liquid interface is therefore nonisothermal; that is, its shape is irregular (Fig. 11a) and is the opposite of the isothermal planar solid/liquid interface that characterizes regular eutectic growth (Fig. 9 and 12).

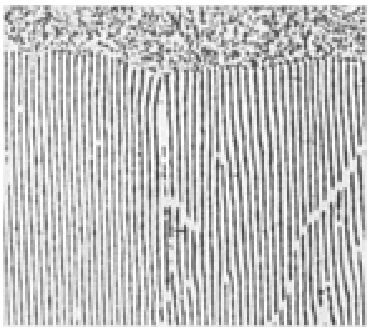

Fig. 12 Nearly planar solid/liquid interface of a regular cadmium-tin eutectic as revealed by quenching. Etched with ferric chloride. 210×.

A mean spacing <λ> and a mean undercooling <Δ*T*> can be defined and are still given by Eq 1 and 2. In this case, *f* (the ratio of the mean spacing <λ> to the minimum undercooling spacing, which is close to λ_{min}; see Appendix 1) is greater than unity. Therefore, the spacings and undercoolings obtained are higher than those observed in regular eutectics (Fig. 10).

Competitive Growth of Dendrites and Eutectics

The solidification of a binary alloy of exactly eutectic composition was examined earlier in this section. In this case, provided the growth is regular, the solid/liquid interface is planar. However, when alloy composition departs from eutectic or when a third alloying element is present, the interface can become unstable for the same reason as in the case of a simple solid/liquid interface. As shown in Fig. 13, two types of morphological instability can develop: single-phase and two-phase.

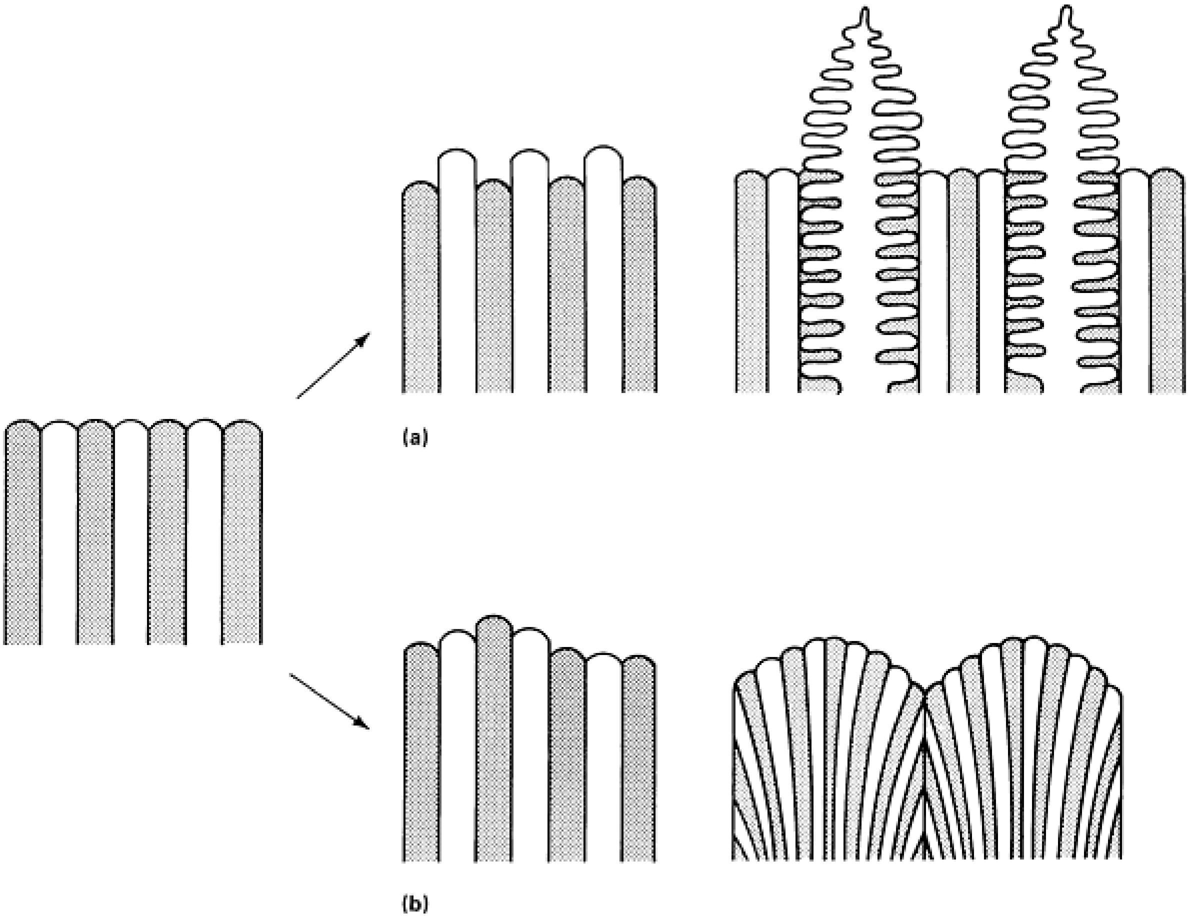

Fig. 13 Types of instability of a planar solid/liquid eutectic interface. (a) Single-phase instability leading to the appearance of dendrites of one phase. (b) Two-phase instability leading to the appearance of eutectic cells or colonies in the presence of a third alloying element.

A single-phase instability (Fig. 13a) leads to the solidification of one of the phases in the form of primary dendrites plus interdendritic eutectic. This situation is primarily observed in off-eutectic alloys because one phase becomes much more constitutionally undercooled than the other. For example, during the solidification of a hypoeutectic alloy, the α phase is heavily undercooled because the liquidus temperature at that composition is much higher than T_E (Fig. 7). The α phase can therefore grow faster (or at higher temperature) than the eutectic.

A two-phase instability (Fig. 13b) is characterized by cellularlike growth and leads to the appearance of eutectic colonies. This situation is observed when a third alloying element that partitions similarly at both the α/L and β/L interfaces produces a long-range diffusion boundary layer ahead of the solid/liquid interface, thus making the growing eutectic interface constitutionally undercooled with respect to this element.

Coupled Zone of Eutectics. The eutectic-type phase diagram appears to indicate that microstructures consisting entirely of eutectic can be obtained only at the exact eutectic composition. In fact, experimental observations show that purely eutectic microstructures can be obtained from off-eutectic alloys over a range of growth conditions (Ref 6). On the other hand, dendrites can sometimes be found in alloys with the exact eutectic composition if the growth rate is high. This

is of considerable practical importance because the properties of a casting can be significantly changed when single-phase dendrites appear.

To explain these observations, one must consider the growth mechanisms of the competing phases (Ref 7). Because of the differing growth characteristics of eutectics and dendrites, the solidification of eutectic (high-efficiency diffusion coupling) can be faster than the isolated growth of one phase (primary dendrites), even for off-eutectic alloys. In this case, the dendrites are overgrown, and a purely eutectic microstructure is obtained over a range of off-eutectic compositions (the volume fraction of both phases in this case is determined by alloy composition and is therefore different from that obtained in the eutectic alloy). Conversely, if one of the phases (for example, β) is faceted, the growth of this phase (and consequently of the eutectic) is slower at a given undercooling. Dendrites of α phase may then grow more rapidly than the eutectic at the eutectic composition; purely eutectic microstructures are obtained only in hypereutectic alloys.

The temperature of a growing eutectic solid/liquid interface is a function of the growth rate. This relationship is used, together with the dendrite tip temperatures of α and β primary crystals, to establish the coupled zone. In the diagrams shown in Fig. 14, each point below the eutectic temperature is associated with a solidification rate through Eq 2 (that is, the lower the temperature, the higher the solidification rate). The coupled zone (a shaded region) then represents the solidification rate dependent composition region in which the eutectic grows more rapidly (or at a lower undercooling) than α- or β-phase dendrites. This zone corresponds to an entirely eutectic microstructure. Outside the coupled zone, the microstructure consists of primary dendrites and interdendritic eutectic.

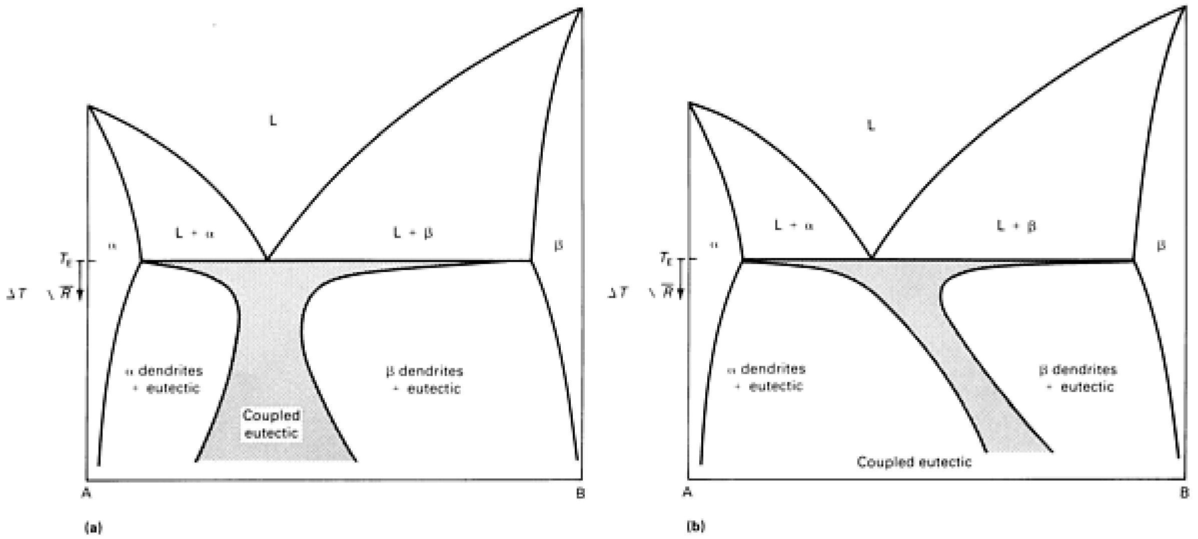

Fig. 14 Coupled zones (shaded regions) on eutectic phase diagrams. The coupled zones represent the interface temperature (solidification rate) dependent composition region in which a completely eutectic structure is obtained. (a) Nearly symmetrical coupled zone in regular eutectic. (b) Skewed coupled zone in an irregular eutectic. In both cases, the widening of the coupled zone near the eutectic temperature is observed only in directional solidification (positive thermal gradient).

Figure 14(a) shows the coupled zone of a regular eutectic system. In this case, a purely eutectic microstructure is obtained at the eutectic composition for all growth conditions. However, in the case of the skewed coupled zone of an irregular eutectic (Fig. 14b, where β is the faceted phase), the alloy composition must be carefully chosen as a function of the growth rate imposed by the casting process if a completely eutectic microstructure is required. For example, the composition of cast iron or aluminum-silicon alloys must often be hypereutectic if one wants to eliminate metal dendrites, especially when using high solidification rate casting techniques.

Appendix 1: Simplified Theory of Eutectic Growth

Solute Diffusion. As shown in Fig. 8, the growing eutectic phases reject solute into the liquid. Because of this solute buildup, the composition at the interface departs from the eutectic concentration. Figure 8 shows that in this case the equilibrium temperature between the liquid and the α or β phase is lower than the eutectic temperature T_E. The average chemical undercooling of the interface ΔT_c is proportional to the amplitude of the composition variation at the interface. The latter is proportional to the rate of rejection of solute (that is, to the solidification rate *R*) and to the distance (the lamellar spacing λ) over which diffusion must occur. Therefore:

$$\Delta T_c = K_c \lambda R \qquad \textbf{(Eq 3)}$$

where K_c is a constant related to the material properties whose value is given by (Ref 2):

$$k_c = \frac{mC_oF(f)}{D} \qquad \textbf{(Eq 4)}$$

where $m = m\alpha m\beta/(m\alpha + m\beta)$ and $m\alpha$ and $m\beta$ are the slopes of the liquidus lines of the α and β phases, respectively (defined so that both are positive); C_o is the length of the eutectic tieline ($C_S\beta$ - $C_S\alpha$, see Fig. 7); and *D* is the diffusion coefficient of the solute in the liquid. Here F(*f*) is a function of the volume fractions $f\alpha$ and $f\beta$ of the phases and can be approximated for a lamellar eutectic by:

$$F(f) \approx 0.335\,(f\alpha f\beta)^{0.65} \qquad \textbf{(Eq 5)}$$

For α-phase fibers, F(*f*) can be approximated by:

$$F(f\alpha) \approx 4.908 \cdot 10^{-3} + 0.3122 f\alpha + 0.6918\, f_a^2 - 2.604\, f_a^3 + 3.238\, f_a^4 - 1.619\, f_a^5 \qquad \textbf{(Eq 6)}$$

Capillarity Effects. The equilibrium transformation temperature between a solid and a liquid phase is a function of the curvature of the solid/liquid interface. The change ΔT_r in this equilibrium temperature (with respect to that for a planar interface) is termed the curvature undercooling and is proportional to the interface curvature; it is positive when the solid phase is convex.

The surface tension balance among α, β, and L (Fig. 9) governs the shape of the solid/liquid interface at the three-phase junction. The interface is therefore characterized by an average (positive) curvature of the solid/liquid interface that is inversely proportional to the lamellar spacing λ. The curvature undercooling can then be expressed as:

$$\Delta T_r = \frac{k_r}{l} \qquad \textbf{(Eq 7)}$$

where K_r is a material constant given by (Ref 2):

$$k_r = 2md\left(\frac{\Gamma_a \sin q_a}{f_a m_a} + \frac{\Gamma_b \sin q_b}{f_b m_b}\right) \qquad \textbf{(Eq 8)}$$

where Γα and Γβare the Gibbs-Thomson coefficients (ratio of surface energy to entropy of fusion) and θαand θβare the contact angles at the three-phase junction for the α and β phases, respectively, as defined in Fig. 9. The parameter δ is equal to unity for lamellar eutectics and equal to $2\sqrt{fa}$ for fibrous eutectics (fibers of α phase).

Operating Range of Eutectics. The total undercooling Δ*T* is given by:

$$\Delta T = \Delta T_c + \Delta T_r = \frac{k_c\, l\, R + k_r}{l} \qquad \textbf{(Eq 9)}$$

Equation 9 is shown in Fig. 15. To determine the spacing, one still requires another criterion. It has been shown that an entire range of spacings is stable under given growth conditions (Ref 2, 8). However, the system will try to grow not too far from equilibrium, that is, close to the minimum undercooling. This is equivalent to the maximum growth rate for a given undercooling (Fig. 15b). Whenever possible, that is, in regular eutectics, the eutectic microstructure will therefore adopt a lamellar spacing close to that corresponding to the minimum undercooling. However, this is not possible in the case of irregular eutectics, because a range of lamellar spacings is observed (Fig. 16). The ratio f of the mean spacing of an irregular eutectic to the extremum spacing λ_{ex} (which is close to λ_{min}) is a material constant and is independent of the growth conditions for normal growth rates (Ref 4).Setting $d\Delta T/d\lambda$ equal to 0 in Eq 9 and setting $<\lambda>$ equal to $f\ \lambda_{ex}$ leads to the relationships:

$$<\lambda>^2 R = \phi^2 \frac{K_r}{K_c} \qquad \textbf{(Eq 10)}$$

$$\frac{<\Delta T>}{\sqrt{R}} = \left(\phi + \frac{1}{\phi}\right)\sqrt{K_r K_c} \qquad \textbf{(Eq 11)}$$

$$<\Delta T>\ <\lambda> = (f^2 + 1)K_r \qquad \textbf{(Eq 12)}$$

Equations 10, 11, and 12 describe the growth of both regular ($f \approx 1$) and irregular ($f > 1$) eutectics. In the latter case, the value of f can be approximated (supposing that β is the faceted phase) by (Ref 4):

$$\phi = 0.5 + \left[F'(f_\beta)\left(1 + \frac{f_\beta\, m_\beta}{f_\alpha\, m_\alpha} \cdot \frac{\Gamma_\alpha \sin\theta_\alpha}{\Gamma_\beta \sin\theta_\beta}\right)\right]^{-1/2} \qquad \textbf{(Eq 13)}$$

where $F'(f\beta) \approx 0.03917 + 0.6047 f\beta - 1.413\ f_b^2 + 2.171\ f_b^3 - 1.236\ f_b^4$.

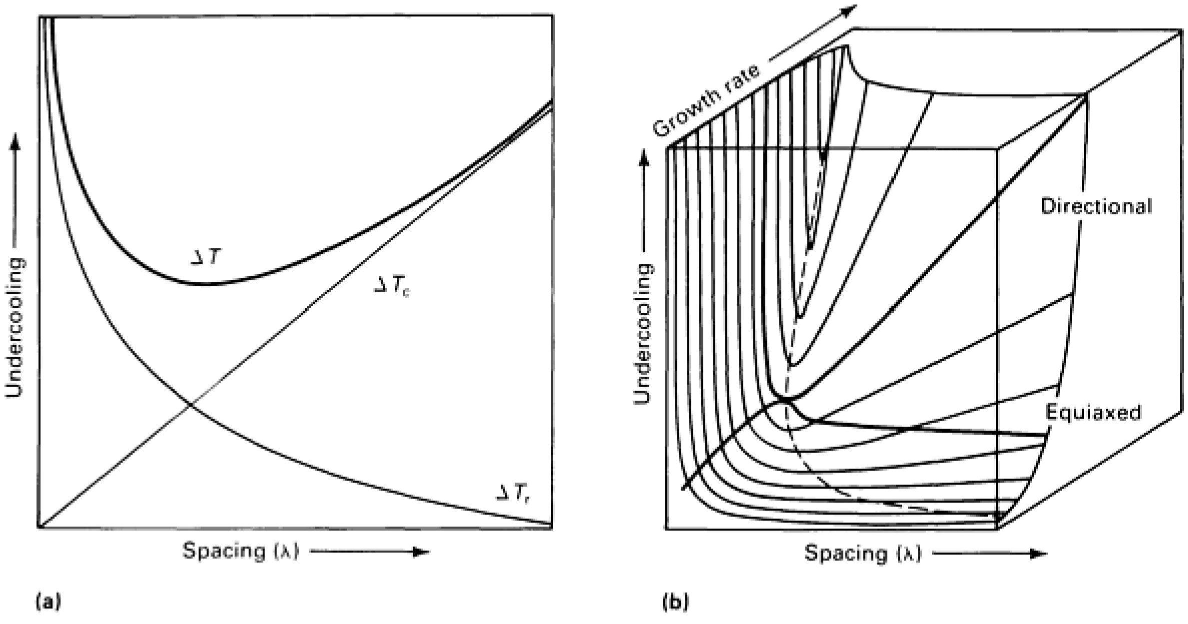

Fig. 15 Total growth undercooling of eutectic interface (Eq 9) as a function of spacing λ. (a) Constant growth rate. (b) Extremum valley (broken line) corresponding to minimum undercooling at an imposed solidification rate (directional growth) or to the maximum growth rate for a given undercooling (equiaxed growth). Appendix 2: Eutectic Growth at Very High Solidification Rates

Rapid solidification processing (for example, the laser surface treatment of eutectic alloys) has led to very interesting properties. The microstructures obtained are extremely fine, and spacings as small as 10 nm have been observed. It can be shown that Eq 10, 11, and 12 are no longer valid in this case (Ref 9). There are three main reasons for this, as follows.

First, at very high solidification rates, the sidewise diffusion shown in Fig. 8(b) becomes less effective because, as a result of the very high surface energy involved, the lamellar spacing decreases only as $1/\sqrt{R}$ (Eq 1), while the diffusion distance in the growth direction decreases as $1/R$. Therefore, the thermodynamic advantage of coupled eutectic growth as compared to separate growth (Fig. 8) is diminished and can even disappear completely.

Second, the high growth undercooling at high R values lowers the interface temperature where the diffusion occurs. The diffusion coefficient of the solute in the liquid decreases strongly when the temperature is lowered, thus slowing the growth rate and reducing the spacing.

Third, the parameter C_0 (Eq 4) is a function of the metastable phase diagram below the eutectic temperature and can differ significantly from its equilibrium value at high undercoolings. In addition, at very high solidification rates, solute segregation has no time to occur. The solute atoms are then trapped in the growing phases (Ref 10), and a metastable

supersaturated phase is formed. Because of these phenomena, there is a critical solidification rate (for many systems, of the order of 0.1 to 1 m/s) beyond which the eutectic microstructure can no longer form (Ref 9).

Solidification of Peritectics

H. Fredriksson, The Royal Institute of Technology, Sweden

Introduction

Peritectic reactions or transformations are very common in the solidification of metals. Many interesting alloys undergo these types of reactions--for example, iron-carbon and iron-nickel-base alloys as well as copper-tin and copper-zinc alloys.

Phase diagrams are very instructive when describing peritectic phase transformations. Figure 1 shows a phase diagram with a peritectic reaction. This diagram shows that, under equilibrium conditions, all alloys to the left of I will solidify to α crystals. Similarly, all alloys to the right of III will solidify to β crystals. Alloys between II and III first solidify to α crystals and then transform to stable β crystals. Alloys between I and II also solidify to α crystals, but they are partially transformed to β crystals later.

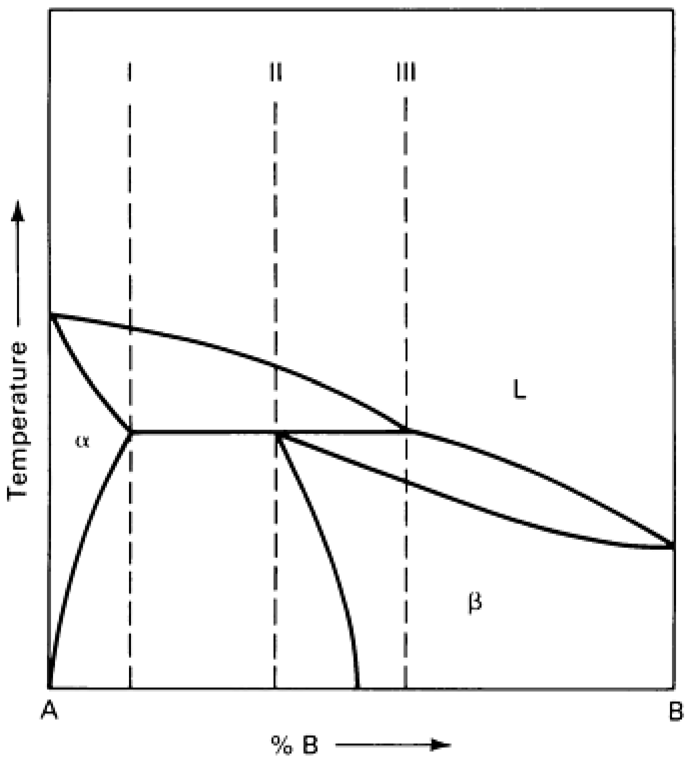

Fig. 1 Phase diagram with a peritectic reaction.

The volume fraction of each phase will be given by the lever rule if the alloy solidifies under equilibrium conditions (the lever rule is defined in the article "Interpretation and Use of Cooling Curves (Thermal Analysis)" in this Volume). In most cases, the lever rule will not give the volume fraction of the different phases. This is because the kinetics as well as the diffusion rate in the solid phases are determining the time for reaching equilibrium.

In this section, the kinetics involved in different peritectic systems will be discussed, and the definitions introduced by Kerr to distinguish between a peritectic reaction and a peritectic transformation will be used (Ref 1). During a peritectic reaction, all three phases (α, β, and liquid) are in contact with each other. In the peritectic transformation, the liquid and the α phase are isolated by the β phase. The transformation takes place by long-range diffusion through the secondary β phase. Later in this section, the reaction in multicomponent systems, particularly in iron-base alloys, will be discussed. The influence of different nucleation conditions for the secondary phase will also be addressed. Finally, the possibility of precipitating metastable β crystals instead of a crystals in an alloy with a composition to the left of point III in Fig. 1 will be reviewed. Additional information is available in the article "Peritectic Structures" in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Peritectic Reaction

Depending on surface tension conditions, two different types of the peritectic reactions can occur:

- Nucleation and growth of the βcrystals in the liquid without contact with the α crystals
- Nucleation and growth of the βcrystals in contact with the primary α phase

In the first case, the secondary phase is nucleated in the liquid and does not contact the primary phase. This is because of the surface tension conditions. Following nucleation, the secondary phase grows freely in the liquid. At the same time, the primary phase will dissolve. The secondary phase will not develop a morphology similar to a precipitated primary phase. This type of peritectic reaction has been observed for the reaction $\gamma + L \rightarrow \beta$in the Al-Mn system (Ref 2). There has also been a tendency for the secondary phase to grow around the primary phase at increasing cooling rates. Similar reactions have been observed in Ni-Zn (Ref 3) and Al-U (Ref 4) systems.

In the second type of reaction, which is the most common, nucleation of the secondary β phase occurs at the interface between the primary α phase and the liquid. A lateral growth of the β phase around the α phase then takes place. This type of reaction is illustrated in Fig. 2 and 3. Figure 2 shows the growth process in a unidirectionally solidified copper-tin alloy containing 70% Sn, in which the ε phase and the liquid react to produce the η phase. Figure 3 shows how the precipitated primary phase will partially dissolve by diffusion of solute through the liquid from the secondary phase boundary to the primary phase boundary.

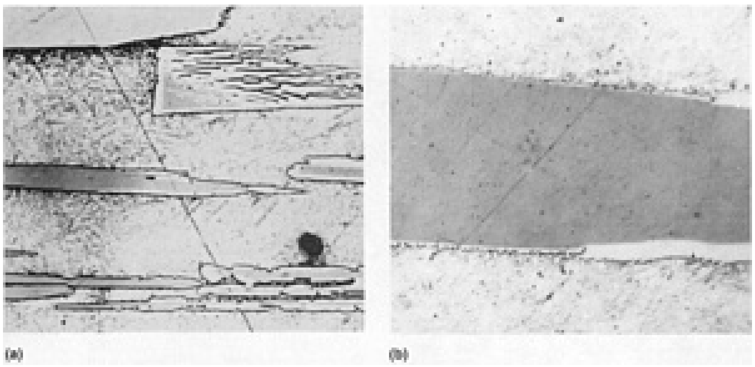

Fig. 2 Peritectic reaction (a) in a unidirectionally solidified Cu-70Sn sample. (b) Larger magnification of the middle section of (a).

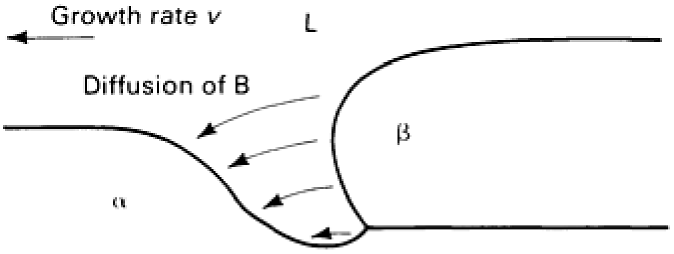

Fig. 3 Peritectic reaction by which the secondary solid β phase grows along the surface of the primary solid α phase.

A remelting process is normally much faster than a solidification process and there are no forces hindering dissolution. The dissolution will therefore occur at the same rate as the precipitation of the secondary phase. Using the maximum growth rate theory described in Ref 2, it can be shown that the thickness of the secondary phase is influenced by the growth rate and by the surface tension σ, where the expression $\sigma^{L/\beta} + \sigma^{\alpha/\beta} - \sigma^{L/\alpha}$ is the dominating factor. The larger this expression, the thicker the β layer will be.

Nucleation of the secondary phase on the primary phase is sometimes favored. When this occurs, a number of crystals will be formed around the primary phase. This type of reaction has been reported in Ref 3 for the Cd-Cu system and is illustrated in Fig. 4.

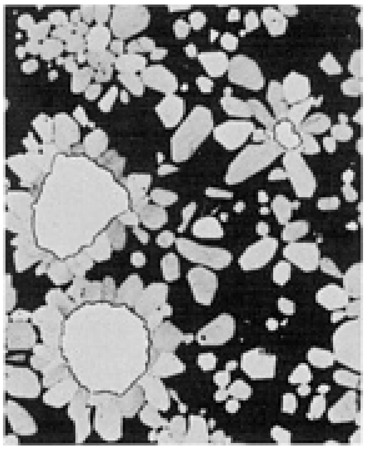

Fig. 4 Microstructure in a Cd-10Cu sample that has passed a peritectic reaction. The primary Cu_5Cd_8 crystals are white, the dark matrix is cadmium, and the peritectically formed $CuCd_3$ is gray.

The Peritectic Transformation

The thickness of the β layer will normally increase during subsequent cooling. There are three reasons for this:

- Diffusion through the β layer
- Precipitation of β directly from the liquid
- Precipitation of β directly from the α phase

The precipitation of β directly from the liquid and the solid depends on the shape of the phase diagram and the cooling rate. The diffusion process through the β layer depends on the diffusion rate, the shape of the phase diagram, and the cooling rate.

To explain the transformation process, an isothermal case will first be analyzed. This has been discussed in Ref 5 and 6. From those calculations, one can assume that the growth of the β layer is controlled by the diffusion through it at a temperature just below the peritectic temperature. The diffusion process and the concentration profile and its relation to the phase diagram are illustrated in Fig. 5.

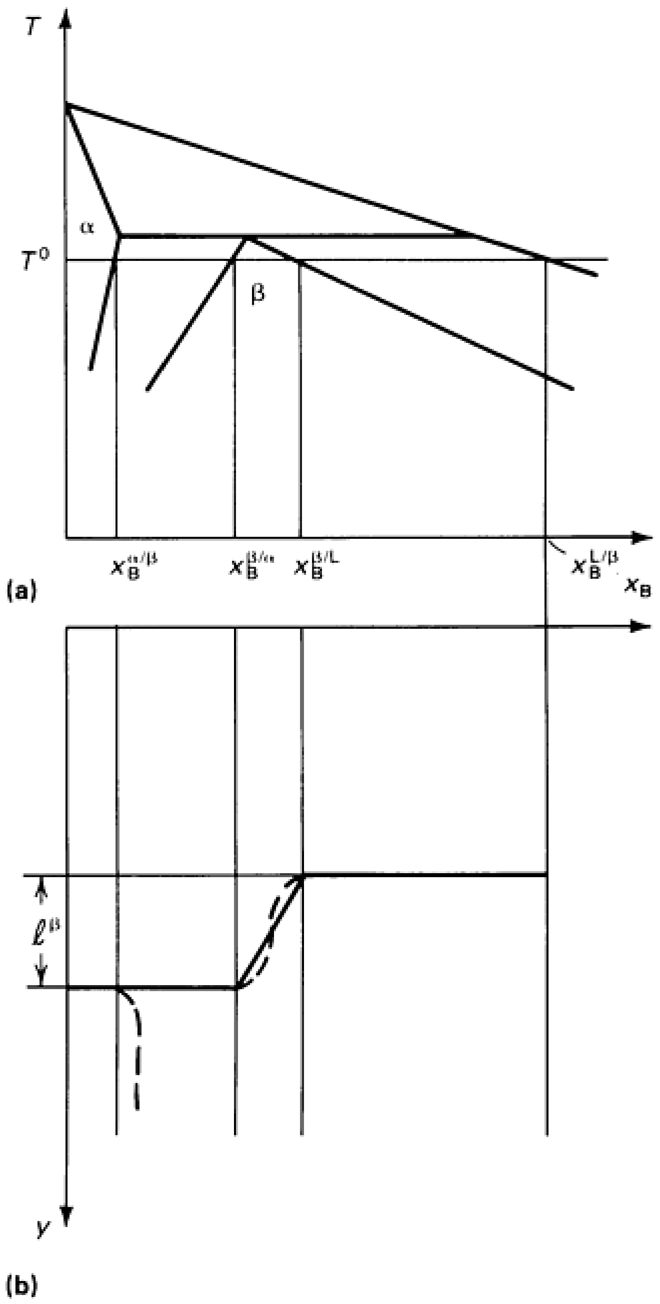

Fig. 5 The peritectic transformation in a system with a high diffusion rate in the β phase. (a) The phase diagram. (b) Concentration distribution. The dashed lines in the concentration profile are for a system with a low diffusion rate in the βphase where the volume fraction of β increases with decreasing temperature. See Eq 6 and corresponding text. See also Fig. 7(b).

A mass balance gives the following:

$$a \rightarrow b : \frac{(x^{b/L} - x^{b/a})}{\mathbf{l}^{b}} = \frac{d\mathbf{l}^{b/a}}{dt}.(x^{b/a} - x^{a/b}) \qquad \textbf{(Eq 1)}$$

and

$$L \to b : D^b \frac{(x^{b/L} - x^{b/a})}{\mathbf{l}^b} = \frac{d\mathbf{l}^{b/L}}{dt}.\left(x^{L/b} - x^{b/L}\right) \quad \textbf{(Eq 2)}$$

where $\mathbf{l}^b$ is the thickness of the β phase, *t* is the time, and D^β is the diffusion coefficient in the β phase. All other terms are concentrations that are defined in Fig. 5:

$$\frac{d\mathbf{l}^b}{dt} = \frac{d\mathbf{l}^{b/a}}{dt} + \frac{d\mathbf{l}^{b/L}}{dt} = \frac{D^b}{\mathbf{l}^b}.(x^{b/L} - x^{b/a}).\left(\frac{1}{x^{b/a} - x^{a/b}} + \frac{1}{x^{L/b} - x^{b/a}}\right) \quad \textbf{(Eq 3)}$$

Integrating Eq 3 results in:

$$(\mathbf{l}^b)^2 = D^b.(x^{b/L} - x^{b/a}).\left(\frac{1}{x^{b/a} - x^{a/b}} + \frac{1}{x^{L/b} - x^{b/a}}\right) \quad \textbf{(Eq 4)}$$

Equations 3 and 4 show that the growth rate increases with increasing undercooling. For example, at the peritectic temperature, the expression $(x^{\beta/L} - x^{\beta/\alpha})$ is 0 and increases with increasing undercooling. Equations 3 and 4 also show that the growth rate is dependent on the diffusion coefficient. For substitutionally dissolved alloying elements in face-centered cubic metals, the diffusion coefficient near the melting point is of the order of $\leq 10^{-13}$ m^2/s. In such a case, the growth rate will be very low and the time for the peritectic transformation will be unrealistically large. In a normal casting process, the reaction rate will be so low that the amount of β phase formed by the peritectic reaction will be negligible in comparison with the precipitation of β from the liquid. For body-centered cubic metals and for interstitially dissolved alloying elements, the diffusion rates are much higher than for substitutionally dissolved elements in face-centered cubic metals. The diffusion process has in this case a much larger influence on the precipitation process.

The peritectic transformation in iron-carbon alloys will be analyzed in the following paragraphs. The iron-carbon phase diagram is very similar to the diagram illustrated in Fig. 5(a). A detailed numerical calculation of the transformation for one alloy has been performed (Ref 7). However, a simpler analytical model will be used in this discussion (Ref 8). The model is the same as the isothermal model described earlier, but is used with the assumption that the boundary conditions change during cooling. Equation 3 can therefore be used. In Eq 3, $d\mathbf{l}^b/dt$ can be expanded to $(d\mathbf{l}^b/dT)(dT/dt)$, where dT/dt is the cooling rate of the sample. Using the phase diagram, the concentrations can be transferred to a temperature. If the slope of the lines in the phase diagrams and the cooling rate are both assumed to be constant, Eq 3 can be simplified in the following way:

$$\mathbf{l}^b d\mathbf{l}^b = A.\frac{dt}{dT}.dT \quad \textbf{(Eq 5)}$$

where A is a constant. By integrating Eq 5 under the assumption of a constant cooling, one can obtain a relation that can be used to calculate the temperature interval under which the peritectic transformation takes part. This has been done in Ref 8, and the result of those calculations are shown in Fig. 6. Figure 6 shows that the peritectic reaction in iron-carbon alloys is very rapid and is finished at a maximum of 6 to 10 K below the peritectic temperature. The shape of the curve is a result of the change in the volume fraction of ferrite with the carbon content. The curve is in agreement with the results of other experiments (Ref 7, 9).

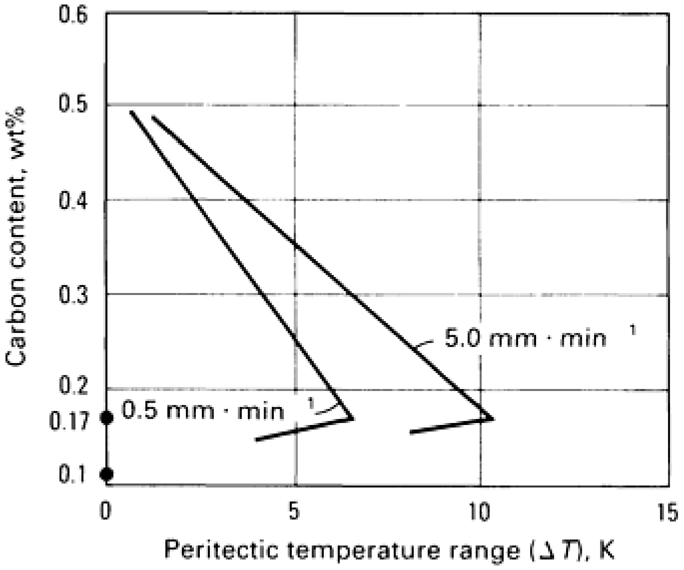

Fig. 6 Temperature range of peritectic reaction in iron-carbon alloys as a function of carbon content and the solidification rate. The temperature gradient *G* is 6000 K/m.

In addition to the effect of the growth of the β layer due to diffusion, the effect of the phase diagram must also be considered. This was not taken into consideration when deriving Eq 3 and in the above discussion for iron-carbon alloys. The effect of the phase diagram is illustrated in Fig. 5(a) and 7(a). Figures 5(a) and 7(a) show two different types of phase diagrams, in which the slopes of the α/β regions are different. In the first case (Fig. 5a), the β layer will increase in thickness both at the interface α/β and at the interface β/L. In the second case (Fig. 7a), the β layer will increase only at the side against the liquid and will decrease at the side against the α phase. These two cases are somewhat more difficult to treat theoretically than the isothermal example or the case involving a high diffusion rate.

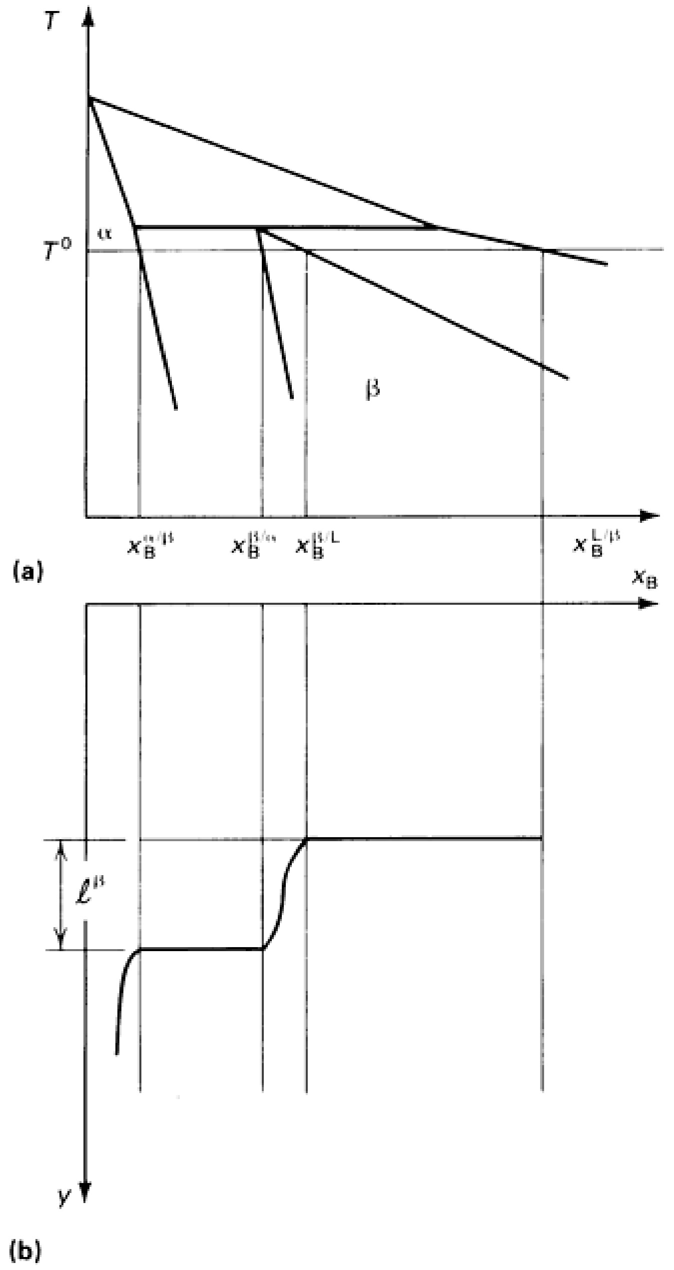

Fig. 7 The peritectic transformation during continuous cooling in a system with a low diffusion rate and where the volume fraction of β increases with decreasing temperature. (a) The phase diagram. (b) Concentration distribution.

The concentration profiles for the transformation are given in Fig. 5(b), as shown by the dashed lines, and 7(b). Equation 3 will now be changed in the following way:

$$\frac{d\mathbf{l}^b}{dt} = \frac{D^b}{(x^{a/b} - x^{b/a})} \cdot \left(\frac{dx^b}{dy}\right)_{y=\mathbf{l}^{a/b}} + \frac{D^b}{x^{L/b} - x^{b/L}} \left(\frac{dx^b}{dy}\right)_{y=_{y=\mathbf{l}^{b/L}}} + \frac{D^a}{x^{a/b} - x^{b/a}} \left(\frac{dx^a}{dy}\right)_{y=\mathbf{l}^{a/b}} + \frac{\mathbf{l}^L dx^L}{x^{L/b-} x^{b/L}} \qquad \textbf{(Eq 6)}$$

where the first and second terms on the right-hand side describe the increase in thickness due to diffusion into the β phase and α phase, respectively, from the boundary α/β. The third term describes the increase in thickness due to diffusion into the β phase from the boundary β/L. The last term is the increase in the β phase due to the changing of the composition in the liquid dx^L with a decrease in the temperature dT according to the phase diagram.

Solving Eq 6 is a difficult task that can be accomplished only by using numerical methods. One simplification of this equation has been performed (Ref 2). It was assumed that the diffusion distance corresponded to the thickness of the β phase and that there are no concentrating gradients in the α phase. The results of these calculations for a Cu-20Sn alloy are shown in Fig. 8. A close agreement was achieved between the experiments and the theory.

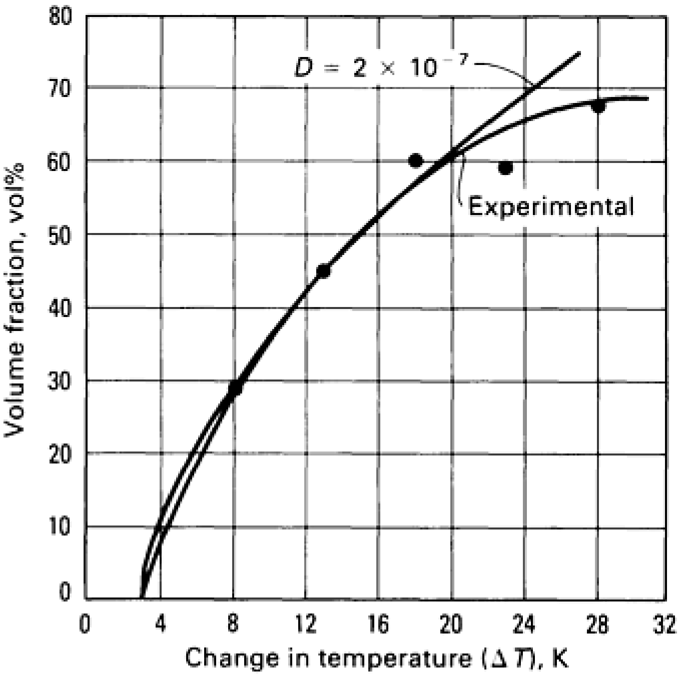

Fig. 8 Thickness of the secondary phase layer as function of temperature below the peritectic temperature in the Cu-Sn system. The solidification rate was 100 mm/min. The diffusion units are given in cm^2/s. The volume fraction is defined as $1^b/\lambda$ where λ corresponds to the dendrite arm space.

Equation 6 has been solved in Ref 8 by assuming that diffusion into the β phase could be described in the same manner as in Ref 10 for back diffusion during segregation at a primary precipitation. The model was used to calculate the concentration distribution of austenite for iron-nickel alloys, as shown in Fig. 9. These calculations are in agreement with experiments reported in Ref 11 and 12.

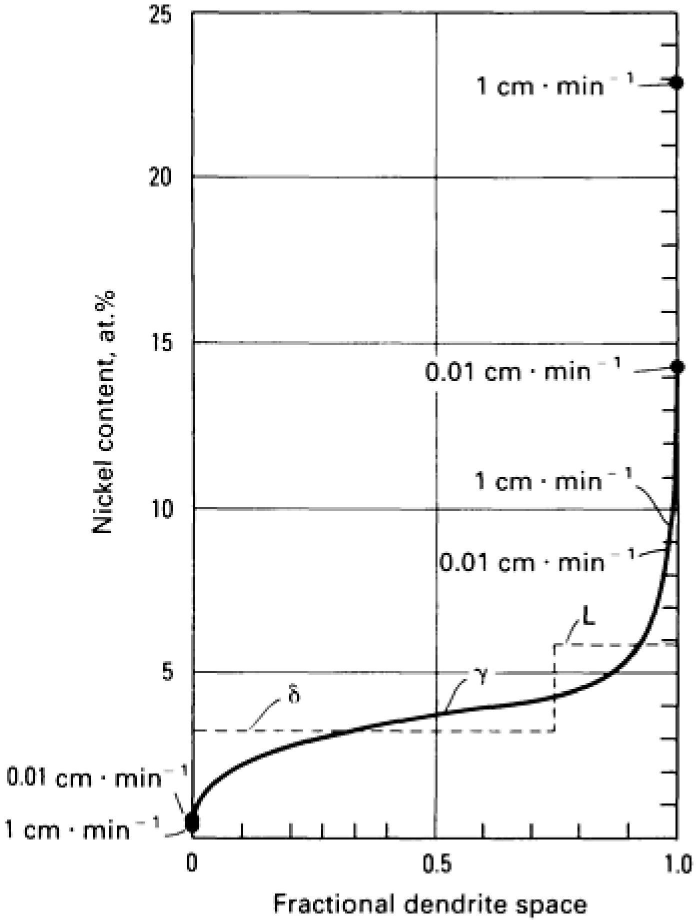

Fig. 9 Nickel distribution after peritectic reaction in a steel containing 4 wt% Ni. The temperature gradient was 60 K/cm. Calculations were made at different solidification rates. The dotted line shows the nickel distribution at the start of the peritectic reaction. δ is primary ferrite, γ is austenite. Source: Ref 11.

Cascades of Peritectic Reaction

The theoretical analysis shows that the rate of the peritectic transformation is influenced by the diffusion rate and the extension of the β phase region in the phase diagram. If the diffusion rate is small, the peritectic transformation will be negligible compared to the peritectic reaction. The thickness of the β phase envelope surrounding the α phase is determined by the peritectic reaction followed by an increase in thickness due to a precipitation directly from the liquid.

In many systems, one peritectic reaction at a high temperature is followed by one or more peritectic reactions at lower temperatures. If the diffusion rate is low in the initially formed peritectic layer, a second peritectic layer can be formed when the second peritectic temperature is reached. This type of series of peritectic reactions, referred to as a cascade, has been studied in Ref 3. The resulting microstructure formed in a Cd-25Ni alloy is shown in Fig. 10.

Primary Metastable Precipitation of Beta

In many systems, the secondary β phase has been observed to form as a primary phase for alloys with a composition on the left-hand side of point III in Fig. 1. This is especially true for iron-base alloys (Ref 11, 12).

The possibility of forming a metastable β phase directly from the liquid will now be examined. Different cooling rates will be chosen, and binary iron-nickel alloys will be considered. In Fig. 11, the metastable extensions of the equilibrium between liquid and ferrite and between liquid and austenite are represented by broken lines. The melting point of pure iron as austenite is 11 °C (20 °F) below the melting point of pure iron as ferrite. It can be seen that there is a difference in the partition coefficient between ferrite and liquid on one hand and austenite and liquid on the other.

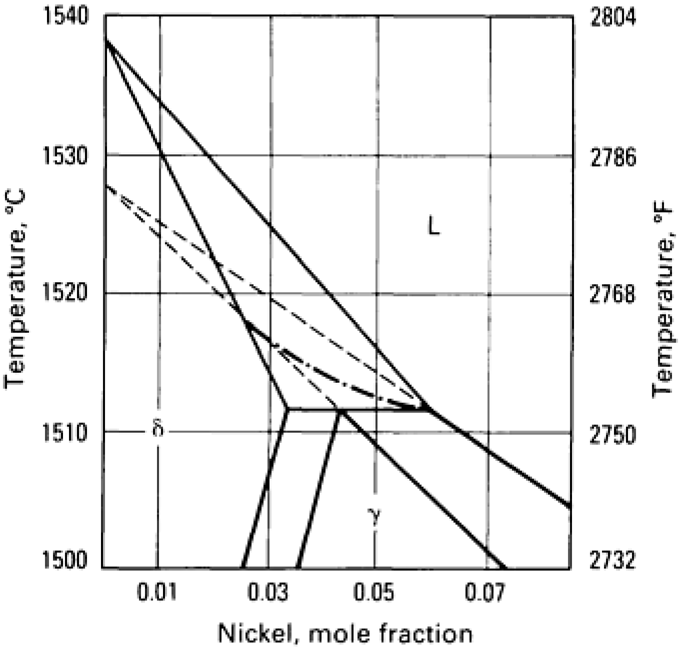

Fig. 11 The binary Fe-Ni system. The broken line shows the undercooling at which ferrite, δ, and austenite, γ, grow at the same rate. Source: Ref 13.

The growth rates were calculated for needles of ferrite and austenite. The alloy composition is chosen to the left of the peritectic point, and the calculations of the growth rates were carried out for different undercoolings.

Only ferrite can form at low undercoolings. Austenite can also form if the temperature is chosen just below the extension of its liquidus line, but ferrite grows faster and should therefore dominate in the solidification process. However, below a critical line, austenite will have the highest growth rate and may dominate, although the temperature is still above the peritectic temperature. This kinetic advantage of austenite is due to its partition coefficient being smaller than that for ferrite. The critical line is indicated by a broken line in Fig. 11. The partition coefficient of an element can be closer to unity for ferrite than for austenite in ternary alloys and ferrite will then have the kinetic advantage and will be favored by a high cooling rate.

It has also been reported that an aligned structure can be formed in peritectic systems (Ref 14). However, it has been argued that this type of structure is formed when α and β primary phases are growing at the same rate (Ref 2). In addition, the composition of the liquid must be chosen so the sum of the volume fraction of the two solid phases will be unit.

Peritectic Transformations in Multicomponent Systems

Alloys often consist of more than two alloying elements. However, very little information is given in the literature about the peritectic reaction in multicomponent alloys. Recent investigations of iron-base alloys have shown that peritectic reactions are very common in stainless steels (Ref 11, 15). The peritectic reaction in these alloys gives the same type of distribution as that shown in Fig. 9. In stainless steels, the peritectic reaction will transfer to a eutectic reaction if the chromium content is increased to 20% or more. This transition is also influenced by the molybdenum content, as shown in Fig. 12.

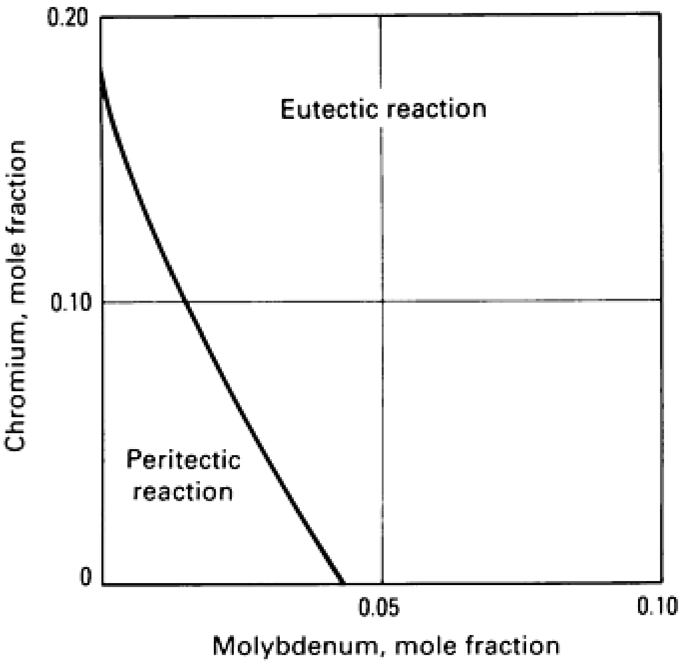

Fig. 12 The transition from a peritectic to a eutectic reaction as a function of chromium and molybdenum content in a stainless steel containing 11.9% Ni.

Both chromium and nickel are substitutionally dissolved elements. Iron-base alloys often consist of carbon with some other elements. Carbon is interstitially dissolved and has a very high diffusion rate. The other alloying elements are primarily substitutionally dissolved with very low diffusion rates. This gives rise to transformations that are determined by the movement of the substitutional elements, and carbon is distributed according to equilibrium conditions. As a result, a normal peritectic transformation does not occur. To fulfill the criterion that carbon should follow the equilibrium conditions, liquid must be formed at the border between ferrite and austenite. This reaction is illustrated in Fig. 13. This type of reaction has been both experimentally and theoretically analyzed in Ref 15.

Columnar to Equiaxed Transition

S.C. Flood, Alcan International Ltd., Great Britain; J.D. Hunt, University of Oxford, Great Britain

---

Introduction

IN GENERAL, as-cast metal exhibits three distinct zones of grain structures:

- A chill zone of very small crystals produced by rapid cooling at the extreme edge
- A zone of long, thin columnar crystals lying along the direction of heat flow and stretching in from the chill zone
- A region of roughly spherical equiaxed crystals at the center of the casting

All three zones may not be present in a particular case; however, when a casting contains columnar and equiaxed grains, the transition between the two morphologies (the columnar to equiaxed transition) is usually narrow, and the columnar and equiaxed zones are quite distinct. A great deal of effort has been devoted to understanding the mechanisms behind the development of macrostructure during solidification because the grain structure influences the properties of a casting and the worked metal inherits characteristics from the as-cast state. This section will focus on the formation of the equiaxed zone as the crucial process that determines macrostructure.

In the absence of an equiaxed zone, the casting will be wholly columnar. Equiaxed grains grow ahead of the columnar dendrites, and the columnar to equiaxed transition occurs when these equiaxed grains are sufficient in size and number to impede the advance of the columnar front. The extent of the equiaxed zone is the result of competition between the columnar and the equiaxed grains. The formation of an equiaxed zone requires both:

- The presence of nuclei in the bulk
- Conditions that promote their growth relative to the columnar dendrites

In the 1960s and 1970s, the tendency was to explain trends in the columnar to equiaxed transition only in terms of different mechanisms for the supply of equiaxed nuclei. It was assumed that the nuclei will develop into an equiaxed zone if they are present. The ability and tendency of the grains to grow were not considered. However, if the equiaxed growth is slow relative to the columnar or if it is restricted to a narrow undercooled region ahead of the columnar front, then, although equiaxed nuclei are present, the columnar growth could still dominate the macrostructure; it would simply absorb the small equiaxed grains as it advances. Grain growth was neglected until recently, but over the last few years, many papers have considered this aspect of equiaxed zone formation. The important processes of sedimentation and convective motion of the grains have yet to be covered satisfactorily.

Influence of Casting Parameters

Macrostructure is found to be affected by such factors as superheat, alloy system, composition, fluid flow, mechanical disturbance, inoculation, and the addition of grain refiner, and casting size. The important trends are summarized in Table 1. The various mechanisms and models for the columnar to equiaxed transition need to be discussed and evaluated with reference to these experimental observations.

Table 1 Casting parameters affecting macrostructure

Casting variables	**Effects**	Ref
Superheat	Increased superheat increases the extent of columnar growth; the trend is less noticeable in large castings.	**1, 2, 3, 4, 5, 6, 7, 8**
Alloy system	Low values of $-m_L(1 - k)C_o/k$ favor columnar structure; high values, equiaxed structure.	**7, 9, 10, 11**
Composition	Increased alloying content (C_o) tends to decrease the extent of columnar region; some investigators report that the columnar region is not a simple function of alloy concentration.	**5, 6, 7, 8, 9, 10, 11, 12**

Fluid flow (natural or forced)	Increased fluid flow decreases the extent of the columnar region.	**1, 2, 3, 5, 13, 14, 15, 16**
Inoculation grain refining	Producing nuclei is not sufficient to give an equiaxed zone. Grain size is cooling rate dependent. Grain-refining additions can reduce the extent of columnar growth.	**5, 6, 11, 17, 18, 19**
Mechanical vibration	Mechanical vibration promotes grain refinement and can extend the equiaxed zone.	**20, 21**
Size	**Superheat has less effect on the grain structure of large castings. Increasing cross section yields increasing proportion of equiaxed grains. Most sensitive to height of casting**	**3, 7, 22**

Origin of the Equiaxed Nuclei

The production of an equiaxed zone requires the existence of small crystallites, or nuclei, in the bulk during freezing. Three mechanisms for the provision of these nuclei have been proposed, and they are used to form the basis for the discussion of the effect of the casting parameters on columnar to equiaxed transition:

- Constitutional supercooling driven heterogeneous nucleation
- Big bang mechanism
- Dendrite detachment mechanism

Experimental observations were interpreted as proving one mechanism to be valid at the expense of the other two. In retrospect, however, the view that the nucleation of grains in the bulk occurs by a single mechanism is unrealistically limited, because both the big bang and dendrite detachment mechanisms are strongly supported by the experimental evidence.

Constitutional Supercooling Driven Mechanism. It has been proposed that sufficient constitutional supercooling (CS) might be produced ahead of the growth front to cause the heterogeneous nucleation of equiaxed grains (Ref 23). Researchers have predicted that constitutional supercooling exists ahead of a planar front when (Ref 24):

$$\frac{G_L D}{v} < \frac{-m_L C_o (1-k)}{k} \quad \textbf{(Eq 1)}$$

where G_L is the temperature gradient in liquid, v is the velocity, m_L is the liquidus slope, C_o is the initial alloy composition, k is the distribution (or equilibrium partition) coefficient, and D is the solutal liquid diffusion coefficient.

The right-hand side of Eq 1 is the constitutional supercooling parameter. Constitutional supercooling also occurs ahead of cells and dendrites, but is less than that ahead of a planar front because, in cells and dendrites, solute is rejected laterally, as well as forward.

The fact that constitutional supercooling exists in the bulk melt during the freezing of an alloy is not disputed. It can be easily measured and is usually necessary for the growth of grains ahead of the columnar front (pure materials do not freeze in an equiaxed fashion under normal casting conditions, although they can be made to do so by vigorous stirring both to fragment the growth front and to remove the bulk superheat).

Furthermore, CS-driven heterogeneous nucleation is obviously important when an efficient substrate, such as a grain refiner or inoculant, is present. However, the evidence that it is generally the crucial mechanism determining the columnar to equiaxed transition is not convincing. This evidence falls into two groups.

First, many workers have reported correlations at the columnar to equiaxed transition between C_o and a combination of G_L and v, namely, G_L/v or $G_L/v^{0.5}$ (Ref 12, 25, 26, 27, 28, 29, and 30). Because these quantities affect the degree of constitutional supercooling ahead of the columnar front (Eq 1), these correlations were thought to provide evidence for the CS-driven nucleation mechanism.

Second, a correlation between the constitutional supercooling parameter and macrostructure is observed experimentally. Low values of the constitutional supercooling parameter were found to give large-grain columnar structures, while high values produced equiaxed structures (Ref 9). It has been shown that the size of the equiaxed zone was related to the constitutional supercooling parameter (Ref 10).

However, the relationship among C_o, G_L, and v at the columnar to equiaxed transition and the dependence of the equiaxed zone on the constitutional supercooling parameter can be rationalized in terms of the growth of the grains, and it does not necessarily indicate the influence of constitutional supercooling on heterogeneous nucleation. The variables G_L, v, and C_o affect the growth of the equiaxed grains by controlling the degree and extent of the undercooled liquid in the bulk. A simple steady-state growth analysis suggests that some relationship of the form $G_L/v \propto C_o$ at the columnar to equiaxed transition is not unexpected, owing to the influence of these variables on the growth of the grains (see the section "Predicted Versus Observed Behavior" in this article). Furthermore, the same combination of variables that is the constitutional supercooling parameter also appears in the growth analysis, via the kinetic expression for the dendrite tips (Ref 11, 31, 32, 33, and 34).

The CS-driven nucleation mechanism has been criticized because constitutional supercooling in an alloy must exist ahead of the columnar front at an early stage of freezing (because the liquid temperature gradient drops rapidly and a solute layer is soon established ahead of the columnar front), but the columnar to equiaxed transition does not occur until some

time later (Ref 35, 36). Chalmers has shown, through the mechanical isolation of the center of a casting with a metal cylinder, that the CS nucleation mechanism is not solely responsible for equiaxed growth (Ref 35). The center solidified as fine, equiaxed grains without the cylinder, but when the center was mechanically isolated, these grains were replaced by fewer and coarser grains, even though the center was still constitutionally supercooled. In addition, another researcher has shown that equiaxed grains can be produced in a melt in the absence of heterogeneous nuclei prior to solidification Ref 37, 38).

Big Bang Mechanism. In this mechanism, equiaxed grains result from the predendritic nuclei formed during pouring by the initial chilling action of the mold. The grains are then carried into the bulk by fluid flow and survive until the superheat has been removed (Ref 35). The survival of chill nuclei until the superheat is dissipated is quite likely at moderate superheats, because of the large latent heat of solidification of metals.

Big bang nucleation has been observed in cooled, saturated NH_4Cl solution (Ref 39, 40). A sharp change was noted, with increasing superheat, from a very large number to zero crystals remaining in the liquid after pouring. When nuclei produced by the initial chill survived, they grew into equiaxed crystals and settled to occupy only the bottom part of the casting.

Predendritic grains have been observed trapped in the columnar and equiaxed zones (Ref 41). They are rounded and smooth, as would be expected if they had been in contact with liquid for a long time. However, the origin of these nuclei is uncertain; although they could have originated during pouring, they might have been produced by dendrite remelting. The existence of the chill zone has been viewed as evidence in support of big bang nucleation.

Unlike the CS theory, the big bang theory can explain the effects of superheat and convection in the early stages of casting. Variations in superheat and convection do not significantly alter the onset and extent of constitutional supercooling in the melt, yet they do exert considerable influence on the cast structure (Ref 1, 2). Increasing the pouring temperature reduces the size of the equiaxed zone and coarsens the grain sizes, and reducing the convection by the introduction of a static magnetic field can eliminate the equiaxed zone altogether. The big bang mechanism provides two viable explanations:

- Increasing the superheat diminishes the chilling of the melt upon pouring and increases the time taken for the bulk superheat to dissipate; consequently, fewer nuclei are produced upon pouring; and fewer still survive to grow into equiaxed grains (Ref 40)
- Decreasing convection reduces the number of nuclei formed at the edges of a casting that reach the center

Chalmers suggested that mechanically isolating the center of the casting alters the macrostructure by obstructing the flow of chill nuclei (Ref 35). However, another researcher modified Chalmers experiment by leaving a gap at the bottom of the central cylinder (Ref 42). Thus, the grain structure at the center was shown to be the same whether the casting was filled by pouring down the central tube or into the outer section. This cast doubt on the Chalmers big bang interpretation because the two pouring arrangements (down the central tube or into the outer section) should have washed different numbers of chill nuclei into the central section if the mechanism were operative. Another weakness of the big bang theory is its inability to account for equiaxed zone formation in the absence of a chilled mold (Ref 37).

Dendrite Detachment Mechanism. Other researchers noticed that convective mixing or stirring during solidification of organic analogs produced a large number of nuclei in the liquid (Ref 39). It was therefore postulated that fluctuations in the growth rate caused dendrite arms to melt off and then float into the center (Ref 39). Remelting due to surface energy occurred under isothermal conditions, but recalescence, either locally or throughout the entire casting, was thought to be the main mechanism for dendrite arm detachment. Remelting was promoted by the presence of sufficient solute to alter appreciably the melting point of the solvent. It was proposed that convection could cause dendrite detachment mechanically because the yield point of the metal is negligible near its melting point (Ref 43). It was also demonstrated that side-arm remelting can occur at very low interdendritic fluid flow velocities (of the order of 40 $\mu m \cdot s^{-1}$, or 1600 $\mu in. \cdot s^{-1}$) (Ref 44).

The surface dendrite layer at the top of a casting is an important source of equiaxed grains (Ref 39, 45). Other researchers thought that the coarse equiaxed structure produced in their large castings, with high superheats and an applied constant magnetic field, was caused by grains showering from the top; the superheat and lack of convection would have been detrimental to the survival and creation of big bang nuclei and detached dendrite arms (Ref 3). Dendrite fragments

rejected ahead of the columnar front as a result of density-driven interdendritic flow and subsequent channeling are a further source of equiaxed grains (Ref 46).

Dendrite detachment is consistent with the influence of convection. Reducing the convection in the bulk by applying a static magnetic field (Ref 1, 2) or by utilizing the Coriolis force (Ref 13) reduces the extent of the equiaxed zone and coarsens the grains, or even eliminates the zone completely. Conversely, increasing the convection by imposing an alternating magnetic field promotes the equiaxed zone and refines the grain structure (Ref 14). Convection should favor dendrite detachment by mechanical means or local remelting and then transport the dendrite fragments ahead of the front. In delayed field experiments, researchers have found that the big bang and dendrite detachment mechanisms both operate (Ref 1). However, in the absence of pouring turbulence, the removal of the magnetic field when the central temperature reached the freezing plateau did not produce an equiaxed zone (Ref 2). This implied that the dendrite detachment mechanism did not operate. However, of the three nucleation mechanisms, only dendrite detachment can explain the formation of an equiaxed zone when heterogeneous nuclei were absent and the mold exerted no chilling effect (Ref 37).

Factors Supporting All Three Mechanisms. Constitutional supercooling would seem not to drive the nucleation of equiaxed grains except in the presence of a grain refiner or other efficient substrate. In the following section, it is seen that the effect of composition is probably due to its influence on the growth of the grains, not to its influence on their nucleation. There is strong evidence to support the big bang and dendrite detachment theories. Neither of the two mechanisms is compatible with all of the observations, but a combination of the two is consistent with most of them. In particular, the big bang theory can effectively explain the superheat effect (in terms of nucleation, but growth arguments can also rationalize the effect of superheat to some extent), and dendrite detachment is frequently observed in analogs and is consistent with the influence of convection on macrostructure. The big bang and dendrite detachment mechanisms would appear to be very efficient. Many big bang nuclei are probably produced upon pouring if the mold is cold, and it is likely that the dendrite detachment mechanism will provide a large number of nuclei during solidification because of the ease of fragmentation of the dendrites. Additional information on nucleation, solidification, and structure is available in the articles "Nucleation Kinetics," "Basic Concepts in Crystal Growth and Solidification," "Solidification of Eutectics," "Solidification of Peritectics," "Microsegregation and Macrosegregation," "Behavior of Insoluble Particles at the Solid/Liquid Interface," and "Low-Gravity Effects During Solidification" in this Volume.

Growth of Equiaxed Grains

Two modes of equiaxed growth have been observed (Ref 4, 40, 47, 48, and 49):

- Grains in the bulk that sediment out to form a pile at the base of the casting which then impede the advancing columnar front
- Equiaxed grains attach themselves to the columnar front and then start to develop some columnar characteristics

Sedimentation produces the fully equiaxed zone, and adhesion gives the branched columnar structure (Ref 4, 40, 47, 48, and 49). The combination of sedimentation and adhesion leads to a macrostructure of the form shown schematically in Fig. 1. The branched columnar zone increases with height because the front is obstructed at a later time by the sedimenting grains at higher positions. Sedimentation is due to the change in the density of the grain as a result of solidification shrinkage (~6%), not because of solute rejection during freezing, because most of the rejected solute is trapped interdendritically within the envelope of the grain.

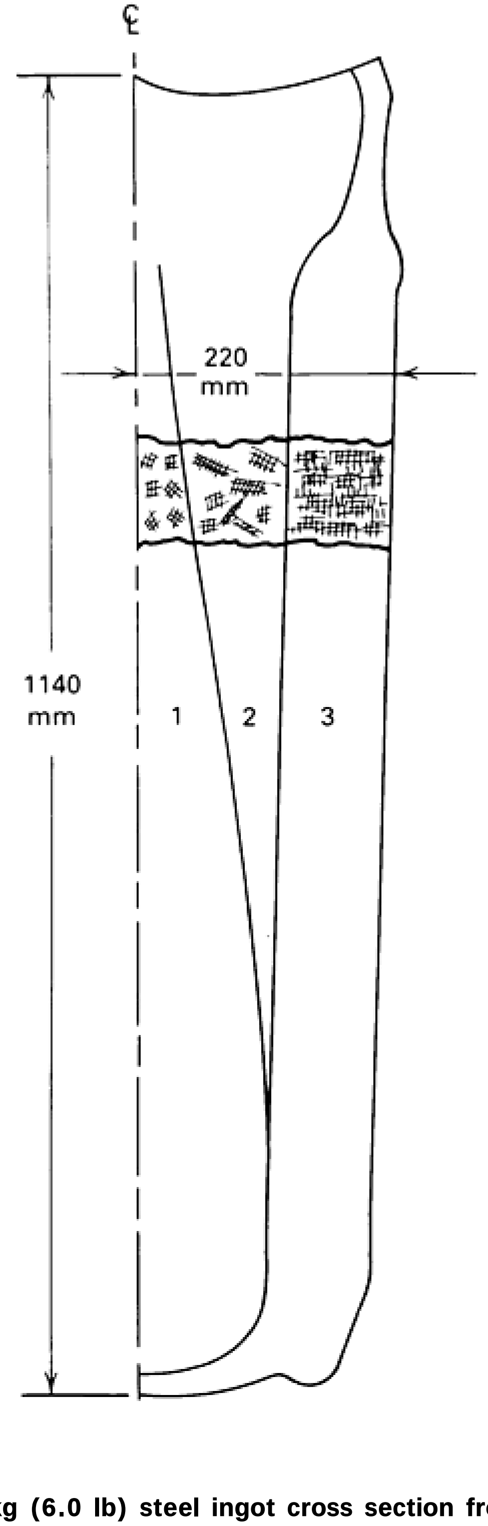

Fig. 1 Structure diagram of a 2.7 kg (6.0 lb) steel ingot cross section from a 220 × 220 mm (8.7 × 8.7 in.) square ingot that is 1140 mm (44.9 in.) long. Diagram illustrates equiaxed (1), branched columnar (2), and columnar (3) crystals. Source: Ref 6

Analog investigations have shown that equiaxed growth starts at an early stage in an undercooled layer just ahead of the columnar dendrite tips, before the superheat has been removed from the center of the casting (Ref 40, 50, 51). Calculations support this and indicate that two regions can arise (Ref 5, 52):

- Equiaxed growth continues to be confined to a narrow undercooled layer; the dimensions of the layer then determine the extent of the equiaxed growth
- Superheat is removed from the center at an early stage; equiaxed growth then occurs right to the center

In the first case, the equiaxed growth might be sufficient to obstruct the columnar dendrites. Growth then continues by the inward movement of an equiaxed front. The continuation of the equiaxed nature of the front requires a sufficiently frequent rate of adhesion of equiaxed crystals from the bulk; otherwise, the attached equiaxed grains at the front will develop a columnar character (Ref 6).

An equiaxed zone forms when the equiaxed grains in the bulk are sufficient in number and grow rapidly enough to obstruct the columnar front. There is a growth competition between the columnar and equiaxed grains. The crucial factors that determine the outcome are the degree and extent of the constitutional supercooling in the liquid, and the velocity of the columnar front. It is possible for equiaxed nuclei to exist ahead of a columnar front and yet not develop into an equiaxed zone because of the conditions being unfavorable for their growth.

An equiaxed zone is encouraged by a shallow temperature gradient in the bulk. Several investigations have shown that the equiaxed zone can be reduced or suppressed by maintaining higher temperatures in the melt and by reducing natural convection (Ref 13, 15). For example, the thermal gradient and bulk temperature were both found to be greater in space experiments than on earth; and nuclei introduced ahead of a columnar front in space did not grow, while on earth the same casting arrangement yielded a large equiaxed zone (Ref 16). It was also suggested that electromagnetic stirring promotes equiaxed growth not by increasing the dendrite detachment but by flattening the thermal profile in the bulk and increasing the rate of heat transport, because, even without stirring, natural convection is sufficient to create a large number of nuclei (Ref 53).

Growth Models

Early work on the columnar to equiaxed transition concentrated on the production of new crystals, but recently more attention has been paid to their growth. Lipton *et al.* (Ref 7), Fredriksson and Olsson (Ref 6), and Flood and Hunt (Ref 5, 52) have produced models of the competition between the columnar and equiaxed grains. In all three models, a columnar front advances into a melt, and equiaxed grains grow ahead of it. The important result of these models is that they reproduce the experimentally observed trends in the columnar to equiaxed transition by considering the growth of the equiaxed grains and without recourse to nucleation arguments. A fixed number of potential grains per unit volume was assumed to exist in the bulk at all times throughout a simulation. The discussion that follows points out the salient features of these models.

Description of Columnar Front. Lipton *et al.* and Fredriksson and Olsson specify the velocity with a $t^{-0.5}$ relation and then deduce the front undercooling from an expression linking velocity and undercooling. Lipton *et al.* use the Kurz-Fisher expression (Ref 54), and Fredriksson and Olsson use a parabolic relation.

On the other hand, Flood and Hunt calculate the velocity and undercooling dynamically throughout the calculation. They do not fix these parameters *a priori*, because this might prejudice the outcome of the competition between the columnar and equiaxed growth. Unlike the other two models, the Flood-Hunt model accounts for the thermal interaction between the front and the equiaxed grains. The front velocity and undercooling are obtained by invoking continuity of heat flow at the columnar dendrite tips in conjunction with Burden-Hunt velocity relation (which reduces to a $v \propto (\Delta T)^2$ relation in the limit of low gradient) (Ref 31, 32, 33, and 34). The columnar dendrites are modeled as Scheil shapes truncated at a varying undercooling, that is, the solid fraction in the columnar region is described by the Scheil equation up to the tip temperature. The Scheil assumption is good because the mixing of the solute is nearly complete within a very short distance behind the dendrite tips.

Description of Equiaxed Grains. Lipton *et al.* assume the grains to be spherical, with a growth rate controlled by the rate of diffusion of latent heat into the liquid. They relate the final grain size to the square root of the mean temperature difference between the grain and the surrounding liquid, and the duration of this undercooling.

Flood and Hunt and Fredriksson and Olsson adopt a different and arguably more realistic treatment. They describe the grains as bundles of dendrites growing at a rate dependent on the square of the local bulk undercooling. This law introduces the solute diffusion away from the equiaxed dendrite tips. The dendrite tips are assumed to be at the local bulk undercooling, which is a good approximation owing to the high thermal diffusivity of metals; the thermal diffusion fields of neighboring grains will soon overlap. Flood and Hunt and Fredriksson and Olsson include the latent heat liberated by the equiaxed grains. The former assume that the internal solid fraction of the grains is the Scheil fraction for the local temperature; that is, they assume complete interdendritic mixing. On the other hand, Fredriksson and Olsson assume it to be a constant value (of 0.3). The grains are assumed to be stationary in the bulk, but Flood and Hunt argue that, when they consider convective mixing in the bulk, they are in effect allowing for complete mixing of liquid and grains.

Flood and Hunt accounted for the impingement of neighboring equiaxed grains by an Avrami-type treatment (Ref 55). Impingement was separated from the kinetics of growth through the concept of an extended volume fraction of grains.

Treatment of Thermal Transport. Lipton *et al.* and Fredriksson and Olsson consider convective heat transport in the bulk, describing this with the laminar boundary layer theory. Flood and Hunt consider both diffusive and convective heat flow in the liquid.

Criterion for the Columnar to Equiaxed Transition. Lipton *et al.* and Fredriksson and Olsson apply thermal criteria. Lipton *et al.* found that, in an organic analog system, the latent heat evolved by growing equiaxed grains suppressed the thermal boundary layer ahead of the columnar front and that a rise in the temperature of the thermal boundary layer accompanied the onset of the columnar to equiaxed transition (Ref 56). They believe that this rise in temperature corresponded to the overlap of the thermal fields of neighboring grains, which they considered would occur when a grain had grown to a critical size of one-tenth of the intergranular spacing. Consequently, Lipton *et al.* allow the columnar front to advance until it reaches a grain that has grown to this critical size, at which point the columnar to equiaxed transition is said to have occurred. However, as indicated earlier, in metallic systems, the thermal diffusivity is so high that the neighboring grains would probably interact thermally long before reaching the critical size.

On the other hand, Fredriksson and Olsson assume that the columnar to equiaxed transition occurs when the bulk temperature falls to a minimum prior to recalescence. This was based on an experimental correlation and was rationalized by associating recalescence with equiaxed grains that had developed to a size sufficient to obstruct the columnar front. Fredriksson and Olsson thought that this recalescence would also increase the temperature difference between the front and the bulk, causing greater convection, which in turn would enhance crystal multiplication and accelerate the obstruction of the front. However, the increasing temperature difference across the thermal boundary layer would appear not to fit the findings of Lipton *et al.*

Flood and Hunt adopt a criterion based on a probability argument. The columnar to equiaxed transition is assumed to occur when a certain volume fraction of grains exists ahead of the columnar front.

Predicted Versus Observed Behavior. Fredriksson and Olsson and Flood and Hunt calculated cooling curves that show recalescence accompanying equiaxed growth. The nature of the latent heat evolution produced a more curved cooling curve with equiaxed growth than with columnar growth. This difference in character has been noted experimentally (Fig. 2).

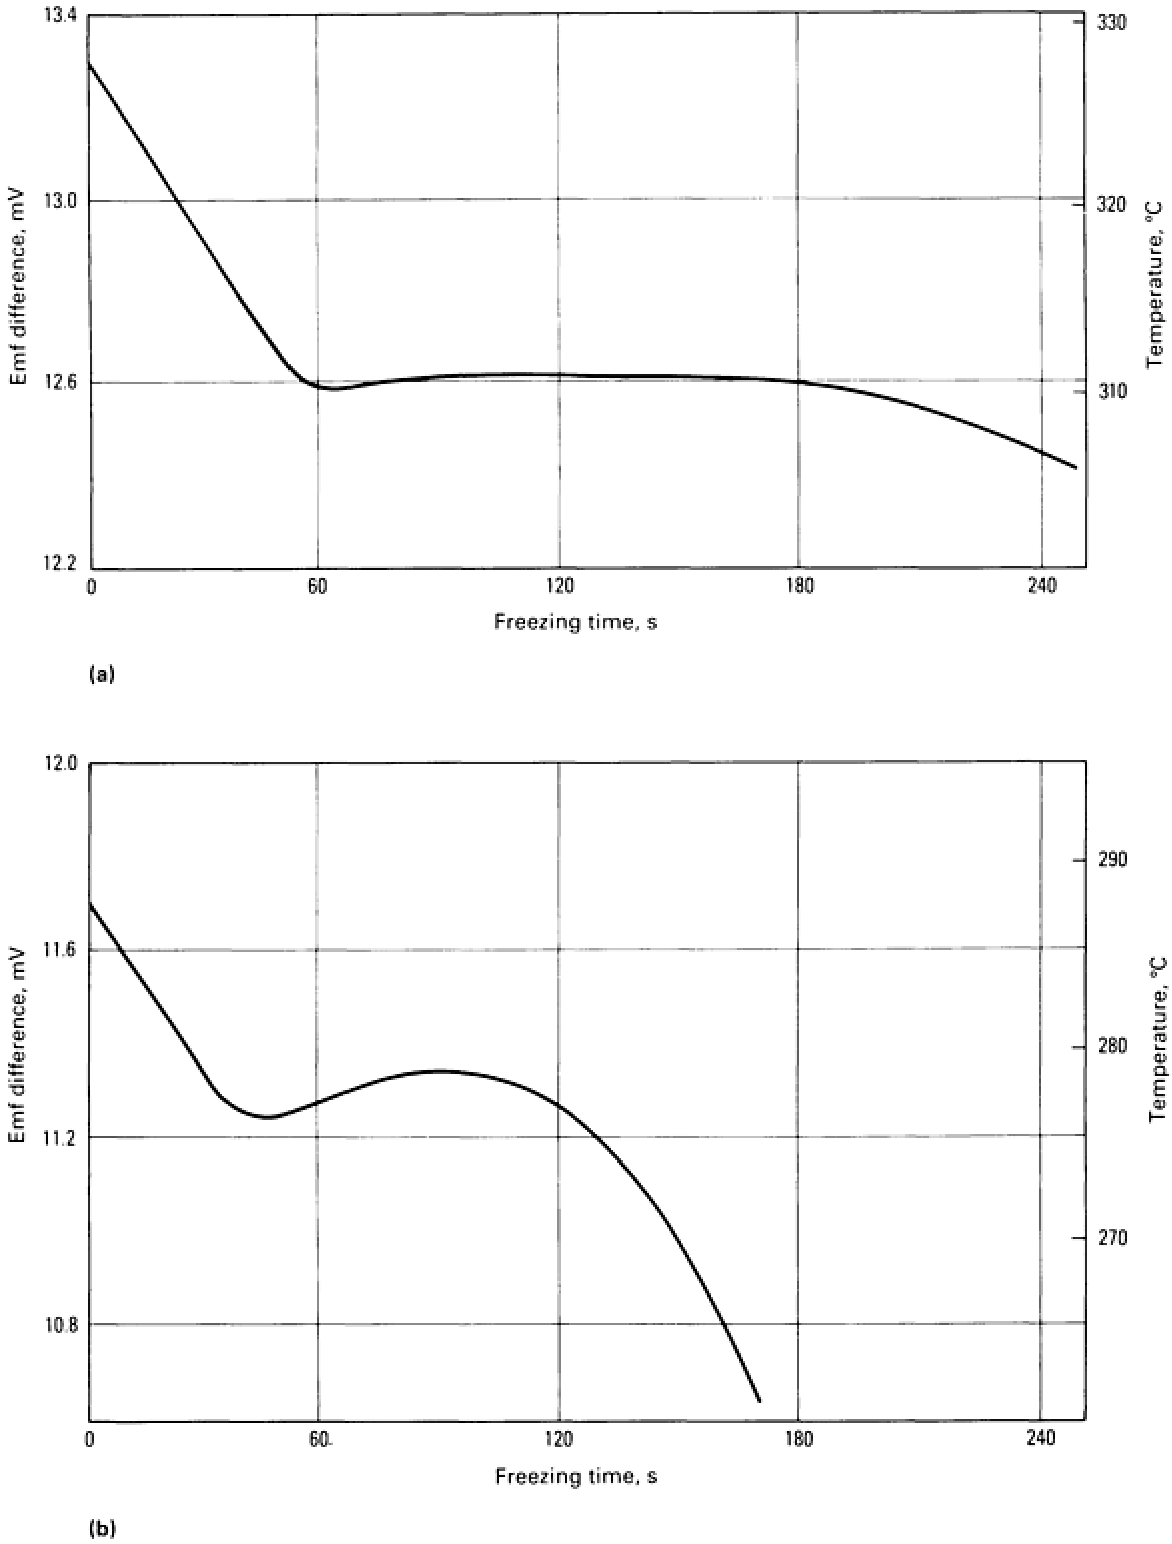

Fig. 2 Comparison of the configuration of cooling curves for a columnar (a) and fully equiaxed (b) growth. (a) The first casting, having a Pb-2.25 Sb concentration and a 0.360 °C · s^{-1} cooling rate. (b) The fourth casting, having a Pb-6.50 Sb concentration and a 0.320 °C · s^{-1} cooling rate. Source: Ref 50

All three growth models predict a decreasing columnar range with increasing alloy content and decreasing superheat, which suggests that these trends do not necessitate a nucleation based mechanism but can be explained in terms of growth. The compositional dependence enters through the velocity-undercooling expression and, in the case of Flood and Hunt, also through the shape of the columnar dendrites (Ref 57). The superheat effect is due to the initial influence of the pouring temperature on growth conditions. Lipton *et al.* and Fredriksson and Olsson calculated a larger and more realistic

superheat trend than Flood and Hunt, but this could have resulted from modeling a different size of casting, employing a different dendrite growth expression, or imposing different cooling rates. However, Flood and Hunt speculated that the lack of a dramatic superheat effect in their results supports the big bang mechanism; consideration of only grain growth is not sufficient to reproduce the influence of superheat. Flood and Hunt also predict a columnar to equiaxed transition sooner after the dissipation of the superheat than Fredriksson and Olsson. However, this would appear to be the case because Flood and Hunt modeled a larger number of grains per unit volume and used a higher kinetic constant (causing higher growth rate).

Flood and Hunt showed that flattening the thermal gradient in the bulk by convection reduces the columnar range by increasing the bulk undercooling and promoting equiaxed growth. Introducing a temperature-dependent nucleation rate into a growth model postponed equiaxed growth until the heterogeneous nucleation undercooling was achieved. If the columnar front undercooling did not fall below this value, then the casting was fully columnar.

Fredriksson and Olsson forecast an increase in the columnar range with increased height or width of the casting, with the columnar to equiaxed transition being more sensitive to the width than to the height. These results are consistent with the findings of other researchers (Ref 22). Lipton *et al.* point out that the columnar to equiaxed transition will occur only if the total solidification time is significantly longer than the time taken for the dissipation of the superheat. This means that small billets and thin slabs will solidify as predominantly columnar, while large sizes will reveal a large portion of equiaxed crystals.

Growth Parameters

The size of an equiaxed grain in the growth models is determined by:

- The time interval between the grains starting to grow and the arrival of the columnar front
- The undercoolings that are experienced during this period

Recognizing this, it is possible to perform a simple steady-state analysis of equiaxed growth that provides some insight into the columnar to equiaxed transition (Ref 11, 57). It suggests that the structure will be fully columnar when:

$$G_L > 0.617(100N_o)^{1/3}\left[1-\left(\frac{\Delta T_n}{\Delta T_c}\right)^3\right]\Delta T_c \qquad \textbf{(Eq 2)}$$

and fully equiaxed when:

$$G_L < 0.617(N_o)^{1/3}\left[1-\left(\frac{\Delta T_n}{\Delta T_c}\right)^3\right]\Delta T_c \qquad \textbf{(Eq 3)}$$

and

$$\Delta T_c = \left[-8\Gamma m_L(1-k)\frac{C_o v}{D}\right]^{1/2} \qquad \textbf{(Eq 4)}$$

where N_o is the number of nuclei per unit volume, ΔT_c is the undercooling at the columnar front, ΔT_n is the critical undercooling for nucleation on a substrate, and Γ is the Gibbs-Thomson coefficient.

These inequalities enable us to rationalize the columnar to equiaxed transition under different casting conditions. For example, in a roll caster in which the heat transfer coefficient is very high, both the velocity and the temperature gradient will be high; therefore, the extent of the equiaxed zone will critically depend on the number of heterogeneous nucleation

sites. In contrast, in a sand casting in which there are low gradients and velocities, equiaxed growth will depend less on the quality of grain refiner and more on its efficiency.

The compositional dependence of the structure in the steady-state analysis stems from the quantity $-m_L$ (1 - k)C_o in the expression for the columnar front undercooling. This quantity, which is introduced through the velocity-undercooling relation for the dendrite tips, is in fact the temperature difference between the liquidus and solidus at a composition of kC_o (and very nearly the constitutional supercooling parameter). At steady state, therefore, Hunt points out that in a peritectic system such as iron-carbon, the tendency to form equiaxed crystals will increase with increasing carbon concentration in the δregion until austenite begins to form, when it will decrease, but will then eventually increase at higher concentrations (see the article "Solidification of Peritectics" in this Volume) (Ref 11). Lipton *et al.* also discuss the ferrite-austenite phase change and note that the undercooling of the columnar front will adapt to the change in properties (mainly m_L and k) and alter the columnar to equiaxed transition (Ref 7).

Fredriksson and Olsson discuss the influence of convection and the sedimentation of grains on the columnar to equiaxed transition, neither of which have been treated adequately to date (Ref 6). They pointed out that, prior to the removal of the superheat in the bulk, convection would cause remelting of many of the free crystals growing in an undercooled layer near the front by transporting them into the center and that, after the removal of superheat, convection would cause crystal multiplication. Sedimentation of crystals would tend to remove free crystals from the melt, and this was thought to have caused a decrease in a measured cooling curve following the recalescence at the columnar to equiaxed transition.

Rappaz and Thévoz have considered the growth of equiaxed grains in detail (Ref 58). They modeled the solute rejection from an individual grain during growth and accordingly corrected the solid fraction within the grain and the supersaturation in the bulk. Flood and Hunt neglected this rejection and assumed, first, that the solid fraction within a grain is given by the Scheil equation and, second, that the bulk composition is constant throughout solidification. Rappaz and Thévoz described the solute field in the liquid, within and outside a grain, by assuming a uniform liquid composition within the grain, by applying a symmetry condition at half the intergranular distance, and by invoking solute conservation. The temperature and composition within a grain were coupled by assuming equilibrium, and a grain was considered to be isothermal. Cooling curves were calculated for a single grain and could be fitted, by adjusting parameters, to provide a good match with experimental results.

However, the computational effort required by their full numerical treatment caused Rappaz and Thévoz to devise a simpler, more approximate analysis so that they could scale up their simulations from a single grain to an entire casting (Ref 59). This analytical model agrees well with the full calculations; it accounts for the solute in a diffusion profile at the edge of a grain and provides an expression for solid fraction that is dependent on grain size and dendrite tip velocity. Thévoz *et al.* (Ref 17) used this solid fraction expression in place of the Scheil assumption in a model of equiaxed growth similar to that of Flood and Hunt (Ref 5, 57). They calculated cooling curves showing a recalescence and predicted a variation in grain size across the casting owing to different local cooling rates. They used a rather complex nucleation model. Early work by other researchers considered the growth of nondendritic spheres, and a similar dependence of grain size on cooling rate was obtained by using a classical heterogeneous law (Ref 18).

The Rappaz-Thévoz model probably over-estimates the rejection of solute from an equiaxed grain. Solute is not rejected over the entire surface of the envelope of a grain. Much of the solute will be trapped interdendritically, and the solute profile at the leading dendrite tips will probably extend over only a few tip radius lengths. The Rappaz-Thévoz model, however, is the first to introduce the accumulation of solute in the bulk. The corrections that it introduces into the Flood-Hunt analysis will be significant toward the end of solidification, because then the solute loss from a grain will have the greatest effect on the solid fraction calculation and the solute fields of neighboring grains will overlap and decelerate growth.

Rappaz and Thévoz introduced a slowing factor into their dendrite velocity relation to fit their calculated cooling curves to the measured ones. Indeed, the growth of equiaxed tips has been measured in analogs as being considerably slower than that predicted by the usual expressions for velocity. This might suggest that a more complex and better analysis of the growth of equiaxed dendrite tips should be developed. However, regardless of the validity of such an analysis, the uncertainty in the material parameters (that is, surface energy and diffusion coefficient) is so great that an error of one or two orders of magnitude in velocity could be expected. It might be suggested that fitting the velocity-undercooling relation is pragmatically more useful than applying a model of dendrite growth when simulating real castings.

Lipton *et al.* have proposed a more sophisticated treatment of the equiaxed dendrite tip (Ref 60). They consider the coupled Ivantsov solutions for the temperature and composition profiles at an isolated unconstrained dendrite tip and then

obtain an operating point by invoking marginal stability. The model should probably be used with caution, however, because it considers an isolated dendrite rather than an array.

Witzke *et al.* treated the redistribution of solute ahead of a columnar front and attempted to calculate the degree of constitutional supercooling in the bulk (Ref 61). The forward gradient term in the solutal transport equation was neglected because, it was argued, it is small compared to another term, yet it is this neglected term that rejects solute into the bulk. In addition, solute would accumulate in the fluid as it passes the front, but this is not included in the treatment. This accumulation would cause the front to melt back and curve. The boundary layer theory predicts that the thermal boundary layer, and therefore the undercooled region, will increase with depth in a casting, and this could explain the observation that crystals formed first near the base of an analog casting (Ref 50, 51).

Columnar Versus Equiaxed Grain Growth

The importance of the relative growth rates of columnar and equiaxed grains has been recognized in recent years. Growth models can predict all the main trends in the columnar to equiaxed transition. The development of an equiaxed zone is dependent on the presence of equiaxed nuclei and is affected by the thermal growth conditions in the bulk and the speed of the columnar front. The effect of composition on the columnar to equiaxed transition would seem to be due to the dependence of the dendrite growth rate on composition. Convection can promote equiaxed growth by lowering the thermal gradient. Experimental evidence suggests that both the big bang and dendrite detachment mechanisms apply and are efficient processes for the creation of equiaxed grains. Although the superheat effect can be predicted by a consideration of growth alone, the big bang mechanism is probably partly responsible. The CS-driven heterogeneous nucleation mechanism is important only when a grain refiner or efficient substrate is present.

The main areas of macrostructural development which have yet to be treated in sufficient detail are the effect of fluid flow during pouring and growth plus the effect of the sedimentation of the equiaxed crystals.

Microsegregation and Macrosegregation

I. Ohnaka, Department of Materials Science and Processing, Osaka University, Japan

---

Introduction

ALL METALLIC MATERIALS contain solute elements or impurities that are randomly distributed during solidification. The variable distribution of chemical composition on the microscopic level in a microstructure, such as dendrites and grains, is referred to as microsegregation. Variation on the macroscopic level is called macrosegregation. Because these segregations generally deteriorate the physical and chemical properties of materials, they should be kept to a minimum.

Equilibrium Phase Diagram and Equilibrium Partition Coefficient

The solute elements in alloys are redistributed during the solidification process so that the chemical potential in the liquid and solid phases is equalized (Ref 1). As the solidification proceeds under the equilibrium condition, the solute compositions in the solid, C_S, and the liquid, C_L, vary along the solidus and liquidus lines, respectively (Fig. 1). The ratio C_S/C_L is referred to as the equilibrium partition or distribution coefficient, k.

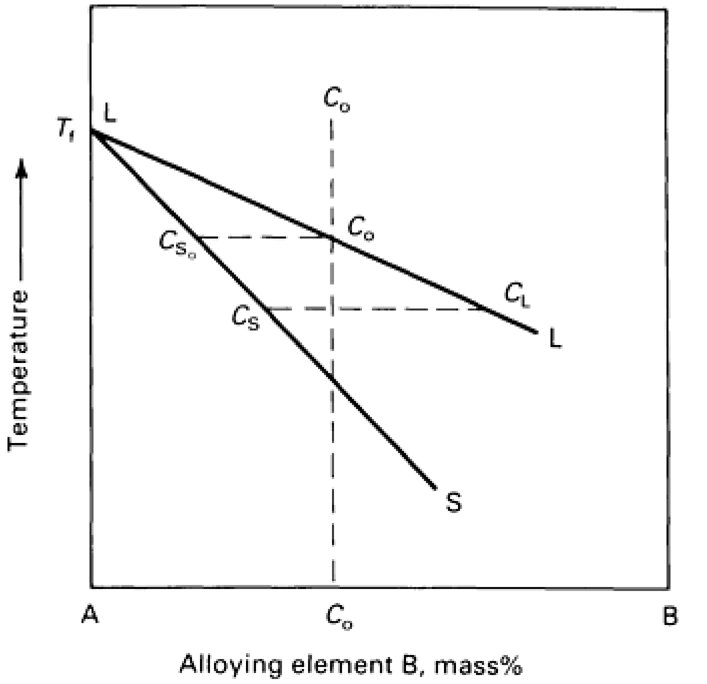

Fig. 1 Schematic of an equilibrium phase diagram of a binary alloy. The liquidus is represented by line LL; the solidus by line LS.

In the equilibrium condition, the liquid and solid composition can be calculated by:

$$C_L = \frac{C_o}{[1-(1-k)f_s]} \quad \textbf{(Eq 1)}$$

where C_o is the initial alloy composition and f_S is the solid fraction, and by:

$$C_S = k\,C_L \quad \textbf{(Eq 2)}$$

After solidification (f_S = 1), the solute composition is designated C_o; theoretically, no microsegregation occurs at this point. In actuality, however, the equilibrium solidification rarely takes place, because the solute diffusion is not so rapid.

Solute Redistribution in Nonequilibrium Solidification

If the solute redistribution in a volume element between platelike dendrites as shown in Fig. 2 is considered and if negligible undercooling at the solid/liquid interface (local equilibrium condition) with no net flow of solute through the volume element is assumed, the liquid composition can be calculated as follows.

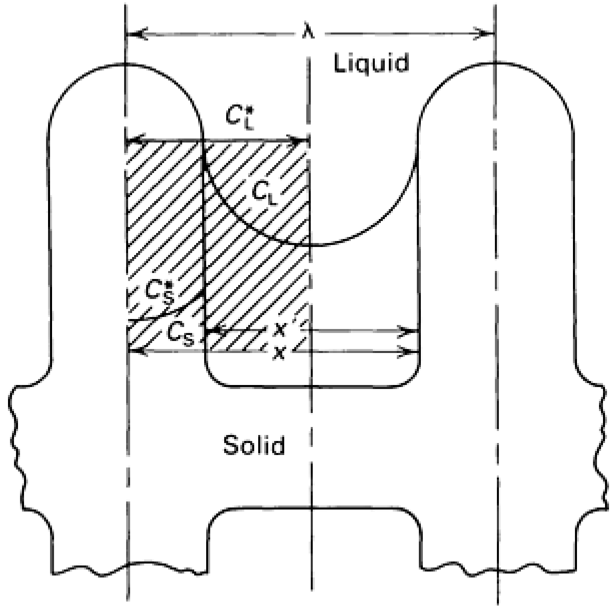

Fig. 2 Solute distribution in a volume element (crosshatched area) between dendrites.

First, in the case of $D_S = 0$ and $D_L = \infty$ (indicating no diffusion in the solid and complete mixing in the liquid), where D_S is the solid diffusivity and D_L is the liquid diffusivity, Eq 3, which is often called Scheil's equation, holds for any solid morphology (Ref 2, 3):

$$\frac{C_L}{C_o} = (1 - f_s)^{(k-1)} \qquad \textbf{(Eq 3)}$$

Second, in the case of $D_S \neq 0$ (finite diffusion in the solid) and $D_L = \infty$, Eq 4a, 5, and 6 have been proposed (Ref 4, 5, 6):

$$\frac{C_L}{C_o} = (1 - y\, f_s)^{(k-1)/y} \qquad \textbf{(Eq 4a)}$$

where

$$y \equiv 1 - \frac{2Bk}{1 + 2B} \qquad \textbf{(Eq 4b)}$$

where B is the back diffusion coefficient in the solid phase

$$B = \frac{4D_s t_f}{l^2}$$

where D_S is the diffusion coefficient in the solid phase, t_f is the local solidification time, and λ is the dendrite arm spacing.

A more accurate or exact solution for this model has been obtained (Ref 5). Equation 4a and a similar equation given in Ref 6 approximate the exact solution below $f_S < 0.9$. Equation 4a is applicable not only to platelike dendrites but also to columnar dendrites if 2B in Eq 4b is doubled. It also agrees with Eq 1 for D_S or B **?** 1 and with Eq 3 for D_S or B **=** 1, respectively. The Brody-Flemings equation (Ref 7) is not applicable for B > 0.5.

Third, there is a solid-state diffusion and solute buildup ahead of the solid-liquid interface. An analytical solution for this actual case has not been obtained.

However, in the case where $D_S = 0$ and a solute boundary layer controls the solute transfer in the liquid, the effective partition coefficient k_{ef} has been derived for semi-infinite volume-element and steady-state conditions (Ref 8):

$$k_{ef} \equiv \frac{C_s^*}{C_o} = \frac{k}{k + (1-k)\exp(-Rd_c / D_L)} \quad \textbf{(Eq 5)}$$

where C^*_S is the solid composition at the interface, R is the growth rate, and δ_c is the solute boundary layer ahead of the interface.

The coefficient k_{ef} can be used for k in Eq 3:

$$\frac{C_L}{C_o} = (1 - f_s)^{(k_{ef}-1)} \quad \textbf{(Eq 6)}$$

and

$$C_S = k_{ef} \cdot C_L \quad \textbf{(Eq 7)}$$

Although Eq 5 cannot be directly applied to dendritic solidification, it is useful for an understanding of the formation of microsegregation. Further, it is applied to evaluate macrosegregation in single-crystal growth.

Microsegregation

In practice, microsegregation is usually evaluated by the Microsegregation Ratio, which is the ratio of the maximum solute composition to the minimum solute composition after solidification, and by the amount of nonequilibrium second phase in the case of alloys that form eutectic compounds. Some data and an isoconcentration profile for an Fe-25Cr-19Ni columnar dendrite (Ref 9) are given in Table 1 and Fig. 3.

Table 1 Microsegregation ratio (numbers without dimension) and amount of nonequilibrium second phase (mass%)

Microsegregation ratio	Alloys, mass%
Mo (1.4-2.0)	**Carbon steel (0.3-0.4C)**
Cr (1-5, increases with C up to 1.4%)	**Fe-(1-3)Cr-C**
Mo (2.7-3.8), Cr (1.4-1.5)	**1.2Cr-0.25Mo steel**
Ni (1.2-1.4), Cr (1.3-1.5), Mo (2.6-3.8)	**2.8Ni-0.8Cr-0.5Mo steel**
Mn (1.3-1.8)	**1.5Mn steel**
Ni (1.06-1.07), Cr (1.3)	**18Cr-8.6Ni stainless steel**
Ni (1.1), Cr (1.1-1.3)	**25Cr-19Ni stainless steel**
Si (1.8-3.1), Mn (1.3-1.8)	**19Cr-15Ni stainless steel**
P (36 for cooling rate $\dot{T}$ = 0.083 K/s) P (30 for cooling rate $\dot{T}$ = 0.167 K/s) P (15 for cooling rate $\dot{T}$ = 0.833 K/s)	**22Cr-20Ni stainless steel**
Al (1.9-2.0), Ti (2.1-2.2)	**Ni-5Al-13Ti**
V (1.3)	**Ti-(2-10)V**
Sn (1.6-3.7, decreases with growth rate)	**Cu-8Sn**
Cu (1-2 vol%)	**Al-2Cu**
Cu (3.9 area% for equiaxed structure; 1.5-3 area% for columnar structure)	**Al-4.5Cu**
Cu (2.8 vol%)	**Al-6.5Cu**
Cu (4.1 vol%)	**Al-6.5Cu-0.26V**
Cu (4 vol%)	**Al-6.5Cu-0.1Ti**

Mg (4-7 area% for equiaxed structure; 1-4 area% for columnar structure)	**Al-10.4Mg**
P (25-26.5 mass%)	**Fe-4P**

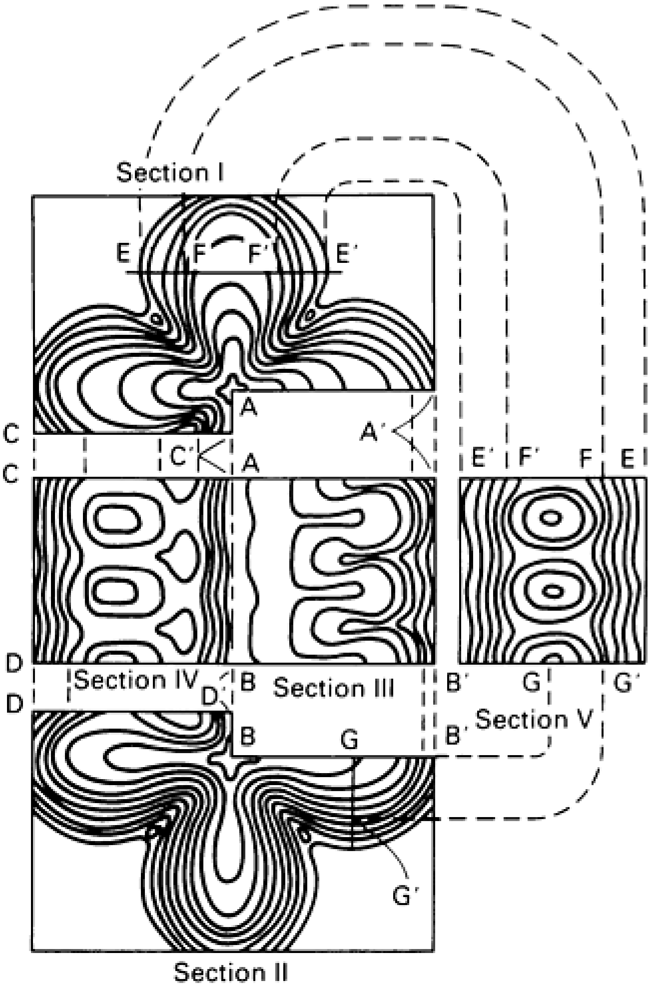

Fig. 3 Isoconcentration profile in an Fe-25Cr-20Ni columnar dendrite.

Equation 3 is often used in the case of the lower back diffusion parameter B (for example, for aluminum alloy castings), and Eq 1 and 4a are used in the case of higher B (for example, for steel castings). However, it is not easy to estimate the real microsegregation as listed in Table 1, because the real phenomena are very complicated and the solid composition after solidification cannot be calculated by Eq 4a if the finite solid diffusion is not negligible. The following points should be considered.

Solidification Mode and Structure. Microsegregation varies considerably with the history of the growth of the solid. For example, microsegregation often increases with cooling rate in the case of equiaxed dendritic solidification, but it decreases in the case of unidirectional dendritic solidification. This is because, in the former case, the liquid composition is rather uniform in the interdendritic liquid, and Eq 4a is applicable. In the latter case, the solute buildup on the dendrite tip cannot be neglected, and equations such as Eq 5 or the Solari-Biloni equation (Ref 10), which considers the solute buildup ahead of the dendrite tip and dendrite curvature, should be used. Alternatively, a numerical calculation is necessary. Estimating the microsegregation in an equiaxed globular grain structure requires information on its formation mechanism and the history of the grain (that is, dendrite melt-off and settling in the liquid).

Morphology of the Dendrite and Diffusion Path. In the case where solid-state diffusion is not negligible, the diffusion path or the morphology of the solid is very important. Although Eq 4a can be applied to the volume element in a

primary or secondary dendrite array, the real diffusion occurs three dimensionally in both dendrites. Therefore, careful attention is required to determine the dendrite spacing λ. One method is to employ the mean value of the primary and secondary dendrite arm spacing, $\overline{l} = (\lambda_1 + \lambda_2)/2$ (Ref 6). Equation 8 is also recommended (Ref 4):

$$\frac{C_L}{C_o} = (1 - y_1 f_{s1})^{[(k_1-1)/y_1]} \left(\frac{1 - y_2 f_s}{1 - y_1 f_{s1}} \right)^{[(k_2-1)/y_2]} \quad \textbf{(Eq 8)}$$

where the subscripts 1 and 2 are used for the state $f_S \le f_{S1}$, and $f_S > f_{S1}$, respectively. Thus, if the diffusion path changes from the primary dendrite to the secondary dendrite at the fraction solid f_{S1}, then λ_1 and λ_2, are used for ψ_1 and ψ_2, respectively.

Phase Transformation. If a phase transformation occurs during solidification, the microsegregation can change considerably because the equilibrium partition coefficient varies with phase. For example, the *k* of phosphorus in steel castings is 0.13 in ferrite and 0.06 in austenite. Therefore, as shown in Fig. 4, in steel castings the peritectic reaction, which is affected by carbon composition, greatly affects microsegregation (Ref 11). If it is assumed that the phase change occurs at $f_S = f_{S1}$, then Eq 8 is also applicable, but it may result in a large error. A more accurate estimation of microsegregation requires numerical calculations that take into consideration the amount of change in each phase (Ref 11, 12).

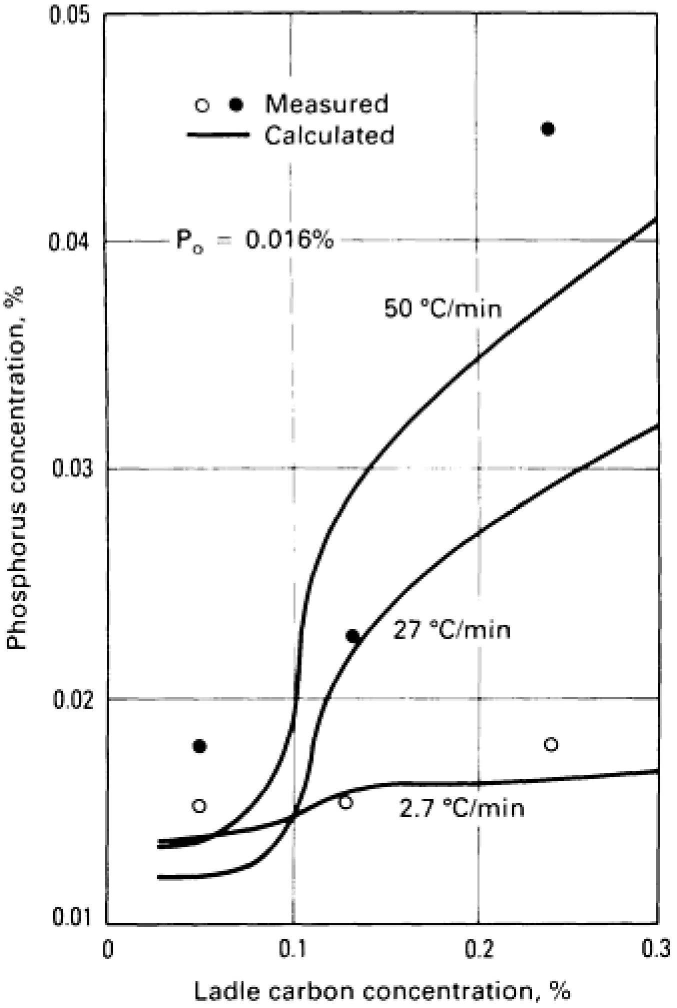

Fig. 4 Effect of carbon concentration and cooling rate on phosphorus concentration in an Fe-C-0.016P dendrite upon cooling to 1537 K.

Effect of Third Solute Element. Figure 5 shows that the partition coefficient is affected by the third solute element (Ref 13). In aluminum alloys, chromium decreases the partition coefficient of magnesium. Further, it should be noted that the dendrite morphology varies with solute elements resulting in a different diffusion effect.

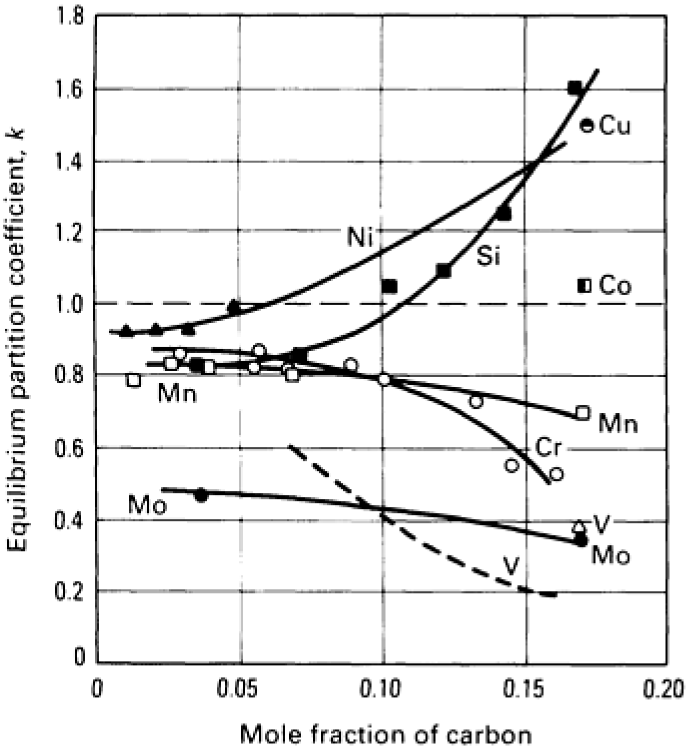

Fig. 5 Variation of equilibrium partition coefficient with third solute elements in an iron-carbon alloy.

Dendrite Coarsening. Because coarsening or remelting of the dendrites occurs during solidification, the dendrite spacing is not constant, and the resolved solid dilutes the liquid composition. Although a numerical analysis has been performed, such effects have not been made clear (Ref 14).

Movement of the Liquid Phase. In many cases, the interdendritic liquid does not remain stationary but moves by solidification contraction or by thermal and solutal convections, resulting in varying degrees of microsegregation.

Temperature and Concentration Dependency of Diffusion Coefficient. Physical properties such as D_S and D_L are temperature and concentration dependent. Because the diffusion coefficient may vary by an order of magnitude in the case of a large solidification interval, both values must be closely monitored. This can be determined by numerical calculation.

Undercooling. In actual use, undercooling at the dendrite tip does exist. However, it is not a factor that affects microsegregation in typical solidification processes, with the exception of welding and unidirectional solidification (Ref 13).

Other Effects. When a very high temperature gradient exists (for example, over 40 K/mm), the Soret effect, which considers solute transport to be a function of a temperature gradient, becomes a factor (Ref 15).

Microsegregation in Rapid Solidification Processing

In rapid solidification processing, the solid growth rate can be very high, resulting in a completely different solute distribution. If the atomic motions responsible for interface advancement are much more rapid than those necessary for the solute element to escape at the interface, microsegregation-free or diffusion-free solidification can occur (Ref 16). The nonequilibrium partition coefficient k_N is considered to increase monotonically with velocity (Ref 17):

$$K_N = \frac{k + [(R.\Lambda)/D_i^*]}{1 + [(R.\Lambda)/D_i^*]} \qquad \textbf{(Eq 9)}$$

where D^*_i is the interface interdiffusivity (Ref 17) and Λ is the interatomic spacing of the solid. However, the solute trapping is also dependent on solute concentration, and the complete equation has yet to be formulated.

Macrosegregation

Macrosegregation is caused by the movement of liquid or solid, the chemical composition of which is different from the mean composition. The driving forces of the movement are:

- Solidification contraction
- Effect of gravity on density differences caused by phase or compositional variations
- External centrifugal or electromagnetic forces
- Formation of gas bubbles
- Deformation of solid phase due to thermal stress and static pressure
- Capillary force

Macrosegregation is evaluated by:

- Amount of segregation (ΔC): $\Delta C = \overline{C}_S - C_o$
- Segregation ratio or index: C_{max}/C_{min} or $(C_{max} - C_{min})/C_o$
- Segregation degree (in percent): 100 $\overline{C}_S/C_o$)

where C_o is the initial alloy composition, $\overline{C}_S$ is the mean solid composition at the location measured, and C_{max} and C_{min} are the maximum and minimum compositions, respectively. For example, the following carbon segregation index has been empirically obtained for steel ingots (except hot top) (Ref 18):

$$(C_{max} - C_{min})/(C_oD)\ (\%) = 2.81 + 4.31\ H/D + 28.9\ (\%Si) + 805.8\ (\%S) + 235.2\ (\%P) - 9.2\ (\%Mo) - 38.2\ (\%V) \quad \textbf{(Eq 10)}$$

where D and H are ingot diameter and height in meters, respectively.

Macrosegregation is especially important in large castings and ingots, and it is also a factor in some aluminum or copper alloy castings of small and medium size. Various types of macrosegregation and their formation mechanisms are described below, mainly for the case of $k < 1$. In the case of $k > 1$, similar but converse results are obtained.

Plane Front Solidification. When plane front solidification occurs, as in single-crystal growth, the formation mechanism of macrosegregation is rather simple, and Eq 6 can be applied. A schematic of the typical solute distribution is shown in Fig. 6. The solid composition of the initially solidified portion is low and has an approximate value of kC_o, which gradually increases with time because of diffusion as the solute is pushed ahead, resulting in a higher concentration at the finally solidified portion or the ingot center. This segregation is termed normal segregation. As seen from Eq 5, the degree of normal segregation increases with decreasing growth rate (*R*) or the solute boundary layer thickness (δ_c), which decreases with increasing intensity of the liquid flow.

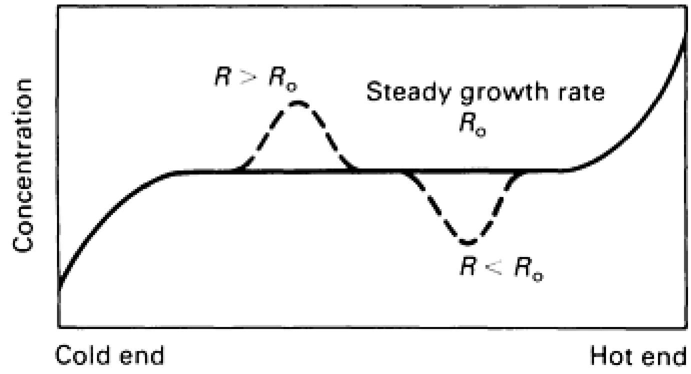

Fig. 6 Typical solute distribution in plane front solidification where *R* is the growth rate.

Further, changes in the growth rate during solidification results in a segregation as shown in Fig. 6. If the growth rate increases suddenly from the steady state to a higher rate, then a larger effective partition coefficient is realized, resulting in a concentration higher than the mean composition, which is termed positive segregation. (The normal segregation is a type of positive segregation.) Conversely, a sudden decrease in the growth rate *R* results in a solute-poor band or negative segregation. If *R* or δ_c varies periodically, then periodical composition change, which is termed banding or solidification contour, occurs. In either case, it is essential to consider the fluid flow and the solute boundary layer δ_c, which typically ranges from 0.1 to 1 mm (0.004 to 0.04 in.) for the single-crystal growth of metals.

Gravity segregation is caused by the settling or floating up of solid and liquid phases having a chemical composition different from the mean value. For example, the initially solidified phase or melted-off dendrites settle in the bottom of the casting because they are of higher density than the liquid. This phenomenon can be the source of negative cone, which often occurs in steel ingots, as shown in Fig. 7. If lighter solids such as nonmetallic inclusions and kish or spheroidal graphites are formed, they can float up to the upper part of the casting.

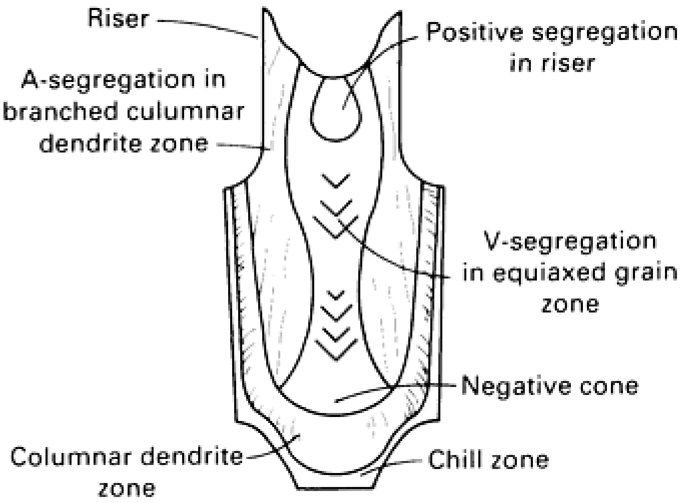

Fig. 7 Typical macrosegregation observed in steel ingots. A-segregation and V-segregation are discussed later in this article.

In steel castings, the interdendritic liquid is often lighter than the bulk liquid and floats up, resulting in positive segregation in the upper part of the casting. Although various types of macrosegregation are caused by the gravity effect, the compositional change between the upper and lower parts of a casting due to the simple gravity effect is called gravity segregation. In centrifugal casting, centrifugal force simulates gravity and can cause compositional changes between the internal and external parts of the casting.

Liquid Flow Induced Segregations in the Mushy Region. If only the liquid flows[*] in the mushy region, where a concentration gradient exists, macrosegregation occurs. Equation 12 can be derived by assuming the local equilibrium condition and the constant liquidus slope and by neglecting the dendrite curvature effect (Ref 20):

$$\frac{\partial f}{\partial t} = \left(\frac{1-b}{1-k}\right)(1-f_s)\left(1+A-\frac{u_n}{U}\right)\frac{1}{C_L}.\frac{\partial C_L}{\partial t} \qquad \textbf{(Eq 11)}$$

where

$$b = \frac{r_s - r_L}{r_s}$$

and ρ_S and ρ_L represent the density of the solid and the liquid, respectively; u_n is the flow velocity normal to the isotherms; and U is the velocity of isotherms. In this equation, $A = 0$ corresponds to zero diffusion in a solid and:

$$A = \frac{kf_s}{(1-b)(1-f_s)} \qquad \textbf{(Eq 12)}$$

corresponds to complete diffusion in a solid.[*]

If it is assumed that there is no shrinkage ($\beta = 0$) and no fluid flow ($u_n = 0$), Eq 12 is integrated to give either the equilibrium or Scheil equations (Eq 1 and 3) depending on the choice of A. For example, in the case of no diffusion in the solid ($A = 0$), Eq 12 is integrated to:

$$\frac{C_L}{C_o} = (1 - f_s)^{[(k-1)/x]} \quad \textbf{(Eq 13)}$$

where ξ $(1 - \beta)$ $(1 - u_n/U)$ and k are assumed to be constant.

The following results can be seen from Eq 13:

- In the case of $\xi = 1$ or $u_n/U = -\beta/(1 - \beta)$, Eq 13 is identical to Eq 3 and the average composition of the solid is C_o, which means that no macrosegregation occurs
- In the case of $\xi > 1$ or $u_n/U < -\beta/(1 - \beta)$, C_L becomes lower than the value calculated by Eq 3, which indicates that negative segregation may occur
- In the case of $0 < \xi < 1$ or $1 > u_n/U > -\beta/(1 - \beta)$, positive macrosegregation occurs. For example, because at the mold wall $u_n = 0$, it results in positive segregation described below

The segregation shown in Fig. 8, which is called inverse segregation, is where solute concentration is higher in the earlier freezing portion (Ref 21). This is caused by the solute-enriched interdendritic flow due to solidification contraction, which is the main driving force, plus the liquid density increase during cooling.** If a gap is formed between the mold and the solidifying casting surface, then the interdendritic liquid is often pushed into the gap by static pressure or by the expansion due to the formation of gas bubbles or graphite in the liquid. This results in severe surface segregation or in exudation, a condition in which a solute-rich liquid covers the casting surface and forms solute-rich beads.

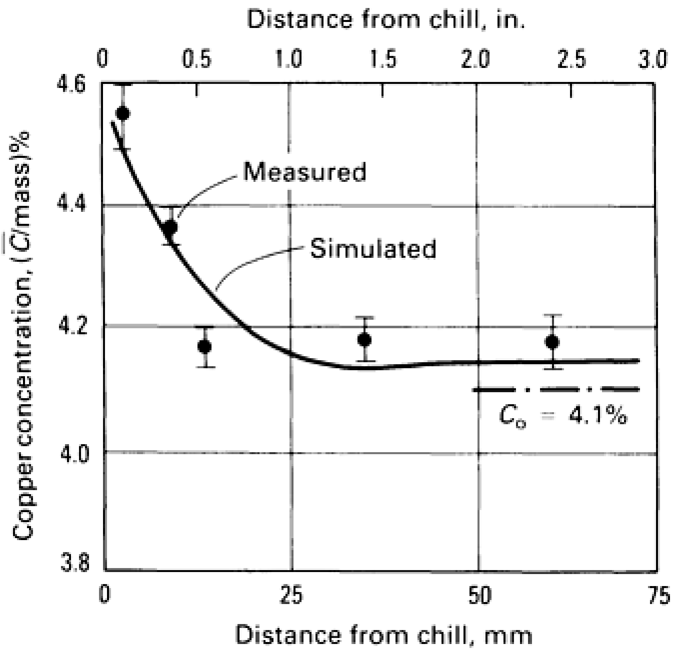

Fig. 8 Inverse segregation in an Al-4.1Cu ingot with unidirectional solidification.

Changes in liquid velocity may cause segregation. For example, the change in the shape of the casting shown in Fig. 9 can change the velocity, resulting in a segregation, as shown in Fig. 10 (Ref 21).

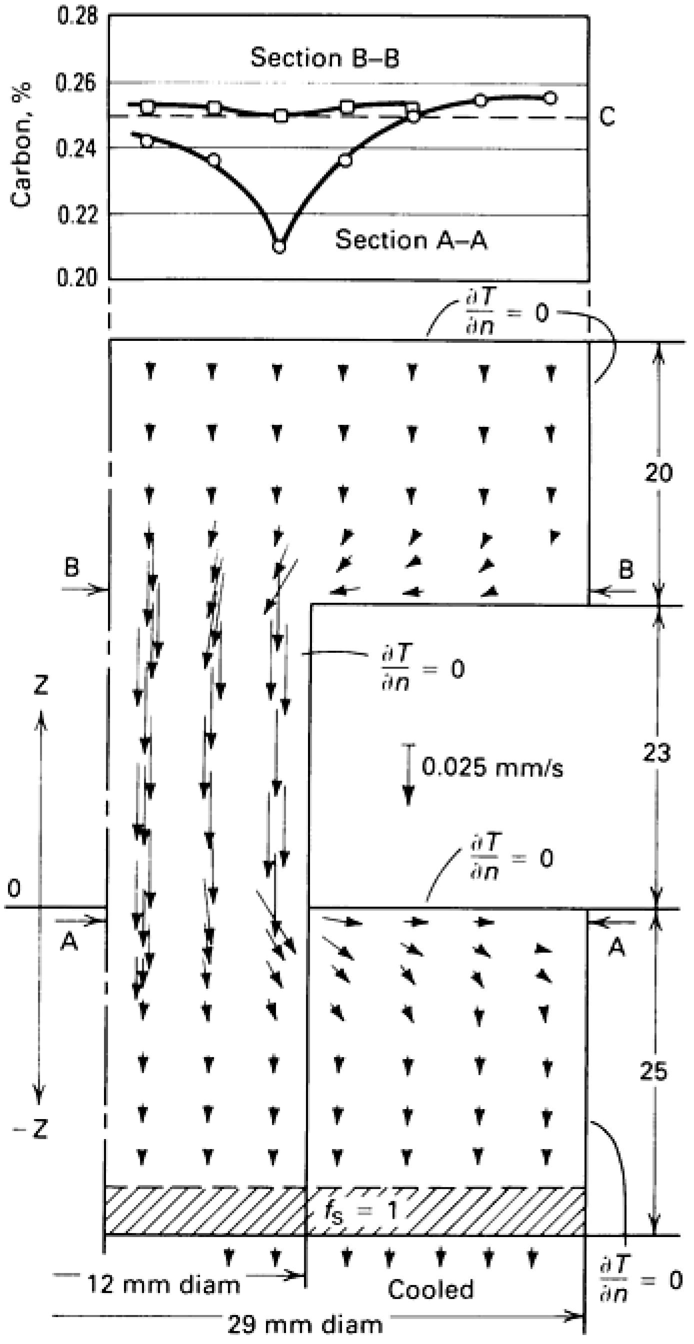

Fig. 9 Simulated fluid flow at 50 s after cooling and macrosegregation in an Fe-0.25C specimen.

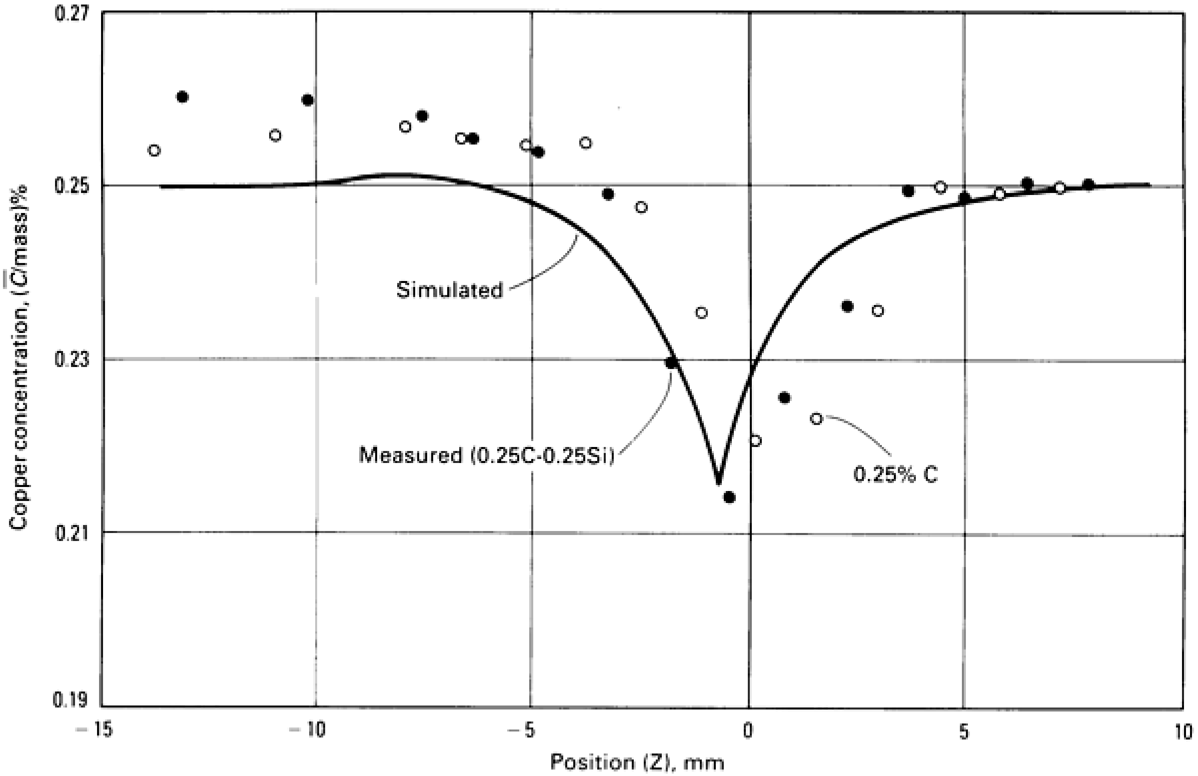

Fig. 10 Macrosegregation observed along Z-direction (cross-sectional mean value) for an Fe-0.25C specimen.

The interdendritic fluid flow is also caused by the change in liquid density due to solute redistribution and cooling (solutal and thermal convection). For example, Fig. 11 illustrates the fluid flow in a horizontally solidifying aluminum-copper ingot, resulting in a segregation, as shown in Fig. 12 (Ref 21).

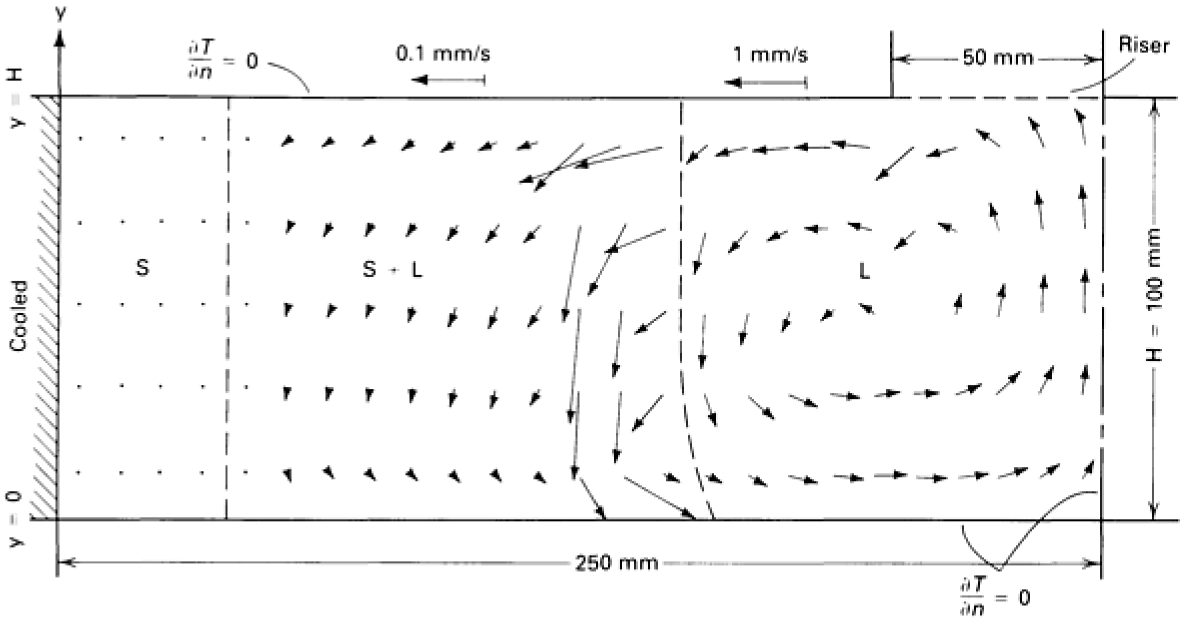

Fig. 11 Simulated fluid flow at 400 s after cooling in a horizontally solidified Al-4.4Cu ingot.

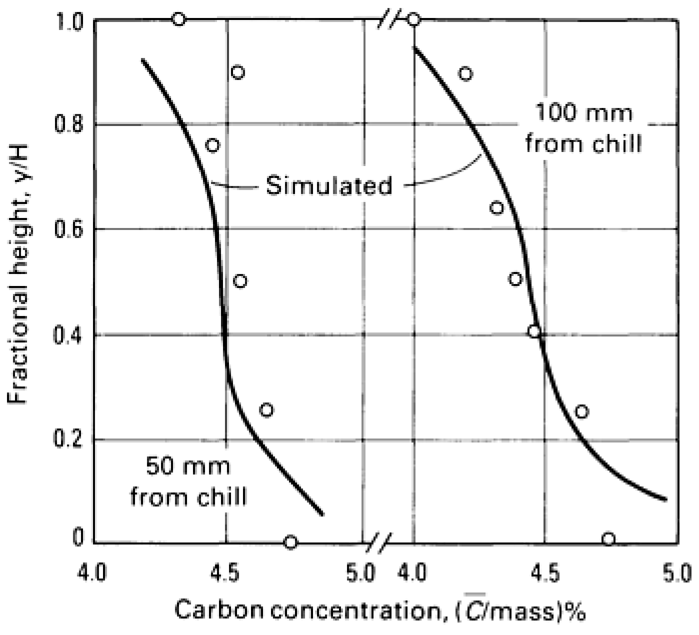

Fig. 12 Solute distribution in the Al-4.4Cu ingot shown in Fig. 11.

The bulk liquid flow can penetrate the mushy region or dendrite array and sweep out the solute-rich interdendritic liquid, resulting in a negative segregation. This is called the washing effect and is thought to be the primary mechanism for the white band, a type of negative segregation often observed in electromagnetically stirred continuous castings. Some researchers claim that the main mechanism is the change in growth rate due to stirring (Ref 23). The washing effect can also be the cause of positive or normal segregation, and the following effective partition coefficient is proposed (Ref 24):

$$k_{ef} = 1 - (1.33 \times 10^{-4})(1-k)(1-f_{sh})\frac{u}{U_{TL}} \qquad \textbf{(Eq 14)}$$

where f_{sh} is the maximum fraction solid below which the washing effect acts, u is the bulk liquid velocity, and U_{TL} is the liquidus isotherm velocity. Although Eq 14 was derived experimentally assuming complete substitution of the bulk liquid for the interdendritic liquid, it has practical applications, especially in the continuous casting industry. However, the washing effect is usually coupled with convection in the mushy region and is strongly dependent on the liquid density change and the permeability (Ref 21, 24).

In continuous slab casting, bulging causes interdendritic flow and results in rather sharp and thin positive segregation at the ingot center. This is called centerline segregation.

The formation of an equiaxed grain structure by electromagnetic stirring or other methods can considerably decrease the segregation because both the solid and liquid are free to move. In this case, Eq 11 does not apply.

Inhomogeneous Solid Distribution and Channel Segregation. Actually, the solid is not uniformly distributed, and liquid pockets often form in the mushy region because of the preferential growth of some dendrites and/or because of the agglomeration of equiaxed dendrites at the advancing interface (Ref 26), as shown in Fig. 13. These liquid pockets may become a semi-macrosegregation or a spot segregation, which is a positive segregation several hundred microns in diameter often observed in the equiaxed region of steel castings continuously cast using an electromagnetic stirring device.

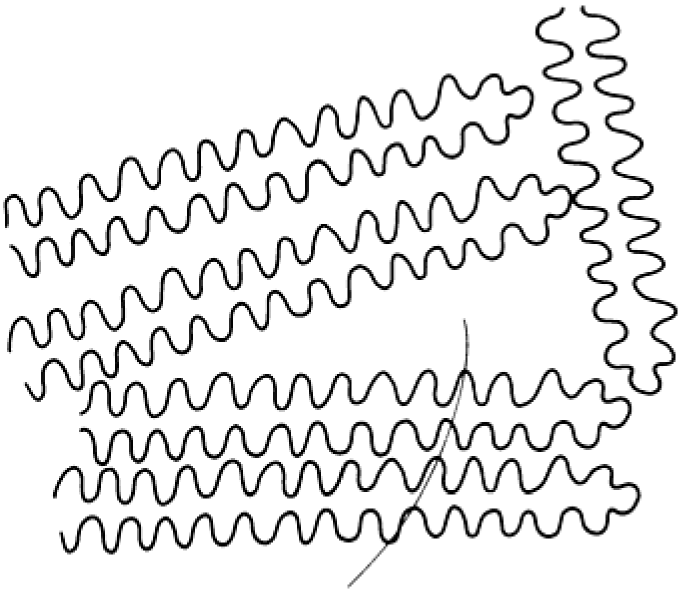

Fig. 13 Liquid pocket in the mushy region.

This inhomogeneous distribution of solid phase may be the origin of a preferred flow channel because the flow resistance of the channel connecting such liquid pockets is small. Further, once the liquid flows and if $u_n/U > (1 + A)$, then $\partial f_S/\partial t$ becomes negative in Eq 11. This means that remelting occurs and that the channel becomes larger. If bubbles are formed in the channel, it accelerates the flow velocity, resulting in enlargement of the channel (pores observed after solidification are often caused by solidification contraction). This is the mechanism of channel segregation. In large steel ingots, rodlike solute-enriched streaks such as the A-shape illustrated in Fig. 7 are often observed; this is termed A-segregation (inverse V-segregation or a ghost). In unidirectionally solidified ingots, the channel segregation is called a freckle.

A practical criterion for A-segregation formation in steel ingots is (Ref 27):

$$\dot{T}\ U_{0.35}^{1.1} < A_c \qquad \textbf{(Eq 15)}$$

where $\dot{T}$ is the cooling rate and $U_{0.35}$ is the velocity of isotherm of fraction solid 0.35 and A_c is a constant dependent on the alloy (Ref 28). If the preferred channel is formed, the solute-rich liquid easily floats up or down, resulting in a severe positive segregation in the upper or lower part of the casting.

The following steps can be effective in preventing channel segregation:

- Increasing the cooling rate or reconditioning the solute element to form a dense packing of dendrites. For example, in steels, lowering the silicon content by carbon deoxidation results in smaller dendrite arm spacing and lower permeability (that is, higher flow resistance)
- Adjusting the alloying element, which minimizes the change in the solute-rich liquid density (see Eq 10)
- Electromagnetic stirring to form equiaxed grains and to obtain a uniform and dense solid distribution

Solid Phase Movement and Segregation. If equiaxed grains are formed or if dendrite melt-off occurs, the solid may migrate because of flow or solidification contraction. In tall steel ingots with equiaxed grain structure, for example, V-shaped solute-rich regions, consisting of blurred rodlike streaks, appear periodically; this is termed V-segregation (Fig. 7). In this case, the equiaxed grains move because of the solidification contraction, and the V-shaped slip faces are

periodically formed by the viscoelastic motion of the equiaxed grains (Ref 29, 30, 31). Because the slip plane contains a loose grain structure, the permeability is greater and preferential flow channels may be formed as described in the case of A-segregation. The solutal convection may also result in a similar segregation, but it is not as severe.

If an external force acts on the mushy region where the solid fraction is high (for example, $f_S = 0.7$), then the grains or the dendrites often open and attract the interdendritic liquid, resulting in a positive segregation. This is termed healing in shape castings and is termed internal cracking in continuous castings. If the interdendritic liquid is insufficient, a hot tear occurs. In centrifugal casting, a periodic external force, such as vibration, may affect the mushy region, resulting in a periodic segregation banding.

Notes cited in this section

* It is usually assumed that the flow follows the D'Arcy law, that is, $\mathbf{u} \propto K\nabla P/(\mu f_L)$ where **u** is the velocity of the interdendritic liquid, K is the permeability (Ref 19), *P* is the pressure, and μ is the liquid viscosity.

** Even in the case of equiaxed grain structure, a similar inverse segregation can occur if the grains do not move as much as is the case in vertically solidified aluminum-copper ingots (Ref 22). However, quite different segregation occurs if the solid moves.

Behavior of Insoluble Particles at the Solid/Liquid Interface

D.M. Stefanescu, The University of Alabama; B.K. Dhindaw, IIT Kharagpur, India

Introduction

THE PROBLEM OF THE BEHAVIOR of insoluble particles at the solid/liquid interface has received the attention of theoreticians since the publication of a paper on the subject in 1964 (Ref 1). Only recently, however, has it been recognized that the problem is relevant to systems of practical significance. For example, porosity results from the incorporation of gaseous bubbles evolved during solidification or generated at the mold/metal interface in castings. If liquid droplets are considered, typical examples are phosphides in cast iron or inclusions in steel, which are incorporated into intergranular regions. In addition, structure formation in monotectic alloys would be explained based on liquid particle behavior at the interface. Finally, spheroidal graphite in cast iron, inclusions in steel, particulate *in situ* composites such as iron-vanadium carbide alloys, and particulate metal-matrix composites are examples in which solid particles interact with the solid/liquid interface during solidification (Ref 2, 3).

Basically, when a moving solidification front intercepts an insoluble particle, it can either push it or engulf it. Engulfment occurs through the growth of the solid over the particle, followed by enclosure of the particle in the solid. If, for various reasons, the solidification front breaks down into cells, dendrites, or equiaxed grains, two or more solidification fronts can converge on the particle. In this case, if the particle is not engulfed by one of the fronts, it will be pushed in between two or more solidification fronts and will finally be entrapped in the solid at the end of local solidification.

It is considerably easier to understand particle behavior at the solid/liquid interface in directional solidification processes, in which particles can only be pushed or engulfed, when a planar interface is maintained. In multidirectional solidification (castings), particles can be pushed, engulfed, or entrapped.

This article will discuss the variables of the process. The available theoretical and experimental work for both directional and multidirectional solidification will also be reviewed.

Particle Behavior in Directional Solidification

The advantage of using directional solidification while studying this problem lies in the possibility of achieving a variety of interface morphologies, such as planar, cellular, or dendritic. Because the nature of the solid/liquid interface plays a major role in particle behavior, the analysis of the process will be structured based on the type of interface.

Planar Interface

There are two basic theoretical approaches to the study of particle behavior at a solid/liquid interface: thermodynamic and kinetic.

The Thermodynamic Approach. Researchers have considered the case of a single particle being engulfed at the liquid/solid interface, assuming that the solid interface remained planar and neglecting buoyancy forces (Fig. 1). As the particle moves from position 2 to 3, the change in free energy per unit area is:

$$\Delta F_{23} = \frac{1}{2}\,(\sigma_{PS} - \sigma_{PL}) - \frac{1}{4}\,\sigma_{SL} \quad \textbf{(Eq 1)}$$

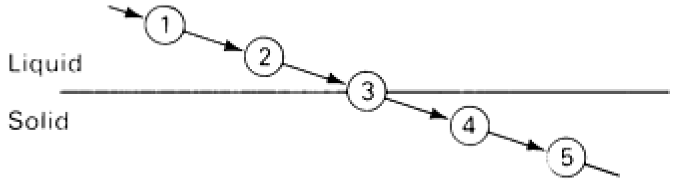

Fig. 1 Schematic for thermodynamic calculations of particle entrapment. Source: Ref 4

Similarly, when moving from 3 to 4, the change in free energy is:

$$\Delta F_{34} = \frac{1}{2}\ (\sigma_{PS} - \sigma_{PL}) + \frac{1}{4}\sigma_{SL} \qquad \textbf{(Eq 2)}$$

where σ is the interface energy between particle (P), liquid (L), and solid (S), in various combinations.

The net change in free energy during engulfment is:

$$\Delta F_{net} = \Delta F_{23} + \Delta F_{34} = \sigma_{PS} - \sigma_{PL} \qquad \textbf{(Eq 3)}$$

If $\Delta F_{net} < 0$, engulfment is to be expected; for $\Delta F_{net} > 0$, pushing should result.

The kinetic approach is based on the simple idea that as long as a finite layer of liquid exists between the particle and the solid, the particle will not be engulfed. In other words, for a particle to be pushed, mass transport in the liquid layer is required between the particle and the solid. The concept of a critical interface rate R_{cr}, below which particles are pushed and above which particles are engulfed, was postulated.

For a particle to be pushed, a repulsive force must exist between the particle and the solid. The nature of this repulsive force is not known, although several possibilities are supported by various investigators.

It has been suggested that the repulsive force may result from the variation in surface free energy Δσwhen the particle approaches the interface (Ref 1):

$$\Delta\sigma = \sigma_{PS} - (\sigma_{PL} + \sigma_{LS}) \qquad \textbf{(Eq 4)}$$

which varies with the particle-solid distance *d* according to Eq 5:

$$\Delta s = \Delta s_o \left(\frac{d_o}{d}\right)^n \qquad \textbf{(Eq 5)}$$

where d_0 is the minimum separation distance between particle and solid, *n* is an exponent equal to 4 or 5, and $\Delta\sigma_0 = \Delta\sigma$ at $d = d_0$. Coulomb forces may also be responsible for a repulsive force F_r:

$$Fr = \frac{e_s e_p}{d^2} \qquad \textbf{(Eq 6)}$$

where e_S and e_P are the charges of the solid and the particle, respectively.

Indeed, it has been demonstrated that particles are electrically charged (Ref 1). However, the researchers dismissed the influence of these charges on the repulsive force on the grounds that no correlation was found between the average charge on the particles in a system and the critical velocity.

Van der Waals type forces were considered to be responsible for the repulsive force in another theoretical treatment (Ref 5):

$$Fr = \frac{p B_3 r}{d_o^2} \qquad \textbf{(Eq 7)}$$

where B_3 is a constant $\cong 10^{-7}$ J, *r* is particle radius, and $d_0 \cong 10^{-5}$ cm. In general, it seems that the repulsive force is described by an equation of the type:

$$Fr = \frac{B}{d_o^n} \qquad \textbf{(Eq 8)}$$

where B is a constant. Repulsive forces of the type found in ionic crystals would obey Eq 8 with n = 2 (Ref 6), while dispersion forces between molecules, as in liquids or gases, will follow the same law with n = 7 (Ref 7).

Assuming that mass transport in the particle-solid gap occurs only by diffusion, that the repulsive force results from differences in surface tension (Eq 5), that there is no viscous drag for small particles, and that viscous drag exists for large particles, researchers have derived Eq 9 and 10 for the critical interface growth rate R_{cr}, (Ref 1). For small particles:

$$R_{cr} = 1/2(n+1)\frac{La_oV_oD}{kTr_b^2} \qquad \textbf{(Eq 9)}$$

For large particles:

$$R_{cr} = \frac{d_shLa_od_1}{6hrr_b^2n}\left[\left(1+\frac{6hrn(n+1)V_oD}{d_shd_1kT}\right)^{1/2}-1\right] \qquad \textbf{(Eq 10)}$$

where L is the latent heat per unit volume, a_0 is the molecular diameter, V_0 is the atomic volume, D is the liquid diffusivity, k is the Boltzman constant, T is temperature, r_b is the radius of any particle irregularity or bump (for particles without irregularities, $r_b = r$), ηis the viscosity of the liquid, d_1 is minimum separation (10^{-7} cm), and h and d_S are contact distances. The contact distances d_1, d_S, and h cannot be calculated, but must be estimated for different systems.

Other researchers have assumed that mass transport occurs by diffusion and fluid flow, that the particle does not wet the solid and has the same thermal conductivity as the liquid, and that the repulsive force is again described by Eq 5 (Ref 8). They derived Eq 11, 12, 13, and 14. For small, smooth particles ($r < r_b$):

$$h^2R^2r^3 = N\frac{4y\,(a)}{9p}kTs_{SL}a_o \qquad \textbf{(Eq 11)}$$

For bigger particles with bumps ($r \geq r_b$):

$$h^2R^2r_b^3 + \frac{2y\,(a)}{9a}g\Delta r\,a_ohRr^3r_b = \frac{4y\,(a)}{9p}kTs_{SL}a_o \qquad \textbf{(Eq 12)}$$

For very large particles (r **?** r_b):

$$hRr^3 = \frac{2a\,NkTs_{SL}}{p\,r_bg\Delta r} \qquad \textbf{(Eq 13)}$$

In the absence of bumps, Eq 14 can be written:

$$hRr^4 = \frac{2a\,kTs_{SL}}{p\,g\Delta r} \qquad \textbf{(Eq 14)}$$

where N is the number of points at which the particle is in contact with the interface (N = 1 for a grain surface or flat interface, N = 2 for a grain boundary, and N = 3 for a triple point), αis a shape factor of the interface (α = 0 for a flat

interface and α 1 for an interface having the same curvature as a particle), ψα) is a function of αequiring assumption for calculation, g is acceleration due to gravity, and Δρis the density difference between the liquid and the particle.

Other researchers assumed mass transport by fluid flow only, repulsion due to molecular forces (Eq 7), and attraction due to the drag on the particle by the viscous melt (Ref 5). They defined two characteristic lengths:

$$l = \left(\frac{V_o s_{SL}}{\Delta SG}\right)^{1/2} \qquad l = \left(\frac{B_3 V_o}{\Delta SG}\right)^{1/4} \qquad \textbf{(Eq 15)}$$

where Δ is the entropy of melting and G is temperature gradient.

Small particles are then defined as having $r < \lambda/l$, while large particles have $r > \lambda/l$. Equations 16 and 17 were derived for small and large particles, respectively:

$$R_{cr} = \frac{0.14B_3}{hr}\left(\frac{s_{SL}}{B_3 r}\right)^{1/3} \qquad \textbf{(Eq 16)}$$

$$R_{cr} = \frac{0.15B_3}{hr}\left(\frac{\Delta SG}{B_3 V_B}\right)^{1/4} \qquad \textbf{(Eq 17)}$$

All the above approaches assume a planar liquid/solid interface, only one particle at the interface, and thermal conductivity of the particle K_P equal to that of the liquid, K_L.

Equation 18 takes into account the difference in thermal conductivity between particle and liquid (Ref 9):

$$R_{cr} = \frac{\Delta s\, d_0}{6(n-1)hr}\left[2-\frac{K_p}{K_L}\right] \qquad \textbf{(Eq 18)}$$

Analysis of Eq 18 shows that the governing variables are Δσ, which can be positive or negative, n (defined in Eq 5), and K_L/K_P, which can be greater than or less than 1. Depending on their relative values, the particles can be either pushed or engulfed. Therefore, as shown in Fig. 2, Eq 18 combines the thermodynamic criterion (Ref 4) with the thermal conductivity criterion (Ref 8).

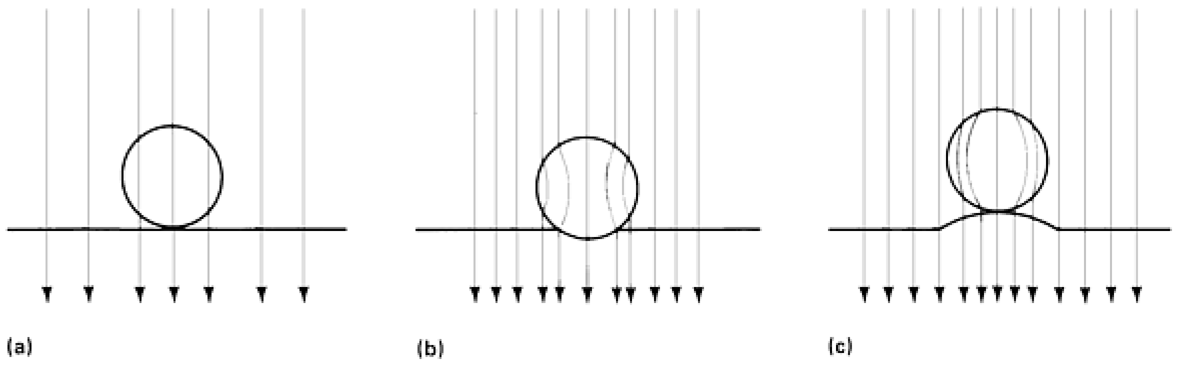

Fig. 2 Influence of thermal conductivity K of particle (K_P), liquid (K_L), and solid (K_S) on the shape of the solid/liquid interface. (a) Flat interface; K_P = K_L and K_S. (b) Engulfment; K_P > K_L and K_S. (c) Bump formation

(pushing); $K_P < K_L$ **and** K_S

The thermal conductivity criterion implies that when K_L **?** K_P a bump is formed, and the particle can roll over. The bump will then remelt, but another bump will be formed adjacent to the new position of the particle. Therefore, the interface will cease to be flat, and the particle will be continuously pushed, making engulfment impossible. Indeed, calculations of R_{cr} using Eq 18 for the Al-SiC system for a particle radius of 50 μm (2000 μin.) result in R_{cr} > 1280 μm/s (51,200 μin./s), a rate at which the interface obviously cannot be flat. In fact, interface destabilization is so extensive that cellular or dendritic solidification will occur. Particles can then be incorporated into the solid by entrapment rather than by engulfment, as will be shown later in this section.

However, if K_P **?** K_L, a trough will form (Fig. 2). However, $\Delta\sigma$and η will also play a major influence in determining the value of R_{cr}.

The role of thermal conductivity on particle behavior has also been emphasized through the empirical heat diffusivity criterion, $(K_P C_P \rho_P / K_L C_L \rho_L)^{1/2}$ (Ref 10). When this ratio is greater than 1, particles are supposed to be engulfed. Good agreement has been found between experimental data and predictions (Ref 2).

Experimental Results. The existence of a critical interface rate R_{cr} has been documented experimentally for both liquid particles (xylene and orthoterphenyl in water) and solid particles (silver iodide, graphite, magnesia, silt, silicon, tin, diamond, nickel, iron oxide, and zinc in orthoterphenyl, salol, and thymol) of various shapes (spherical and irregular) and sizes (1 to 300 μm) (Ref 1). Other researchers have investigated tungsten and copper particles in water, as well as aluminum, silver, copper, silica, tungsten, and tungsten carbide particles in salol (Ref 8, 11). A more accurate analysis of experimental results on glass, Teflon, polystyrene, nylon, and acetal particles (10 to 200 μm in diameter) in biphenyl and naphthalene has concluded that the transition between pushing and engulfment is not sharp, but rather that, for a given system, there are three modes of particle behavior (Ref 4):

- At high rates, particles are engulfed instantly
- At intermediate rates, particles are pushed some distance before being engulfed
- At low rates, particles are pushed along continuously

Computer curve fitting analysis of experimental results has shown that the critical rate depends on particle radius r according to:

$$R_{cr} \cdot r^n = \text{constant} \qquad \textbf{(Eq 19)}$$

where the exponent n ranges from 0.28 to 0.90.

The validity of the thermal conductivity criterion has been confirmed experimentally for a number of metallic particles (tungsten, tantalum, molybdenum, iron, nickel, and chromium) in tin and bismuth (Ref 12). Equations 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, and 19 have been derived for a single particle ahead of a planar interface. When several particles are considered, the interface is expected to exhibit a series of bumps and troughs, eventually resulting in interface breakdown. Therefore, the concept of critical interface rate becomes increasingly difficult to use.

To summarize, a number of process variables can be listed. A first group comprises those included in Eq 18, as follows:

- Particle radius r
- Viscosity of the liquid η
- Surface energy among particle, liquid, and solid (σ_{PL}, σ_{PS}, σ_{LS})

It must be noted that $\Delta\sigma$can be altered by the surface modification of particles (for example, coating or heat treatment) or by changing the chemistry of the melt through the addition of surface-active elements (Ref 13).

A second group of variables, although effective in single particle-planar interface systems, was not considered in the theoretical work summarized in this discussion, because of obvious complications in calculations. The second group consists of:

- Particle shape
- Particle aggregation, that is, gas, liquid, or solid
- Convection level in the liquid
- Density of liquid (ρ_L) and particle (ρ_P)

Equations 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, and 19 have been derived on the assumption of spherical particles. As expected, particles of nonspherical shape will tend to position themselves in front of the moving interface to expose the smallest cross sectional area to the interface, thus minimizing the repulsive force.

Particle aggregation may be important in the process to the extent that particle deformation at the interface may influence R_{cr}. A complicating and difficult-to-quantify variable is the convection level in the liquid. Particle size becomes significant when discussing the importance of convection because for small particles (<15 μm) even microconvection resulting from Brownian forces must be taken into account. For large particles, the primary influences are buoyancy-driven convection (that is, convection deriving from solutal and thermal differences within the liquid) and convection deriving from the Stokes forces imposed by the liquid on the particles (flotation or sedimentation of particles). Buoyancy-driven convection depends on the gravity level. Of course, the difference in density between particles and the liquid will play a significant role in Stokes convection, as shown for the Fe-graphite and Fe-VC systems (Ref 14).

Cellular and Dendritic Interfaces

In metal-ceramic systems of practical importance, such as metal-matrix composites, alloys rather than pure metals, and several particles rather than one particle, must be considered. Because of the impurity of the liquid and the influence of particles, the interface will break down to become cellular, and more likely dendritic. All process variables that influence R_{cr} in the case of one particle-planar interface system will obviously play a role in multiparticle-rough interface (metal-ceramic) systems.

A third group of process variables, particularly important in multiparticle-rough interface systems, consists of:

- Liquid/solid interface shape
- Volume fraction of particles at the interface
- Temperature gradient ahead of the interface

The influence of liquid/solid interface shape on particle behavior during directional solidification is shown in Fig. 3. If the interface is planar, pushing results in clean metal, while engulfment results in metal-matrix composites or oxide dispersion strengthened materials (Fig. 3a). If the interface is cellular, particles can be pushed at the tips of the cells while they are entrapped at cell boundaries, as observed for particles in the ice-water (Ref 1), Pb-1Sn-iron (Ref 15), and water-nylon systems (Ref 15), resulting in an aligned particulate composite (Fig. 3b). When the interface breaks down into dendrites, a more complex situation occurs, with small particles being entrapped in the interdendritic spaces, while large particles are possibly being pushed by the dendrite tips (Fig. 3c). This is actually contrary to the theoretical laws discussed previously.

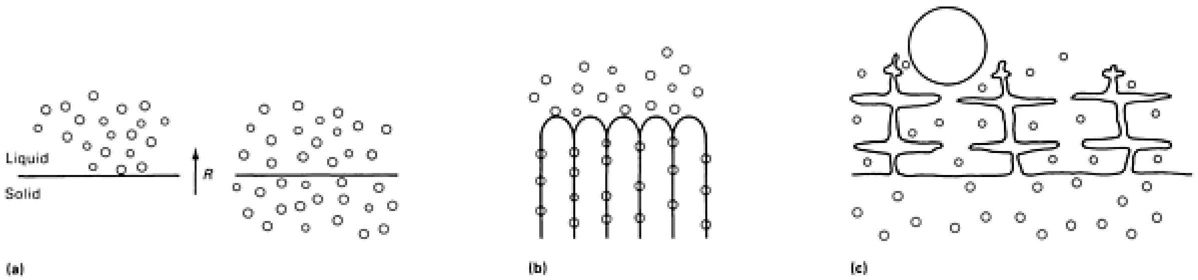

Fig. 3 Influence of interface shape on pushing or entrapment of particles. (a) Planar interface can result in pushing (left) or engulfment (right). (b) Cellular interface showing pushing at interface and entrapment between cells. (c) Dendritic interface; small particles are entrapped in interdendritic spaces while large particles are pushed. Source: Ref 9

The primary cause of interface breakdown, assuming constant growth rate, is the purity level of the metal. Obviously, in metal-matrix composites, the high impurity level favors interface breakdown. Additional sources of perturbation are the particles themselves. Figure 4 shows a comparison between the quench interfaces of two Al-2Mg alloys, directionally solidified under identical conditions (Ref 9). The main difference is that the one shown in Fig. 4(a) did not have silicon carbide particles, while the one shown in Fig. 4(b) did have carbides. The effect of silicon carbide particles in further disturbing the cellular interface is evident.

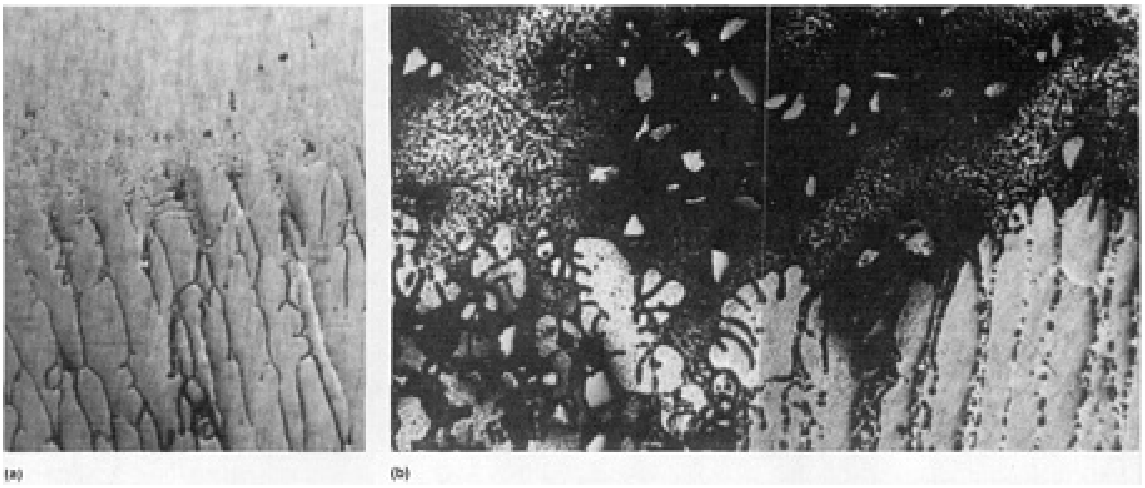

Fig. 4 Effect of silicon carbide particles on the morphology of the solid/liquid interface in Al-2Mg alloys. Solidification conditions were identical for (a) and (b); the solidification direction was upward in each case. (a) Alloy without carbides showing unperturbed cellular-dendritic interface. (b) Alloy with carbides and highly perturbed cellular-dendritic interface

This behavior can be explained by the perturbation of the thermal field ahead of the interface, as discussed earlier in the model that includes the contribution of thermal conductivity. According to Eq 18, R_{cr} becomes too high for engulfment because K_L ? K_P for this particular case; however, entrapment is possible because of the breakdown of the interface (Fig. 4b). Therefore, it is rather difficult to extrapolate equations such as those discussed earlier, which are derived for planar interfaces, to the interpretation of alloy systems where the planarity of the interface is susceptible to disruption by either the particles or the solidification conditions.

The volume fraction of particles must also be considered. At high volume fraction of particles in the melt, viscosity becomes a function of the amount of particles. A first approximation is given by Einstein's equation:

$$h^{*} = h\left(1+\frac{5}{2}f\right) \quad \textbf{(Eq 20)}$$

where η* is effective viscosity, η^0 is the viscosity of the suspending fluid, and f is the volume fraction of particles.

Because R_{cr} ~1/η (see Eq 18), it is expected that engulfment becomes easier as the volume fraction builds up. This trend has been qualitatively confirmed for silicon carbide particles in Al-6.1Ni alloys (Ref 16).

Although Eq 17 hints at some possible influence of temperature gradient *G*, it is difficult to rationalize such an influence in single particle-planar interface systems. On the contrary, experimental evidence for metal-ceramic systems documents the role of *G* rather convincingly. Figure 5 shows that increasing *G* favors pushing over entrapment for aluminum-silicon carbide composites (Ref 9). This could again be rationalized in terms of interface stability. As *G* increases, the planar interface becomes more stable and particles are pushed because engulfment is not possible.

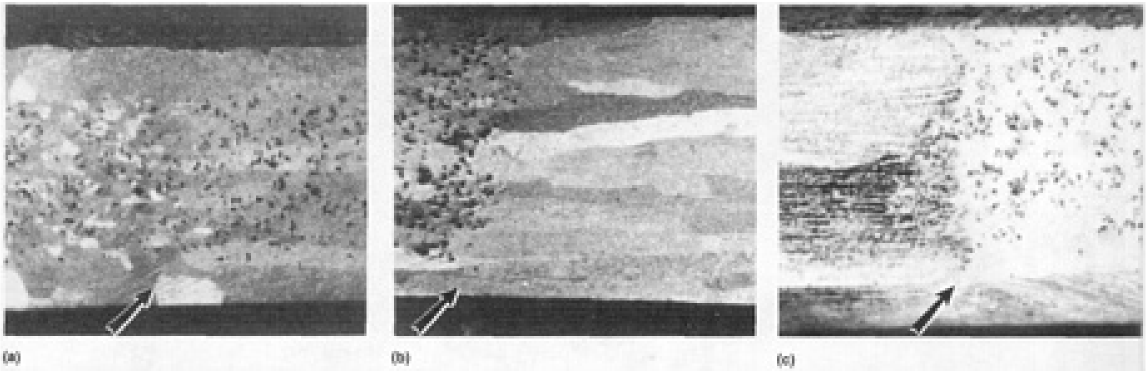

Fig. 5 Effect of temperature gradient *G* at the interface on the behavior of 10 to 150 μm silicon carbide particles in an Al-2Mg alloy. Solidification direction in all three cases was upward; start of directional solidification in (a) and (b) is indicated by an arrow. (a) *G* = 74 °C/cm (340 °F/in.); particles are entrapped. (b) *G* = 95 °C/cm (435 °F/in.); particles are pushed then entrapped due to volume buildup. (c) *G* = 117 °C/cm (535 °F/in.); particles are pushed and accumulate in the quench zone. In (c), the transition from directional solidification to the quench zone is indicated by an arrow.

In general, the influence of most of the above variables on the critical interface rate of entrapment in metal-ceramic systems can be summarized as follows:

$$R_{cr} = f\left(\frac{\Delta s}{hf}, \frac{1}{r}, \frac{K_L}{K_p}, G\right) \quad \textbf{(Eq 21)}$$

Although this correlation cannot be used for calculations and does not take interface shape into account, it can be used as a guide for manipulating parameters to achieve particle entrapment in metal-ceramic systems, because all parameters are measurable and can be used as experimental variables.

Particle Behavior in Multidirectional Solidification

Castings solidify under multidirectional heat flow conditions at much faster rates than those required for planar interface and are mostly made from alloys rather than pure metals. Therefore, solidification in castings normally proceeds by multidirectional growth of dendrites, followed by the solidification of the interdendritic liquid, or by equiaxed growth, with the intergranular liquid solidifying last. Under these conditions, it is still possible to generate some qualitative information on the behavior of particles in front of the melt interface, but any quantification is very difficult. A number of issues must be addressed:

- Solidification structure (dendritic or equiaxed)
- Structure/fineness versus particle size
- Agglomeration of particles

Dendritic Solidification. The first situation to be considered is that when particles are of the order of magnitude of secondary dendritic arm spacing or smaller. If the liquid does not wet the particles, their engulfment is not possible at normal solidification rates in castings. The particles are then pushed by the growing dendrites and are eventually entrapped in the interdendritic regions solidifying at the end (Fig. 6).

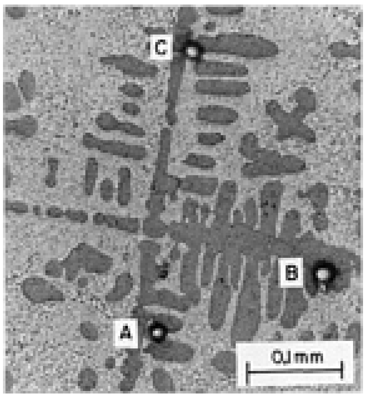

Fig. 6 Iron particles entrapped in interdendritic regions in a cast Pb-50Sn alloy

When the particles are larger than the interdendritic spacing, some pushing may occur by the tip of the dendrites, again with eventual entrapment in the interdendritic space. Because this is a totally random behavior, it may be possible to achieve good particle distribution throughout the matrix, if proper volume fraction of the particles and processing parameters for the composite are used (Ref 17).

Equiaxed Solidification. Figure 7 shows a schematic of possible resulting structures for the case in which particle size is much smaller than grain size. The concept of critical interface rate R_{cr} must now be applied at the level of microvolumes, where grain/liquid interface may be considered as planar.

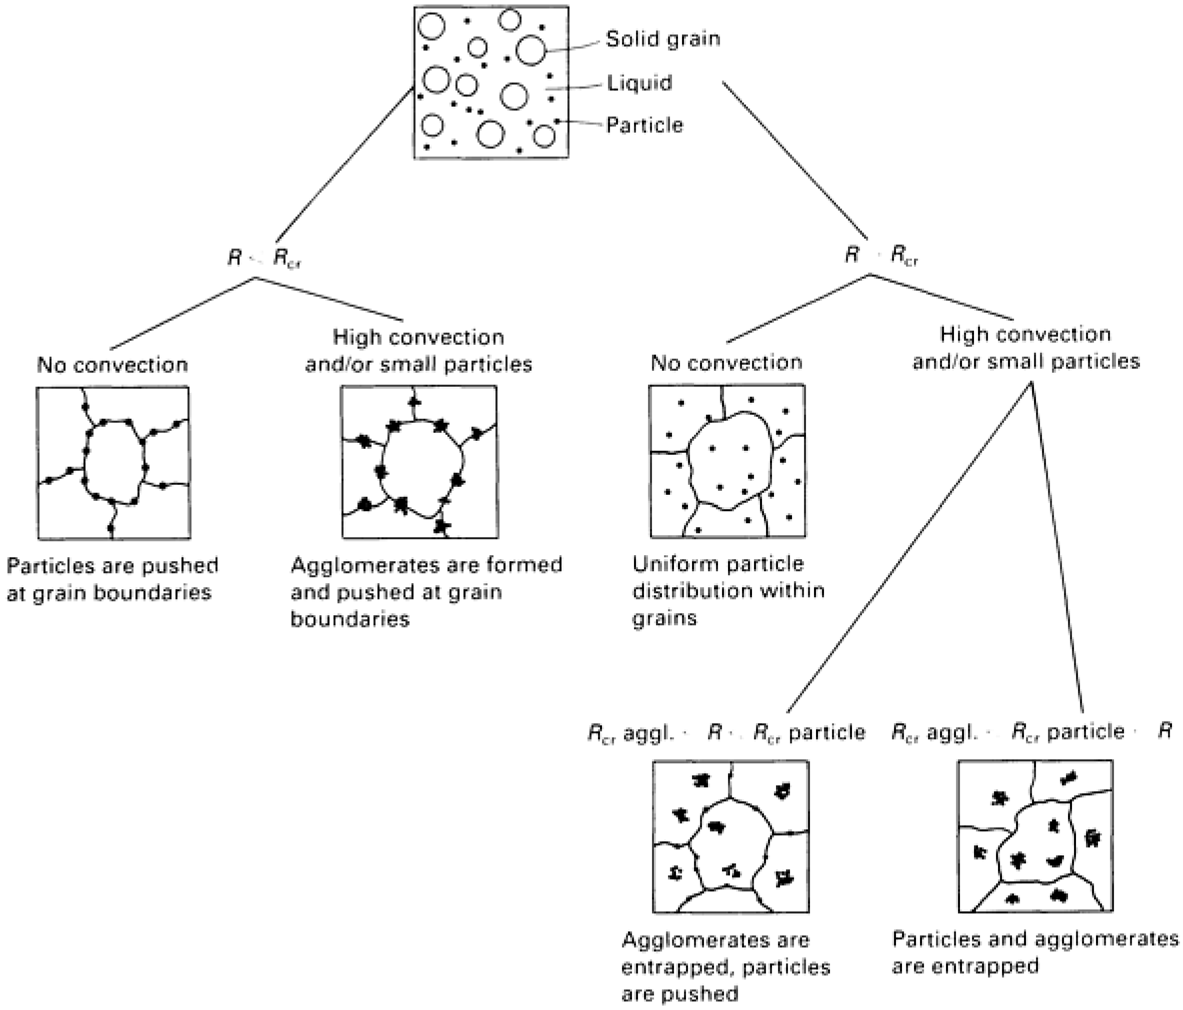

Fig. 7 Possible structures in multidirectional solidification as a function of solidification rate, convection level, and particle size

It is expected that nonwetting particles, which in general will fit into the $R < R_{cr}$ situation, will be pushed toward the grain boundaries. A higher level of convection may yield agglomeration of particles. The agglomerates will also be pushed in the intergranular liquid.

However, if $R > R_{cr}$, which is anticipated when good wetting exists between particles and liquid, particle engulfment is expected, resulting in a uniform distribution of particles within the grains. High levels of convection can cause further complication (Fig. 7). Similar behavior, as for dendritic solidification, is expected for the case of particle size of the same order of magnitude or larger than grain size.

Low-Gravity Effects During Solidification

Peter A. Curreri, NASA, Marshall Space Flight Center; D.M. Stefanescu, University of Alabama

Introduction

SOLIDIFICATION PROCESSES are strongly influenced by gravitational acceleration through Stokes flow, hydrostatic pressure, and buoyancy-driven thermal and solutal convection. Stokes flow of second-phase particles in off-eutectic and off-monotectic alloys and in particulate metal-matrix compositions severely limits casting composition. Porosity in an equiaxed casting is dependent on the hydrostatic pressure.

Buoyancy-independent solidification within the gravitational field at the earth's surface is accomplished only within strict limits. In one dimension, strong magnetic fields can dampen convection, and density gradients can be oriented with gravity for stability. However, magnetic flow dampening in one direction increases flow velocity (segregation and so on) in the transverse direction. Opposition of thermal and solutal convection for many alloy compositions makes stabilization of convection by orientation infeasible even in one dimension.

Space flight provides solidification research with the first long-duration access to microgravity. Supporting commercial and academic interest in solidification in space are several short-duration free-fall facilities. These include drop towers (4 s, 0.0001 *g,* where g = 9.80 m/s^2, or 32.2 ft/s^2), parabolic aircraft flight (30 s at 0.01 *g;* 1 min at 1.8 *g* repetitive cycles), and suborbital sounding rockets (5 min, 0.0001 *g*) (Fig. 1).

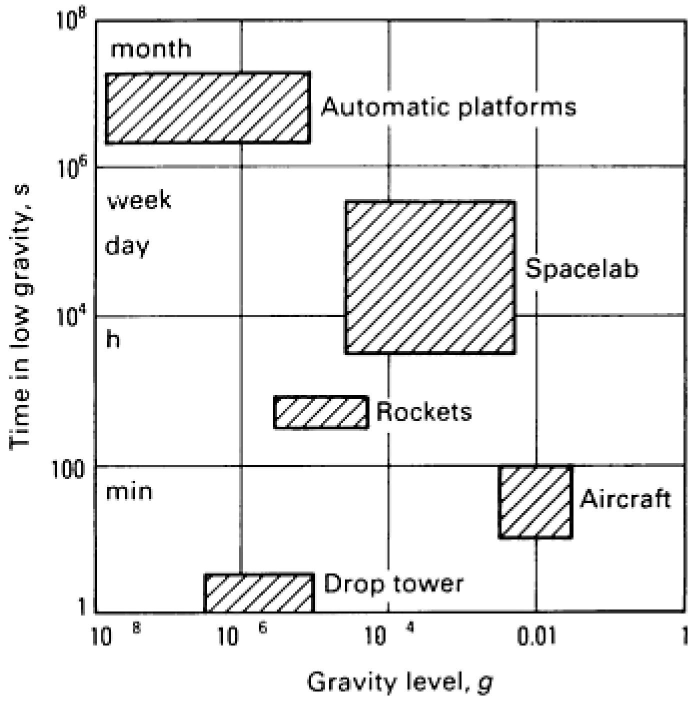

Fig. 1 Available low-*g* experimental systems.

Convection and the Melt Temperature Field in the Liquid

Thermal Convection and Temperature Gradient. Solidification progresses through the melt as a result of the extraction of heat from the liquid at the solid/melt interface. Thermal gradients during solidification are therefore present in the melt, causing density gradients that, under a gravitational field, result in buoyancy-driven convective flows. Convective flow, for constant furnace conditions, can modify the liquid thermal gradient G_L, at the solid/liquid interface.

The sensitivity of the melt thermal profile to convection is a function of the physical properties of the liquid. A dimensionless number from the Navier-Stokes equations that is useful in determining the sensitivity of a melt thermal profile in response to convective flow is the Prandtl number *Pr,* which is defined by:

$$\mathrm{Pr} = \frac{mC_p}{K} \qquad \textbf{(Eq 1)}$$

where μ is viscosity (in N · s/m^2), C_P, is specific heat (in J/kg · K), and K is thermal conductivity (in W/m · K).

At low *Pr,* the convective transport of momentum dominates the convective transfer of heat; thus, thermal convection has less influence on the temperature field. The Prandtl number for liquid metals is generally much less than 1 (of the order of *Pr* = 0.01). Ammonium chloride/water melts (often used as transparent analogs for metal solidification) have *Pr* = 6.

The response of the temperature fields to fluid flow in semi-infinite plates is illustrated schematically in Fig. 2 for high and low *Pr.* The heat flux is along the *z*-axis, that is, upward, so that if conduction alone is considered the temperature profile can be represented by the dashed line, showing the hot temperature T_{hot} at the bottom and the cold temperature T_{cold} at the top. Convective velocity, represented by the dotted curve, results in mass transport to the right in the upper half of the plate compensated by mass transport to the left in the lower half, which produces a convective roll. The effect is higher for low *Pr* (Fig. 2b) than for high *Pr* (Fig. 2a). Nevertheless, materials with low *Pr,* such as liquid metals, have normally high *K,* which reduces the effect of mass transport on the heat transport (temperature profile). The overall result on the temperature profile is indicated by the solid curves. It predicts a rather limited effect of convective flow for metals (Fig. 2b) as compared to some organic or semiconducting materials (Fig. 2a).

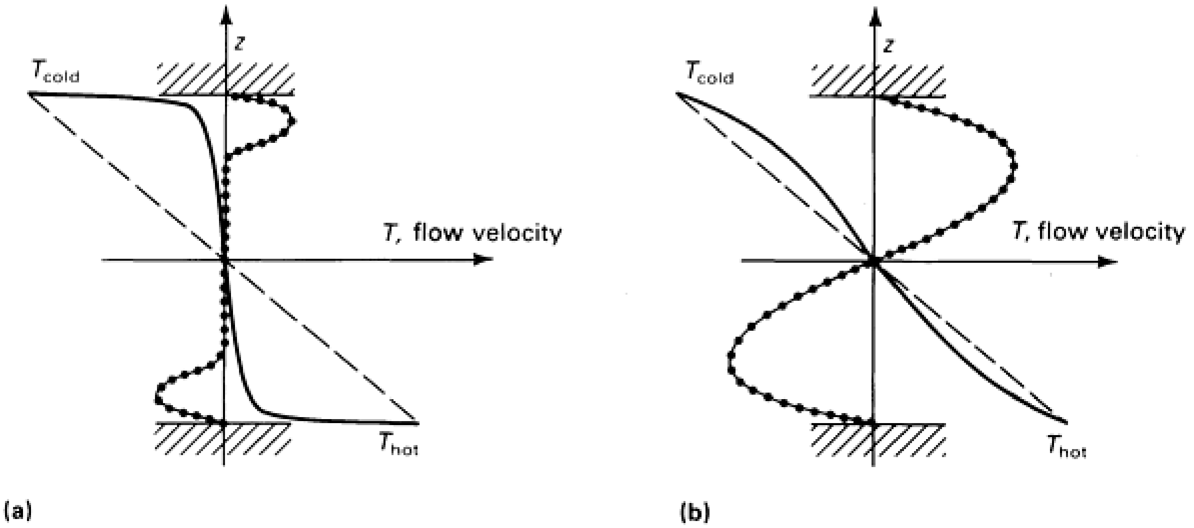

Fig. 2 Schematic of the sensitivity of the temperature field to fluid flow for melts with high and low *Pr.* (a) *Pr* ? 1. (b) *Pr* = 1. Dashed line represents temperature profile from thermal conduction only. Dotted curve is convective velocity, and solid curve is the corresponding temperature profile. Source: Ref 1.

For a given composition and growth velocity, alloy microstructure and solid/liquid interface morphology are dependent on G_L; therefore, the influence of convection on the liquid thermal profile has been extensively modeled. One configuration examined is unidirectional solidification in the vertically stabilized configuration, that is, solidification antiparallel to gravity (less dense hotter fluid upward).

Temperature field numerical results for gallium-doped germanium (*Pr* = 0.01) show that the temperature isotherms in the melt at the crucible center line compress (higher G_L) at high gravity because of convective flow (Ref 2). The thermal gradient at the crucible wall decreases with higher convection. This results from the convective flow of hot liquid toward the crystal/melt interface center that is compensated for by the flow of cold liquid away from the solidification interface at the crucible walls. Thus, under strong convection, the minimum G_L across the solid/liquid interface increases.

Solutal Convection and Temperature Gradient. At the growing interface during alloy solidification, solute of differing density from the bulk liquid is often rejected. Under a gravitational field (even if the system is stable for thermal convection), this results in solutal convection when the solute is less dense than the liquid. Thermal and solutal density gradients combine to cause thermosolutal convection. For metal alloys, the solute convection contribution to the fluid flow is normally large compared to the thermal convection contribution, causing solutal convective flow to dominate.

The laser interferograms of solidifying ammonium chloride shown in Fig. 3 illustrate the development of solutal convection (Ref 3). When the ampule of liquid ammonium chloride is placed on a cold block, solidification begins upward. Growth enriches solute in the liquid ahead of the solid/liquid interface, thereby decreasing its density relative to the bulk melt. The solute-rich layer builds up until a plume of less dense solute breaks away from the interface and travels upward in the melt. The solutally driven convective flow decreases the liquid thermal gradient at the solid/liquid interface. The effect on the temperature field is amplified by the high *Pr* number (*Pr* = 6) of the system. The experiment was repeated in low gravity during aircraft parabolic flight (10^{-2} *g*) and the G_L in low gravity was 15% greater (relative to G_L in 1 *g*) (Ref 4). As expected from Fig. 2, low-gravity experiments with metallic alloys (low *Pr*) find less dependence of G_L on convective flow.

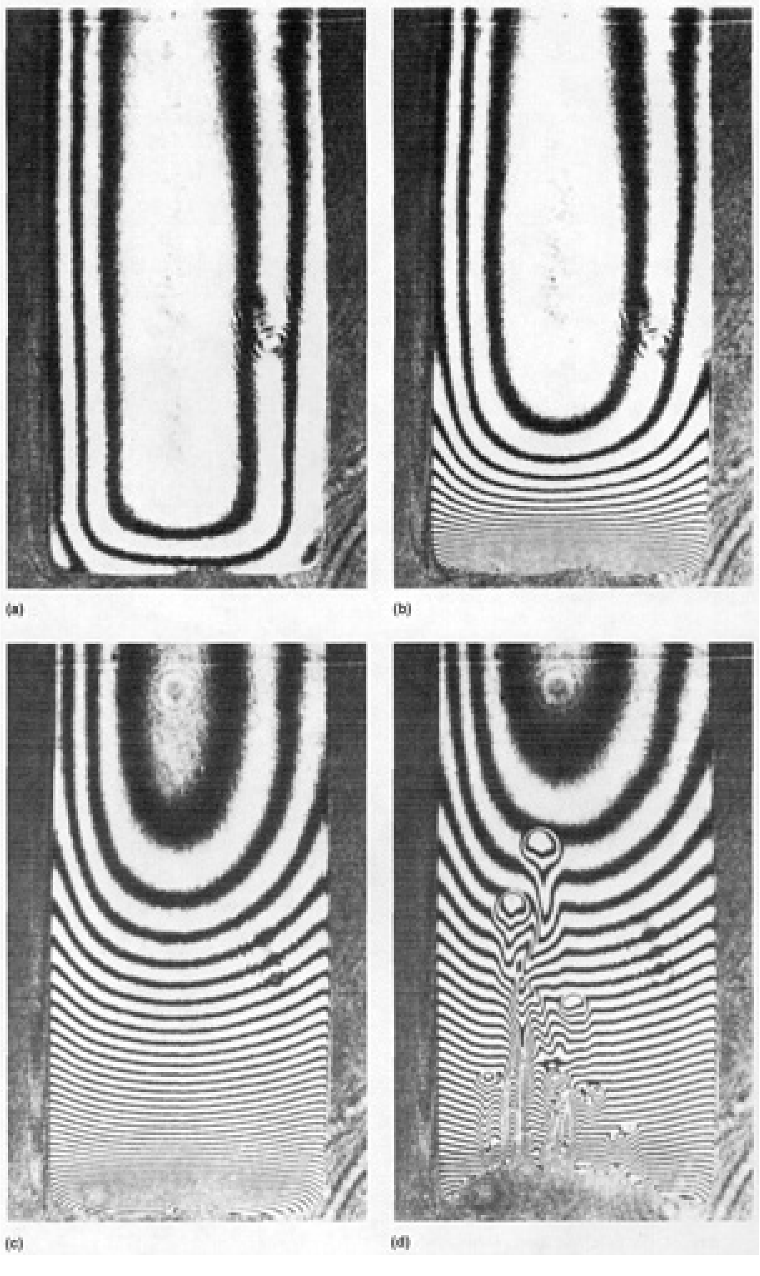

Fig. 3 Laser interferograms of an ammonium chloride/water transparent model during initial solidification upward in normal gravity showing the development of solutal convective plumes at elapsed times of 0.0 s (a),

30 s (b), 90 s (c), and 120 s (d).

Convection and Solute Redistribution

The solute concentration in the solid during alloy solidification differs (unless the partition coefficient is 1) from that in the liquid ahead of the solidification interface. When the liquid ahead of the solidification interface is continually well mixed by convective flow, the resulting solute concentration in the solid (if diffusion in the solid is negligible) continually increases. However, if the solute rejected into the liquid is transported only by diffusion (and Soret diffusion is negligible), a solute-enriched boundary layer forms in the liquid ahead of the solid/liquid interface and increases in solute concentration as solidification progresses until a steady state is reached.

Alloy solidification in the presence of a steady-state boundary layer can, in contrast to the example with strong convection, solidify with a nearly constant composition of the solid. Low-gravity planar growth experiments with tellurium-doped indium-antimony (Skylab, 1972) first demonstrated improved crystal solute homogeneity (over that for growth in 1 *g*) by steady-state diffusion boundary layer controlled growth.

Stagnant Film Models. Variable-thickness diffusion boundary layer (stagnant film) models are often used to assess the influence of convective flow on the solute distribution during solidification. Convective flow is assumed to mix the solute completely in the melt outside the diffusion boundary layer. The boundary layer thickness decreases with increasing convective flow. Inside the diffusion boundary layer, the model assumes that solute transport is by diffusion only. For intermediate convective flow velocity, the model assumes a dynamic diffusion boundary layer that can be calculated via an effective (convective-dependent) partition ratio. At high convective flow, the boundary layer approaches 0, yielding a solid solute concentration that varies insignificantly with solidified fraction until the end of solidification is approached.

Stagnant film models are often used in the literature for simplicity of calculation. The assumption that convective flow does not penetrate the diffusion boundary layer, however, leads to incorrect predictions. The transverse diffusion boundary layers for on-eutectic growth or secondary dendrite arms are much smaller than the momentum boundary layer that the model considers to be affected by convective flow. Therefore, stagnant film models falsely predict that even vigorous convective flow will have no effect for on-eutectic or secondary dendritic spacings.

Numerical Solution of Solute Redistribution. Finite-element methods more accurately model convective flow at the melt/solid interface and the resulting solute segregation. Numerical predictions are qualitatively similar to those of the stagnant film models (Ref 2). However, finite-element calculations reveal that a stagnant boundary layer does not exist in the presence of convection. Flow within the diffusion boundary layer has a strong convective flow contribution. This contribution must be carefully considered in analyzing the effect of convection on microstructure.

Solidification of Composites in Low-Gravity Eutectic Alloys

Buoyancy-driven convection and Stokes flow strongly affect eutectic solidification. The casting of off-eutectic alloys with independently nucleated primary phase (under normal gravity) results in severe macrosegregation due to Stokes flow. An example is the kishing of graphite in castings of hypereutectic gray iron. Solidification in zero gravity eliminates Stokes flow. Low-gravity experiments with off-eutectic iron-carbon alloys have shown that primary graphite flakes or nodules

that float away from the interface in normal gravity are incorporated into the solidifying interface under low gravity (Ref 4). Thus, the solidification of off-eutectic castings with independently nucleated primary particles in zero gravity eliminates macrosegregation due to Stokes flow.

Cooperative growth of on-eutectic alloys has been shown to be strongly influenced by convection. On-eutectic MnBi/Bi was solidified in low gravity on Space Processing Applications (sounding) Rocket flights SPAR VI (R = 6 mm/min, or 0.24 in./min) and SPAR IX (R = 8.3 mm/min, or 0.33 in./min) (Ref 5). Sample microstructures, compositions, and properties were compared to 1 g controls (solidified under identical conditions except for gravity). The eutectic interphase spacing (relative to 1 g controls) for a low-gravity solidified sample decreases by over 50%. This is evident in the transverse sections shown in Fig. 4. A decrease in rod diameter is also apparent for low-gravity solidified samples. The volume fraction of MnBi rods in low-gravity samples is also smaller (about 7%). Thermal data reveal increased interfacial undercooling (3 to 5 °C, or 5 to 9 °F) during low-gravity solidification. Low-gravity solidification produces samples with increased intrinsic coercivity (resistance to demagnetization) (Ref 6).

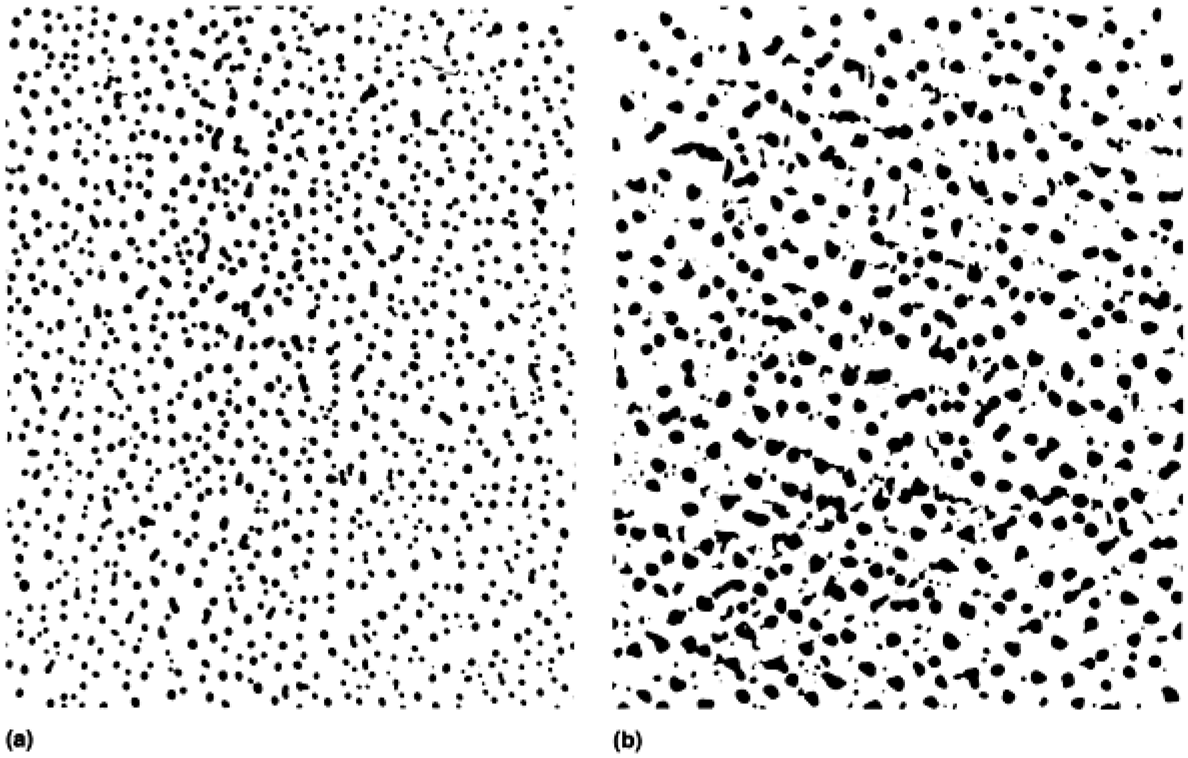

Fig. 4 Transverse sections of bismuth/manganese bismuth rod eutectic solidified in low-gravity (SPAR IX sounding rocket) (a) and a 1 *g* control sample (b). Source: Ref 5.

Phase spacing can also be refined in 1 g by increasing the solidification rate R. Figure 5 shows the interrod spacings λ as a function of R under various processing conditions. It is evident that the orientation of the sample in 1 g has no effect on interrod spacing. At higher R, the spacing appears to obey $\lambda \cdot R^2$ = constant, with the exception of finer spacing for low-gravity samples.

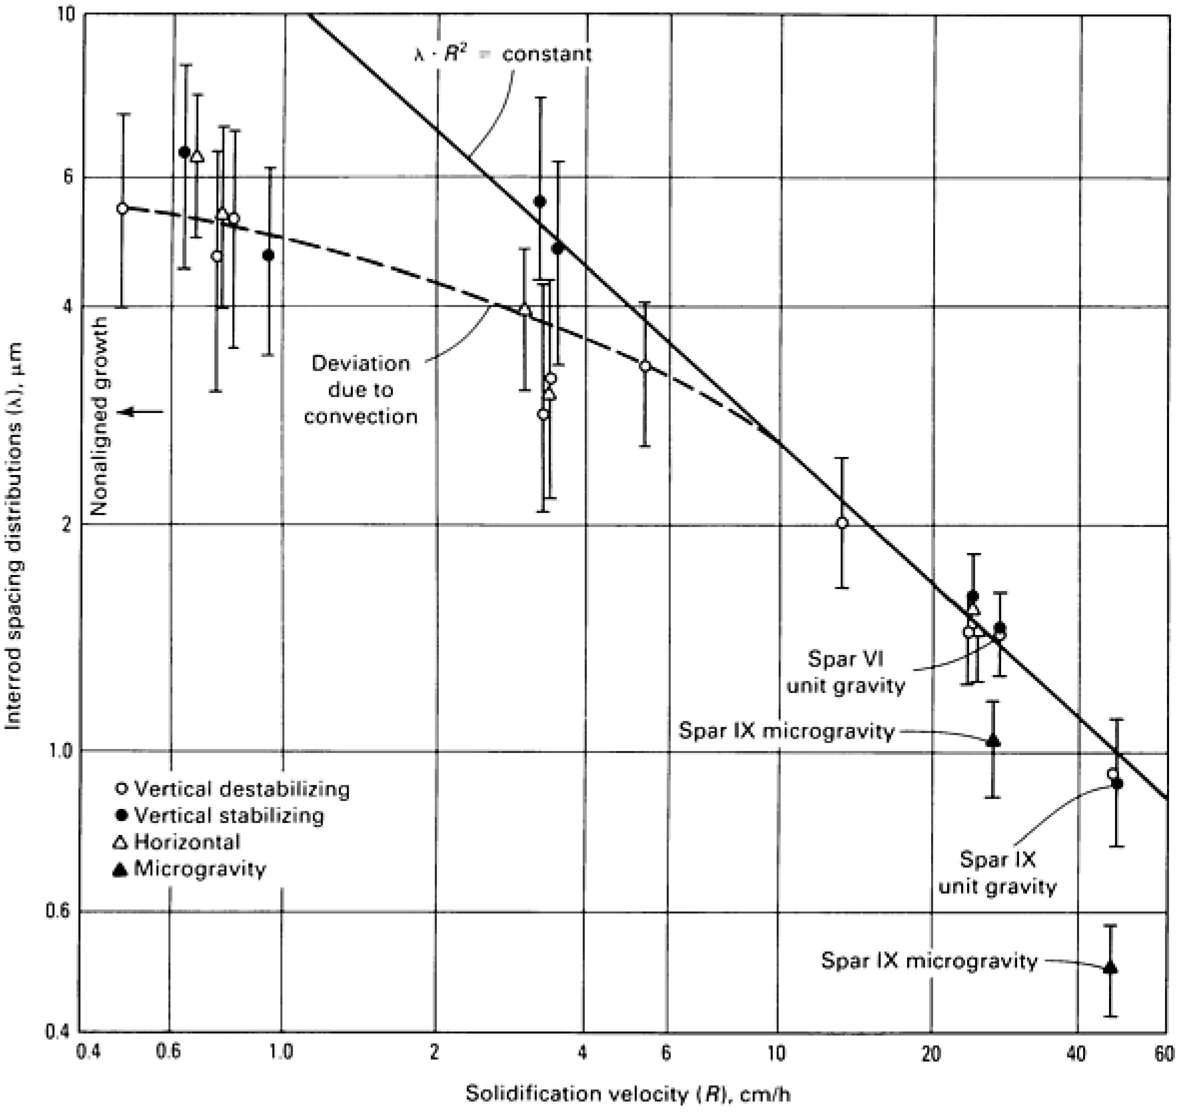

Fig. 5 Interrod spacing for bismuth/manganese bismuth versus velocity for samples solidified parallel and antiparallel to gravity on earth and for low-gravity solidified samples. Source: Ref 6.

Table 1 includes these first results and the data reported from subsequent studies. Interphase spacing refinement during low-gravity solidification is observed for both fibrous (MnBi/Bi and InSb/NiSb) and lamellar (Fe_3C/Fe) on-eutectic compositions. Gravity independence of lamellar spacing is reported for aluminum-copper and a decrease in spacing for low gravity is reported for Al_3Ni/Al. Although results for each alloy were reproducible, there is no obvious trend.

Table 1 Effect of low gravity for on-eutectic interphase spacing

Alloy composition	Low-gravity solidification effect on interphase spacing, %
Lamellar eutectics	
Al_2Cu/Al	**No change**

Fe_3C/Fe	**-25**
Fibrous eutectics	
MnBi/Bi	**-50**
InSb/NiSb	**-20**
Al_3Ni/Al	**17**

Source: Ref 7

The mechanism for the influence of low gravity during on-eutectic solidification on phase spacing has yet to be established. The importance of convective flow is demonstrated for MnBi/Bi by the duplication of low-gravity spacing and interfacial undercooling through solidification in strong (0.3 T, or 3 kG) magnetic field. The effect of gravity on convective flow is relatively well understood. The challenge is to develop a theory that adequately relates convective flow at low gravity to the mechanisms controlling eutectic phase spacing. Several approaches being pursued to develop the needed theory are discussed below in relation to experimental findings.

Analysis of Convective Flow for On-Eutectic Growth. A simple stagnant film model predicts that the presence (or absence) of convection will not affect cooperative on-eutectic growth. Solute redistribution for on-eutectic growth occurs on the scale of the lamellar spacing, which is much smaller than the convective flow momentum boundary layer (of the order of D_L/R, where D_L is the liquid diffusivity). Thus, for steady-state on-eutectic growth at fixed volume fraction, convective flow is not expected to affect lamellar spacing.

More rigorous analysis has demonstrated the invalidity in the above conclusions (Ref 8). The actual flow fields (diffusive and convective) in the liquid ahead of the eutectic solid/liquid interface are numerically calculated. A series of curves for lamellar spacing versus interfacial undercooling for a given *R* can be determined for different magnitudes of forced convective flow (Fig. 6). Growth is assumed to be preferred at the extremum (minimum interfacial undercooling), which then defines the eutectic spacing for a given *R*.

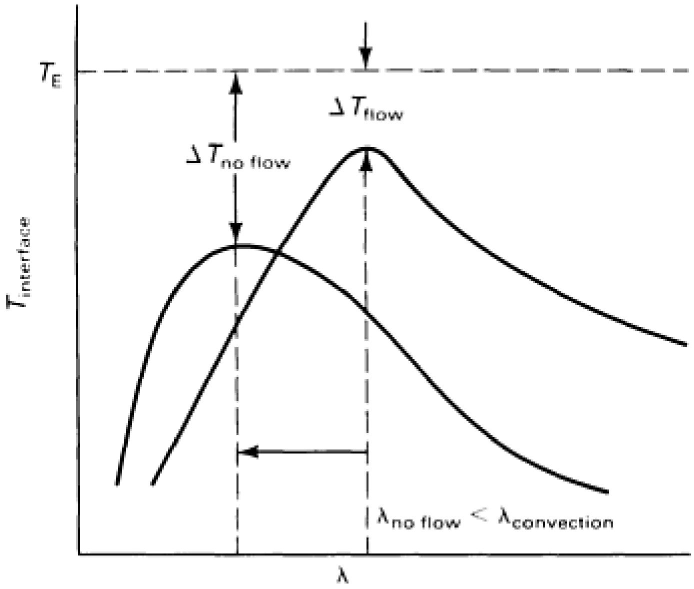

Fig. 6 Predicted evolution of undercooling-interphase spacing relationship with forced convective flow parallel to

the solid/liquid interface from the Quenisset-Naslain model. Source: Ref 8.

The theory predicts that forced convection decreases interfacial undercooling and increases interphase spacing. The theory semiquantitatively predicts phase spacing at high convective flows for Ti/Ti_5Si_3, MnBi/Bi, and Fe/Fe_2Bi. Qualitatively, the theory predicts the low-gravity results for MnBi/Bi eutectic (Table 1).

When the theory is applied to MnBi/Bi low-gravity solidification data, the calculated disturbance in the eutectic diffusion field at 1 *g* is so slight that the calculated eutectic phase spacings for solidification in 1 *g* and in space are essentially equivalent (Ref 9). Thus, the calculated effect of convective flow on the liquid concentration field does not explain the low-gravity eutectic lamellar spacings.

Off-Eutectic Approach. Other researchers have proposed off-eutectic models to account for the influence of low gravity on eutectic spacing (Ref 7). They postulate an arbitrary 1% deviation from eutectic composition. Boundary layer theory is used to predict the effect of convection on the volume fraction term in equations for eutectic spacing.

Off-eutectic models offer several advantages. The solute redistribution boundary layer is of the order of D_L/R, which is much larger than that (eutectic spacing λ) for on-eutectic cooperative growth. Convection has a much more pronounced effect on the concentration field ahead of the solid/liquid interface. The sign of the composition deviation from eutectic determines the sign of the low-gravity induced phase spacing change (low-gravity spacing that is smaller for hypereutectic and larger for hypoeutectic). No change, that is, insensitivity to convection, is also predicted for some materials.

Manganese bismuth/bismuth eutectic samples experience considerable solid/liquid interfacial undercooling during directional solidification in low gravity. Under equivalent solidification conditions (except in 1 *g*), MnBi/Mn essentially solidifies at the eutectic temperature. Volume fractions f_v for MnBi/Bi data show on-eutectic solidification in normal gravity and bismuth-rich off-eutectic solidification in low-gravity (Fig. 7).

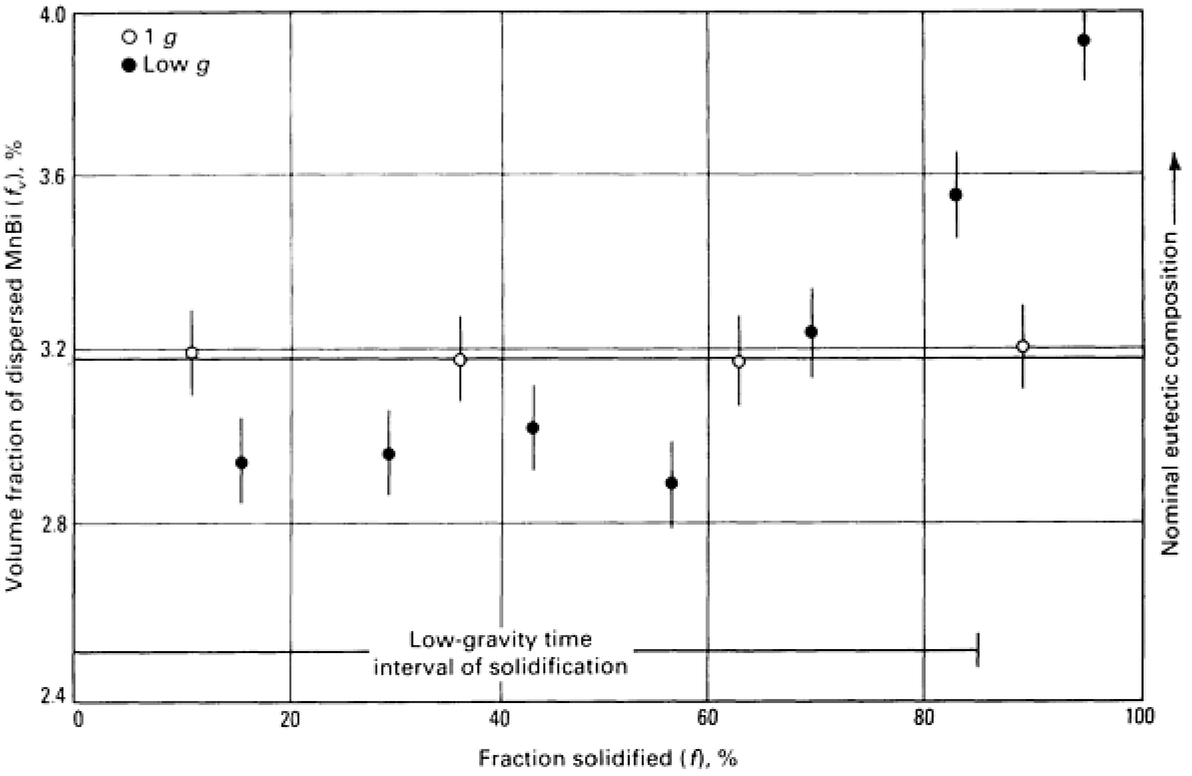

Fig. 7 Solidification temperature (undercooling) data for MnBi/Bi solidified in low gravity relative to 1 *g* controls. Source: Ref 6.

Due to the lack of published data, it is not known if the other alloys in Table 1 also experience increased eutectic solid/liquid interface undercooling in low gravity. Alloy-dependent undercooling in low gravity could explain the data in Table 2.

Table 2 Effect of low gravity on dendrite spacing

Composition	***g*-*g*_{low}**	Low-gravity solidification relative dendrite spacings
NH_4Cl-4%H_2O	1-0.0001	**+30% secondary +10% tertiary**
Al-Cu	1-0.00001	**+150% primary**
Pb-Sn	1-0.0001	**+50% secondary**
MAR-M246	1.8-0.01	**+50% secondary**
Fe-C-Si-P	1.8-0.01	**+20% secondary**
PWA-1480	1.8-0.01	**+20% primary**
Al-Cu	**1-0.001**	**+500% primary**

The off-eutectic model (Favier and deGoer) tested (Ref 7) with the f_v flight data for MnBi/Bi (Fig. 7) predicts $\lambda_{1g} = 1.05\ \lambda_{0g}$. This is only 10% of the observed change. Therefore, the gravity-dependent change in f_v using the Jackson-Hunt expression (and the assumptions that the volume fraction, liquid diffusivity, and temperature change at constant velocity are constant), cannot explain low-gravity eutectic spacings.

Diffusion/Atomic Transport. Neither on-eutectic nor off-eutectic convection models predict the data in Table 1. Convective effects on thermal gradient and growth rate also fail to explain the low-gravity eutectic spacing.

Another approach examines the influence of gravity on solidification through microconvections driven by microscopic concentration and temperature gradients (Ref 7). These microconvections are independent of the previously discussed macroconvection but are indistinguishable from collective atomic motion, that is, liquid diffusion. The effective liquid diffusion coefficient D_{eff} in normal gravity consists of the intrinsic diffusion coefficient plus an atomic transport component due to microconvection. In low-gravity liquid-metal diffusion experiments for zinc and tin, it was found that $D_{eff}(0\ g)$ is less than $D_{eff}(1\ g)$ by 10 to 60% (Ref 7). A decrease in D_{eff} of this order could explain the magnitude of lamellar spacing decrease found for low-gravity solidified Fe/Fe_3C and Bi/MnBi (Ref 7). The low-gravity data for on-eutectic spacing for aluminum-copper and Al_3Ni/Al, however, have yet to be convincingly explained by this approach.

Monotectic alloys contain a miscibility gap or dome in their phase diagrams. During off-monotectic alloy solidification in the temperature region through the miscibility gap, two immiscible liquids exist in equilibrium. Melt processing in normal gravity results in density-driven Stokes coalescence of the liquid droplets and massive segregation similar to that experienced for oil and water dispersions. Powder metallurgical (P/M) methods are therefore used to prepare hypermonotectic compositions. However, the interfacial purity necessary to exploit enhanced electronic property applications of hypermonotectic alloys is difficult to maintain with P/M processing. Thus, off-monotectic alloys have had only limited technical importance.

Low-gravity drop-tower experiments with gallium-bismuth have demonstrated the feasibility of producing high volume fraction immiscible alloys with finely dispersed microstructures (Fig. 8) by low-gravity solidification (Ref 10). Subsequent low-gravity experiments have identified a number of nonbuoyancy-driven coalescence mechanisms. Surface wetting of the crucible by the minority liquid, thermal migration of droplets, interfacial energy differences between the liquid phases and the solid, surface tension driven convection, and nucleation kinetics must all be carefully controlled to obtain fine dispersions of hypermonotectic alloys in low gravity.

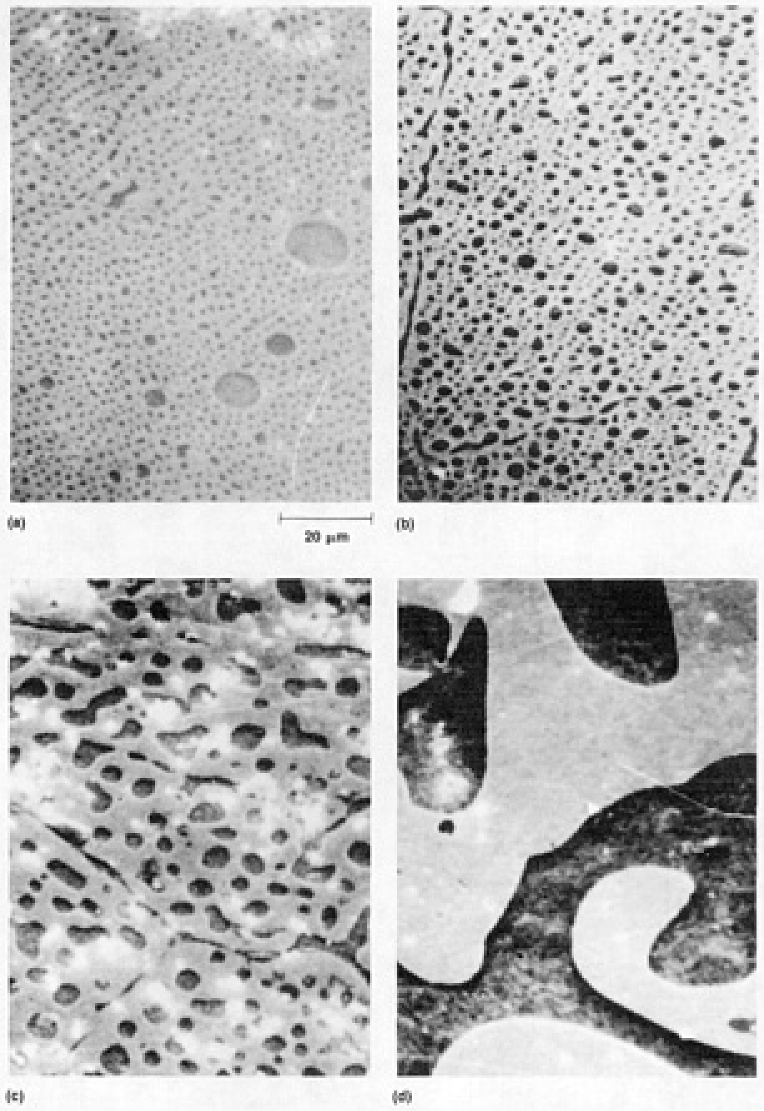

Fig. 8 Photomicrographs of gallium bismuth hypermonotectic alloy samples solidified under identical conditions except gravity. (a) to (c) Low gravity. (d) 1 *g*.

Hypermonotectic solidification in low gravity has often resulted (relative to a sample solidified in 1 *g*) in samples with enhanced electronic properties. Low-gravity solidified gallium-bismuth samples exhibit unusual resistivity versus temperature characteristics and possess a superconducting phase with a higher transition temperature T_c (Fig. 9). Skylab experiments for lead-antimony-zinc and gold-germanium hypermonotectic alloys also report a phase with higher T_c (than that of 1 *g* control samples) for a sample solidified in low gravity. An aluminum-indium-tin hypermonotectic alloy that was directionally solidified during low-gravity parabolic maneuvers also yielded a higher T_c minority phase present only in low-gravity sections (Fig. 10). The low-gravity sections exhibit semi-metal temperature versus resistance characteristics, while the 1 *g* and high-gravity sections are metallic.

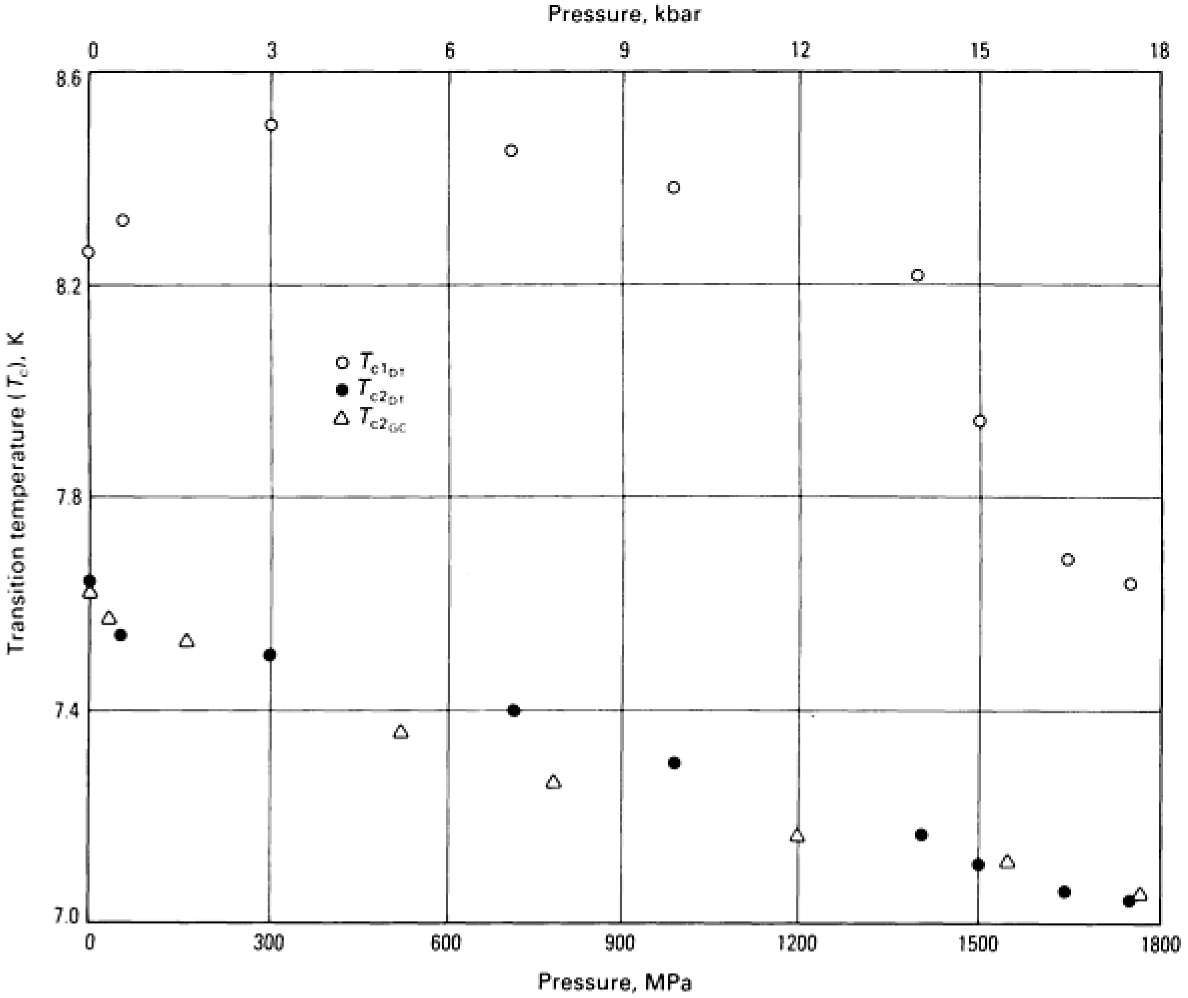

Fig. 9 Superconducting transition temperature T_c for gallium bismuth hypermonotectic samples showing higher T_c phase in low-gravity sample. Ground control (GC) sample: solidified in 1 *g*; drop tower (DT) sample: solidified in the drop tower (10^{-4} *g*). Source: Ref 11.

Ceramic Metal-Matrix Composites. The melt processing of ceramic metal composites, although less commonly employed than powder metallurgy, has some important advantages. These include better matrix particle bonding, control of the matrix solidification, and processing simplicity. Melt processing is, however, severely limited by gravity-driven segregation.

Low-gravity processing eliminates Stokes forces that dominate the segregation process for large (>1 μm, or 40 μin.) particles. This allows the study of normally masked surface energy driven processes. Small-particle suspensions (<1 μm, or 40 μin., where Brownian collisions dominate aggregation) can be solidified without buoyancy-driven convective flows. Low-gravity experimental results can be used to modify ground processing for improved properties, to develop space construction processes (for example, welding of oxide-strengthened composites in space), or to produce unique space-processed materials.

The first low-gravity ceramic metal-matrix composite experiments were performed on Skylab. (Low-gravity results for composite processing are reviewed in Ref 13.) The gravity-driven segregation of silicon carbide whiskers in silver decreased, yielding a composite with improved (relative to normal gravity processing) mechanical properties. These results were confirmed by low-gravity sounding rocket experiments. The solidification of metal-matrix composites with large (1 to 160 μm, or 40 to 6400 μin.) ceramic particles has also yielded more homogeneous dispersions in low gravity. Surface tension driven segregation and the effects of grain boundaries can dominate segregation low gravity. Composites with small (0.1 to 0.5 μm, or 4 to 20 μin.) oxide particles were found to solidify with a more homogenous dispersion and with fewer particle-free areas in low gravity. Because Stokes forces (sedimentation and flotation) are not strong for this size of particle, the improved homogeneity was hypothesized to result from the lack of convective flows.

Morphological Stability of the Solid/Liquid Interface in Low Gravity

The solute composition at the solid/melt interface is dependent on convective flow. Therefore, convection by stagnant film models can be related to the constitutional supercooling criterion for solid/liquid interfacial morphological stability. More detailed analysis shows that it is critical to consider both thermal and solutal convective flow. Numerical analysis has been reported for coupled thermosolutal convection and morphological stability for a lead-tin alloy solidified in the vertical-stabilized Bridgman configuration (Ref 14). The calculated stability diagram for thermosolutal convective flow is shown in Fig. 11. Although the constitutional supercooling criterion predicts stability in the entire field under the constitutional curve in Fig. 11, when thermosolutal convection is taken into account, the stability field is decreased to the shaded region. In low gravity (10^{-4} *g*), calculation predicts higher stability for constant boundary conditions.

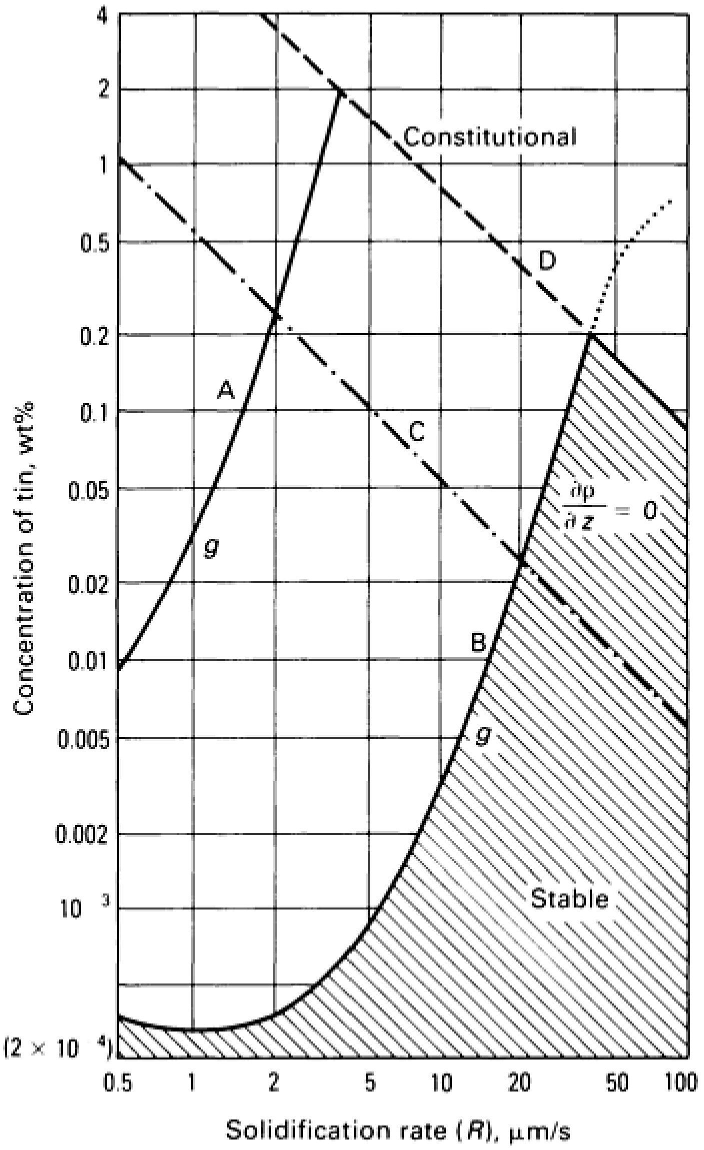

Fig. 11 Calculated stability diagram for critical concentration of tin versus solidification rate for lead-tin (grown in the vertical-stabilized Bridgman configuration). Curves (A, at 10^{-4} *g*; B, at 1 *g*) are the composition above which thermosolutal convection instability occurs. Curve C is the neutral density criterion. Curve D represents the morphological instability criterion. G_L = 200 K/cm. Source: Ref 14.

Morphological Stability

The influence of gravity on the planar-to-cellular transition for an iron-carbon-silicon-phosphorus alloy has been determined in experiments on directional solidification during multiple-aircraft parabolic low-gravity maneuvers (Ref 4). Sample composition, gradient and growth rate were selected such that the interface was only marginally morphologically stable during solidification in 1 *g*. Samples were then solidified under the same conditions except during low-gravity maneuvers (continuous cycling of about 25 s at 0.01 *g* and 1 min at 1.8 *g*). The solid/liquid interface became more unstable in low-gravity and could be made to shift from planar (or cellular) to equiaxed solidification morphology during the shift in aircraft gravity from 1.8 to 0.01 *g* (Fig. 12). Solidification experiments in space also found greater destabilization for the Al-1.0Cu interface in low gravity (Ref 15).

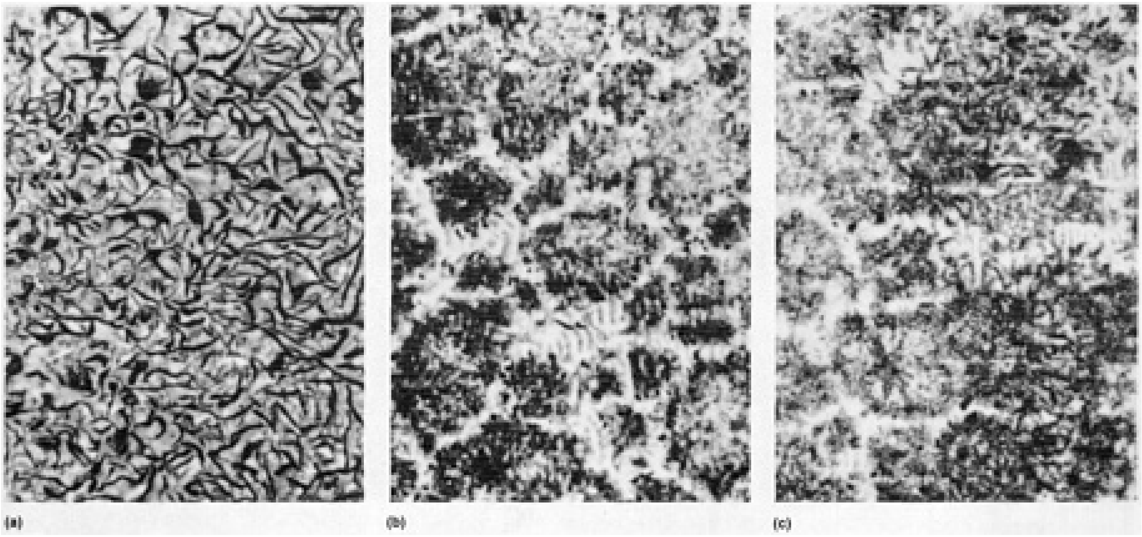

Fig. 12 Shift from planar morphology (a) to equiaxed solidification morphology (b and c) at the high-gravity (1.8 *g*) to low-gravity (0.01 *g*) transition. Microstructures shown are type A graphite (a), independent nucleation type D graphite (b), and independent nucleation eutectic grains (c).

Cellular and Equiaxed Growth

Eutectic cell (grain) size for austenite-flake graphite eutectic iron-carbon-silicon-phosphorus has been shown to increase in low gravity during directional solidification in aircraft low-gravity maneuvers (Ref 4). The cell diameter for nickel-base superalloy was two times greater for low-gravity solidification on Spacelab than that for 1 *g* control samples (Ref 16).

Dendritic Growth and Segregation

Dendritic growth processes are critical to the most common alloy casting techniques. Dendrite arm spacings correlate with mechanical strength. Interdendritic macrosegregation causes nonhomogeneous casting properties, yet controlled segregation is used for precipitation-strengthening processes. Buoyancy-driven convective flow in the liquid perturbs the metal alloy solute concentration profiles (and to a lesser degree, temperature profiles) that control microstructure and properties. Therefore, gravity has a strong influence on the processes of dendritic growth.

Dendrite Tip Growth Morphology and Growth Velocity. Single dendrites of pure succinonitrile have been studied as a function of undercooling, tip growth rate, and orientation with respect to gravity (Ref 17). Gravity-independent diffusion-limited growth occurs at undercooling of 1 to 9 °C (2 to 16 °F). However, at undercoolings less than 1 °C (2 °F), morphology and growth rate are dependent on dendritic orientation to gravity (Fig. 13). The growth rate perturbations observed at small undercooling are consistent with the enhanced transfer of latent heat by natural convection. Low-gravity experiments with Al-0.4Cu have shown that convection can influence dendritic morphology and crystallographic orientation in metallic alloys (Ref 15).

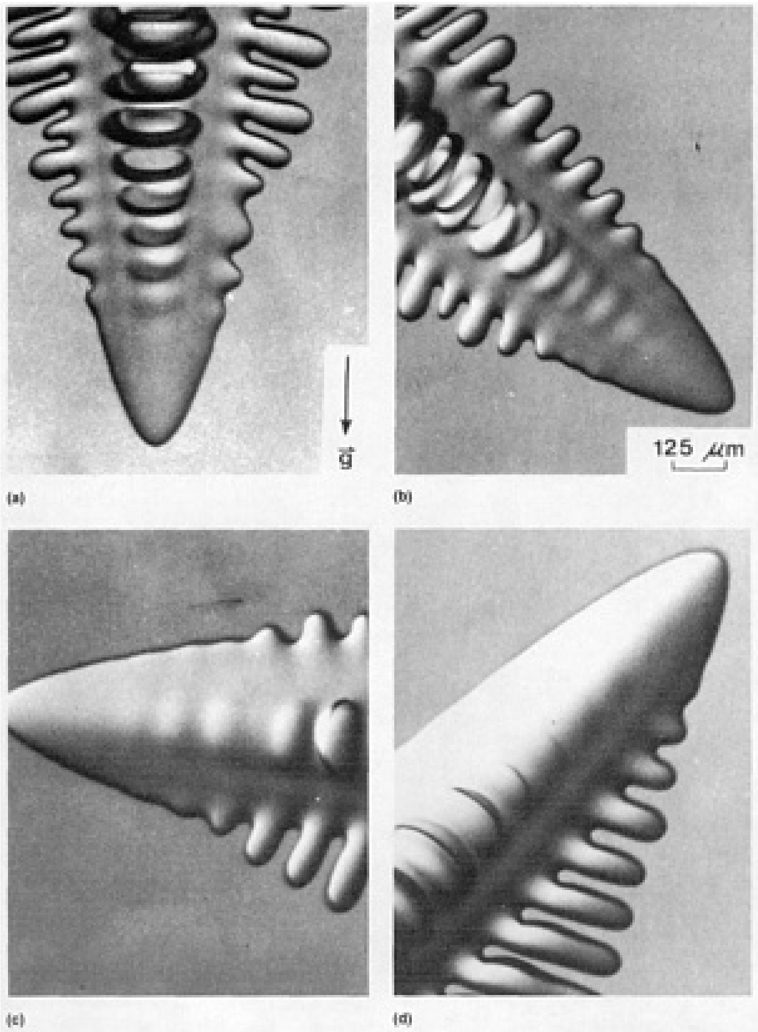

Fig. 13 Influence of orientation of growth direction relative to gravity on the dendritic morphology of succinonitrile (transparent analog model) showing suppression of sidebranches for inclinations above 90° to gravity. Orientation relative to direction of *g* is 0° (a), 45° (b), 90° (c), and 135° (d).

Gravity and Dendritic Spacing. Table 2 lists the results of low-gravity solidification studies on dendrite spacings (Ref 18). The effect of low gravity on secondary dendrite spacings was studied on sounding rockets (5 min at 0.0001 *g*) for ammonium chloride/water metal-model material and for lead-tin binary alloy, and on parabolic aircraft maneuvers for iron-carbon and MAR-M246 superalloy. Primary dendrite spacings have been studied (Ref 19) by solidification on orbital laboratories for aluminum-copper (Fig. 14) and during parabolic aircraft maneuvers for iron-carbon and PWA-1480 superalloy (Fig. 15). In all studies to date in which differences have been noted, regardless of alloy complexity, low-gravity solidification has resulted in coarser dendritic spacing compared to solidification in normal gravity.

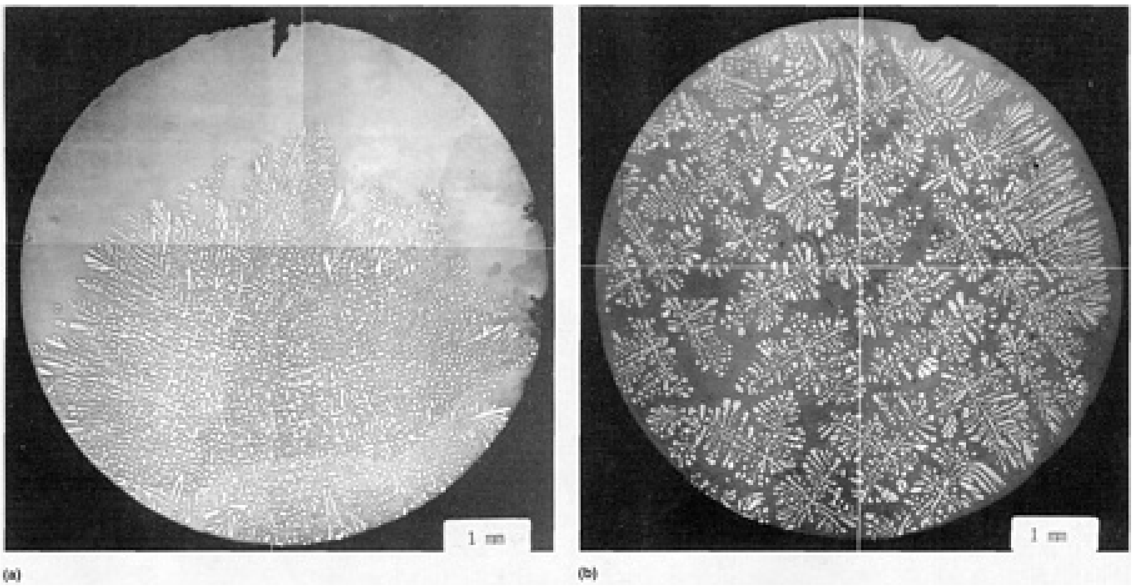

Fig. 14 Transverse sections of Al-26Cu alloy grown vertically in 1 *g* (a) and in orbit on Spacelab (b). The dendrites in the low-gravity solidified sample have coarser, more regularly spaced dendrites and negligible radial segregation. Courtesy of D. Camel and J.J. Favier, Commissariat A L'Energie Atomique (Grenoble, France).

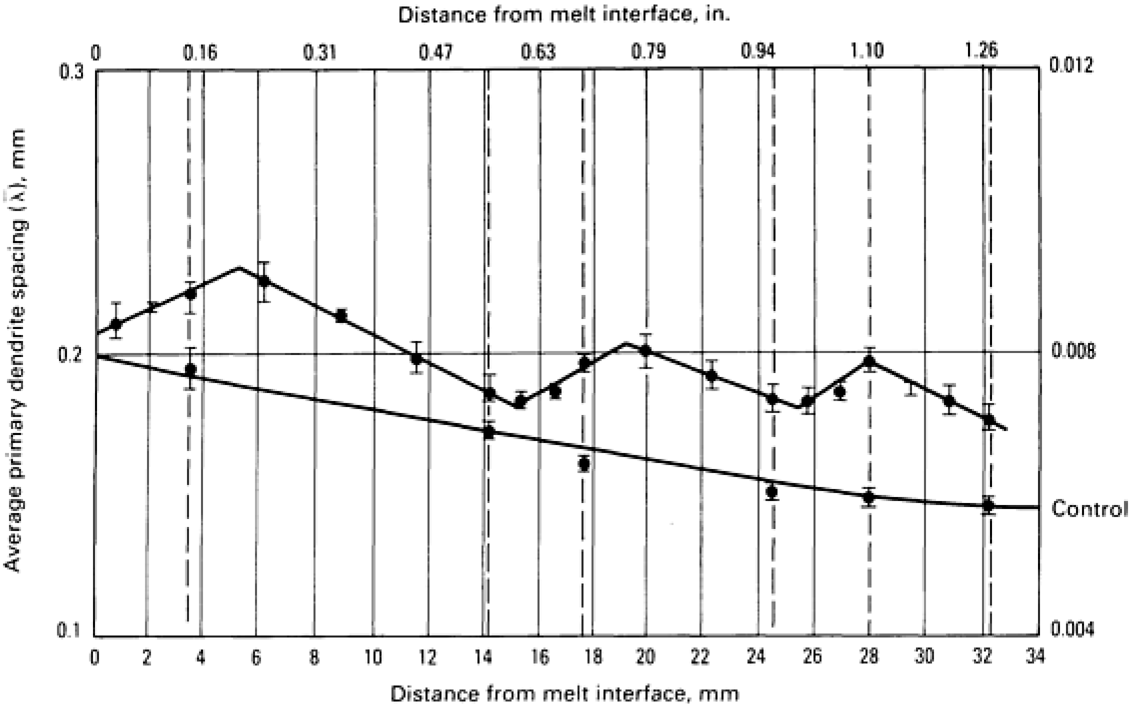

Fig. 15 Average primary dendrite spacing versus solidification distance for PWA-1480 nickel-base superalloy directionally solidified through multiple low-gravity maneuvers. Growth rate is 8 mm/min (0.31 in./min). Source: Ref 20.

Local solidification times t_f for aluminum-copper and Nimonic-90 (cobalt-nickel) alloys have been found to decrease with increasing forced convective flow velocity (Ref 18). Forced convection also decreases primary dendrite spacing. Aluminum-copper secondary dendrite spacings have also been observed to decrease with decreasing t_f (Ref 18).

Convection influences t_f by improving mold-metal heat extraction and by increasing solute transfer. The behavior of local solidification time in low-gravity dendritic solidification remains to be established. Continued increase in t_f with the elimination of natural convection in low gravity should increase dendrite spacings.

Buoyancy-Driven Interdendritic Solute Transport. A primary dendrite spacing difference of a factor of ten has been noted between ammonium chloride/water metal-model grown parallel (down) and that grown antiparallel (up) to gravity (Ref 18). Ammonium chloride, as the metal analog in the ammonium chloride/water model, freezes dendritically. Water (analogous to the alloying element) is the rejected solute. It is believed that the spacing difference is due to buoyancy-driven fluid flow. For upward growth, less dense rejected solute (water-rich) is driven from the interdendritic region by buoyancy-driven flow. For downward growth, the solute density gradient is convectively stable (similar to conditions in low gravity); solute transport, and therefore dendrite spacing, is limited by diffusion.

The influence of gravity on solute transport, and therefore interdendritic constitutional supercooling, can explain the adjustment of primary spacing to gravity level for a superalloy during solidification through multiple aircraft parabolas (Fig. 15 and 16). Buoyancy-driven flow is expected to increase interdendritic solute transport. This is consistent with available low-gravity data (Table 2), in which all tested alloy types result in unchanged or increased primary spacing.

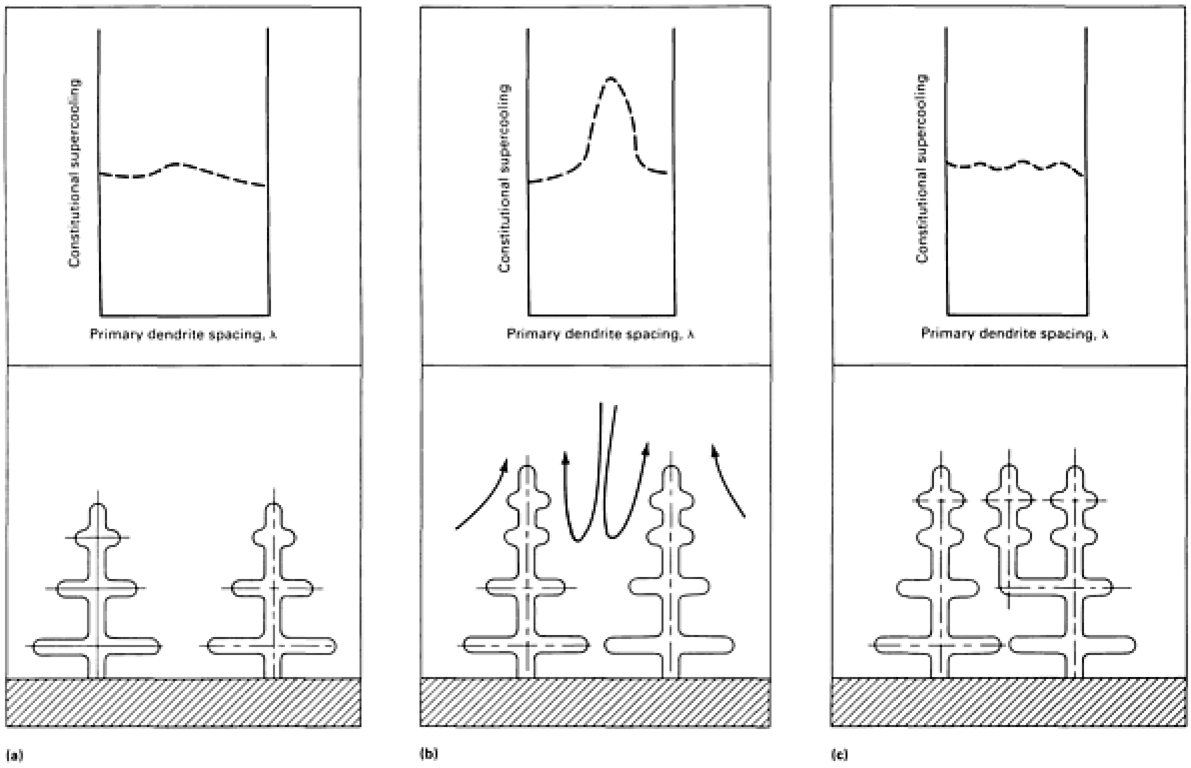

Fig. 16 Mechanism for decreasing primary dendrite spacing in directional solidification during the low-gravity to high-gravity portion of aircraft parabolas. (a) Dendritic growth in low gravity. Solute transport is by diffusion. (b) Dendritic growth continues in high gravity. Solute transport is increased by buoyancy-driven convection. Interdendritic constitutional supercooling increases. (c) Ternary arm driven by increased constitutional supercooling grows to the dendrite tip growth front, decreasing interdendritic spacing. Source: Ref 18.

Dendrite Coarsening. The expected effect of low gravity on the coarsening rate is dependent on the coarsening mechanism. Zero gravity eliminates convective transport of interdendritic rejected solute. Increased average solute concentration reduces dendrite curvature and therefore reduces dendrite coarsening by the arm coalescence model. However, thinning of dendrite arms will cause increased coarsening with increased solute concentration for the arm-melting model.

Dendrite arm coarsening for aluminum-copper alloy has been measured by interface quenching experiments in an orbital low-gravity laboratory (Ref 21). Initial results show a lower dendrite coarsening rate in low gravity. This confirms earlier suggestions that dendrite arm coarsening for aluminum-copper occurs primarily by coalescence (Ref 18).

Interdendritic Fluid Flow--Macrosegregation. Thermal solutal convection and solidification shrinkage produce interdendritic fluid flow that is directly related to casting macrosegregation and porosity. Interdendritic flow perturbs concentration and temperature fields that determine local solid composition in the casting. Aluminum-copper dendritic solidification perpendicular to the gravity vector has been analyzed as a function of the magnitude of gravity. Macrosegregation under normal gravity causes copper fraction across the casting to vary by 45%. Because flow due to solidification shrinkage is perpendicular to the thermal isotherms, theory predicts negligible macrosegregation in zero gravity (Ref 22). The low-gravity dendritic directional solidification of off-eutectic Pb-Sb, Bi/Mn-Bi, Al-Cu (Fig. 17), and Sn-Pb has resulted in negligible macrosegregation, indicating diffusive solute transport (Ref 18).

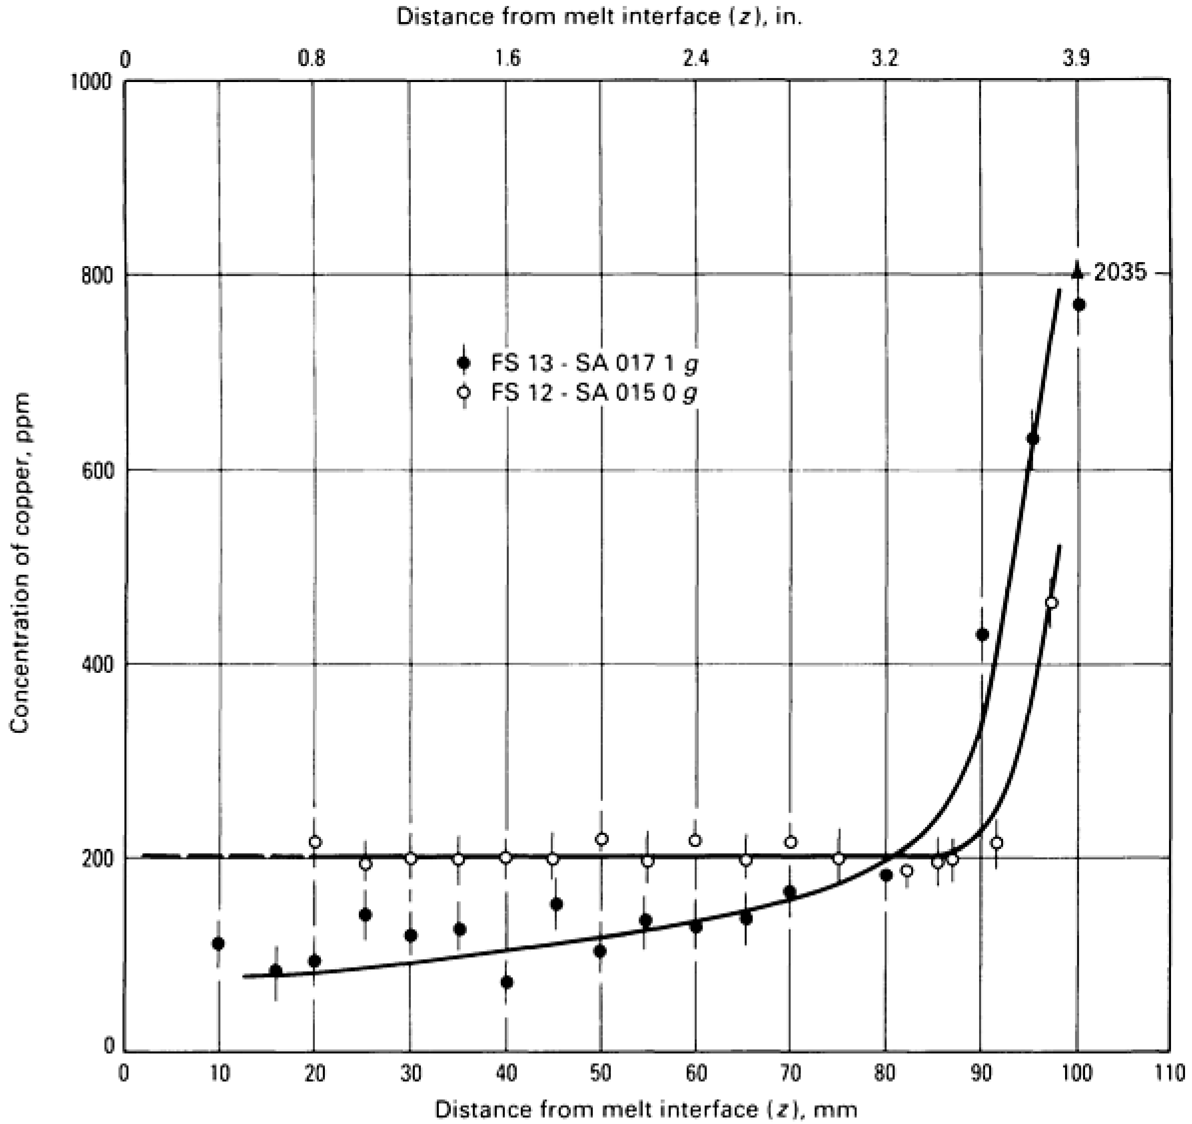

Fig. 17 Copper concentration versus distance for directionally solidified aluminum-copper samples showing decreased macrosegregation for the low-gravity solidified sample. Source: Ref 15.

Macroscopic Dendritic Solid/Liquid Interface Shape. The dendritic solidification of off-eutectic alloy in the convectively stable configuration (both the solid and denser liquid down) minimizes buoyancy-driven macrosegregation. This configuration, however (except for compositions where thermal and solutal buoyancy forces balance), produces interfacial steepling and dendritic clustering casting defects (Ref 23). The denser solute-rich liquid settles into solid/liquid interfacial depressions. The increase in solute concentration causes the depressions to deepen. The interfacial curvature increasingly exceeds the curvature of the isotherm, producing interfacial steepling. Thus, for dendritic directional solidification, the convectively unstable configuration results in macrosegregation, and the convectively stable configuration results in solid/liquid interface steepling, producing dendritic clustering in the solidified casting.

Channel-Type Segregates. Ingots of commercial alloys often contain defects consisting of vertical solute-rich lines of refined grain structure termed channel-type segregates or freckles. Superalloy and transparent model studies have demonstrated that this casting defect results from interdendritic thermal solutal convective flow (Ref 18). Recent process models agree quantitatively with experimental data. When interdendritic flow solutally enriches a particular mushy zone area, local dendritic remelting occurs. The increased interdendritic channel size results in decreased resistance to flow and further remelting. This process results in local solute enrichment of the order of 30%. The debris of remelted dendrite arms act as nuclei refining the channel grain structure. In low gravity, the elimination of thermosolutal convective flow removes the driving force for channel-type segregate formation.

Grain Multiplication and Casting Grain Structure

At the chill surface of a casting, convection is a major cause of grain multiplication. Conversely, chill zone formation in castings can be prevented by damping convective flow (Ref 18). Transparent model studies have shown that convective pulses at the dendrite roots cause dendrite remelting. Dendrite fragments are swept from the solid/liquid interface by the convective flow, which simultaneously dissipates superheat. The fragments nucleate new grains that grow in the equiaxed region of the casting. Experiments with metal alloys and with model materials (Fig. 18) have shown that the grain refinement by this mechanism increases under forced convection; conversely, it is absent in low gravity (Ref 24).

Solidification of Eutectic Alloys: Aluminum-Silicon Alloys

Douglas A. Granger, Alcoa Technical Center; R. Elliott, University of Manchester, Great Britain

---

Introduction

SOME 238 COMPOSITIONS for foundry aluminum alloys have been registered with the Aluminum Association. Although only 46% of this total consists of aluminum-silicon alloys, this class provides nearly 90% of all the shaped castings manufactured. The reason for the wide acceptance of the 3*xx.x* alloys can be found in the attractive combination of physical properties and generally excellent castability. Mechanical properties, corrosion resistance, machinability, hot tearing resistance, fluidity, and weldability are considered the most important.

From the standpoint of applications, the 3*xx.x* series can be subdivided into the binary nonheat-treatable types and the heat-treatable age-hardening alloys, which may contain magnesium, copper, and nickel alone or in combination. Compositions of the most commonly used aluminum-silicon alloys are presented in Table 1, and their physical characteristics are summarized in Table 2.

Table 1 Compositions of common aluminum-silicon alloys

Alloy	**Product**[(a)]	Nominal composition, %[(b)]				
		Cu	**Mg**	**Mn**	**Si**	Others
355.0	S, P	1.2	0.50	0.50 max	5.0	**0.15Ti**
A356.0	S, P	. . .	0.35	0.35 max	7.0	**. . .**
A357.0	S, P	. . .	0.60	0.03 max	7.0	**0.15Ti, 0.04Be**
360.0	D	. . .	0.50	0.35 max	9.5	**. . .**
380.0	D	3.5	. . .	0.50 max	8.5	**. . .**

Sand castings											
C355.0	1	1	1	1	3	3	3	1	4	2	**2**
A356.0	1	1	1	1	2	4	5	2	4	3	**2**
A357.0	1	1	1	1	2	3	4	2	4	2	**1**
B443.0	**1**	**1**	**1**	**1**	**2**	**5**	**5**	**2**	**5**	**4**	**1**

The attributes of the 3*xx.x* alloys are best exemplified by the most widely used alloy of the class--A356. Table 3 lists the properties that can be obtained by different casting processes, heat treatments, and small adjustments in composition. Detailed information on the properties and applications of aluminum casting alloys is given in the article "Aluminum and Aluminum Alloys" in this Volume.

Table 3 Minimum tensile properties of Alloy A356.0 castings produced using various processes

Casting process	Condition	Ultimate tensile strength		Yield strength		Elongation, %
		MPa	ksi	MPa	ksi	
Sand cast	As-cast	130	19	50	7.3	**5**
Sand cast	T6	234	34	166	24	**3.5**
Permanent mold	As-cast	160	23	80	11.6	**3**
Permanent mold	T61	255	37	179	26	**5**
Squeeze cast	As-cast	195	28	124	18	**15**

The properties of aluminum-silicon alloys are strongly dependent on the casting process used, the chemical additions made to control eutectic structure, primary silicon and grain structure, and molten metal treatment to reduce hydrogen gas content and to remove inclusions. Each of these topics will be discussed separately in this section.

Grain Structure

In general, a small equiaxed grain structure is preferred in aluminum alloy castings because it improves such casting attributes as resistance to hot tearing and mass feeding and because it enhances most mechanical properties and surface finishing characteristics. Property improvements largely result from an increase in soundness, although an important contributor is the overall increase in the homogeneity of an equiaxed casting compared to a nonuniform columnar-grain structure. A more homogeneous structure results in less segregation so that the casting responds better to heat treatments, and defects such as porosity and intermetallic constituents are more uniformly distributed and therefore less harmful.

The principal manner in which reducing grain size increases resistance to hot tearing is by lowering the coherency temperature (Ref 1); however, in aluminum-silicon alloys the combination of a large volume fraction of eutectic liquid and relatively low coherency temperature means that, in practice, foundry alloys with greater than about 5% Si already exhibit a low cracking tendency compared to an Al-4.5Cu alloy (Ref 2). In Fig. 1, susceptibility to hot cracking is indicated by a hot tearing index of less than 50. This occurs in an Al-4.5Cu alloy with a grain size of approximately 350 μm (0.014 in.) to a grain size of approximately 1300 μm (0.052 in.) in an Al-4.5Cu-5Si alloy (Ref 3).

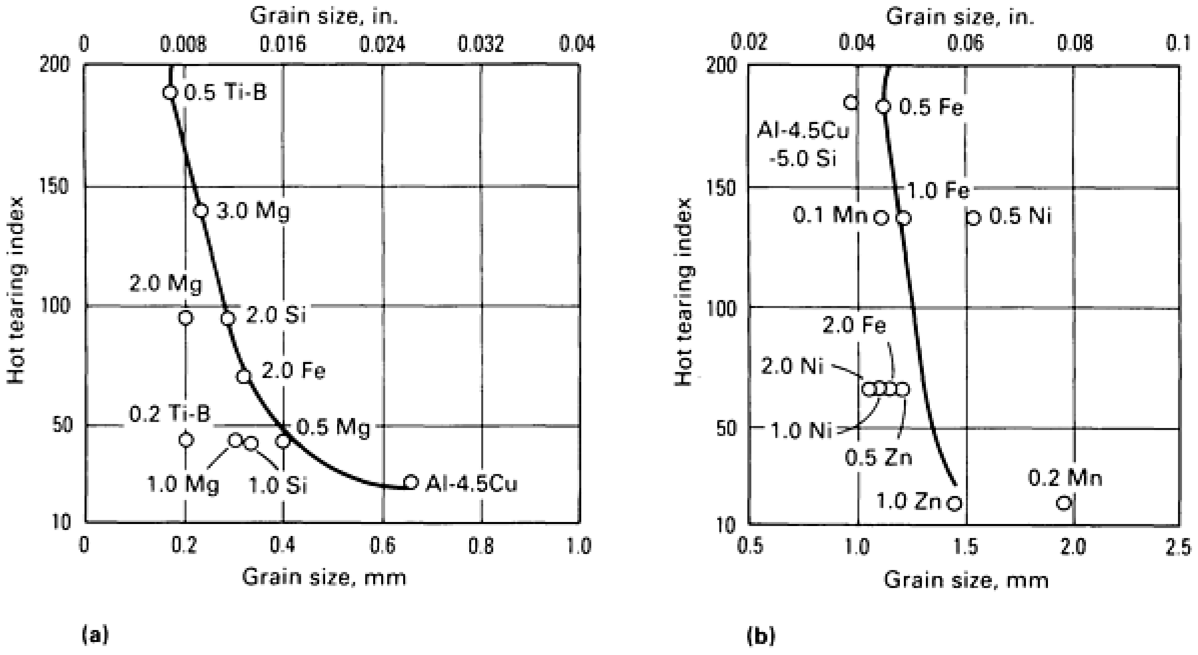

Fig. 1 Effect of grain size on the hot tearing tendency of Al-4.5Cu (a) and Al-4.5Cu-5Si (b) alloys with various additives. Source: Ref 2.

Mass feeding and reduced shrinkage porosity are claimed for grain refinement, although there is a lack of substantive evidence in the literature (Ref 4). In aluminum-silicon alloys, the most direct and quantifiable impact of a reduction in grain size (and the accompanying increase in grain-boundary area) is a more uniform distribution of gas porosity and eutectic colonies. For the same hydrogen content, there is a measurable reduction in the volume of gas porosity in a grain-refined casting compared to a nonrefined casting (Ref 5). The reduced volume fraction of gas porosity is also reported to improve resistance to fatigue crack growth (Ref 6).

Grain Structure Control. Reduction in grain size is brought about by the efficient heterogeneous nucleation of the α-aluminum phase. This can be achieved through crystal multiplication using mechanical or fluid flow forces to detach dendrite arms, but in practice chemical additives are used to provide the necessary nuclei.

Other factors that affect the ultimate cast grain size are alloy composition, freezing rate, temperature gradient in the melt, and casting method. The commercially available chemical additives, usually provided in the form of aluminum-base master alloys, perform well over the range of alloy compositions and casting conditions used in practice.

Mechanism of Grain Refinement. An efficient heterogeneous nucleus for α-aluminum is one that will provide a surface for growth at, or just above, the liquidus temperature of the alloy. It is generally acknowledged that the $TiAl_3$ constituent meets all the necessary criteria (Ref 7). The aluminum-titanium binary alloy contains $TiAl_3$, but because $TiAl_3$ is soluble in molten aluminum, it is necessary to add titanium to levels greater than 0.15% in order to retain grain-refining effectiveness. At this concentration, the peritectic point is exceeded (Fig. 2), and the first phase formed in the alloy upon solidification is the $TiAl_3$ constituent. However, this high level of titanium can give rise to coarse intermetallic particles, which are detrimental to mechanical properties. Moreover, the reduction in grain size is not as great as can be achieved with the aluminum-titanium-boron master alloys. These master alloys, which contain 3 to 10% Ti and a Ti:B ratio ranging from about 3 to 50, comprise soluble $TiAl_3$ particles and insoluble boride particles in an aluminum matrix (Fig. 3). The ternary master alloys are effective at titanium levels significantly lower than the peritectic level, typically 0.01 to 0.03% Ti; this suggests that the boride particles play a dominant role in nucleation Ref 8.

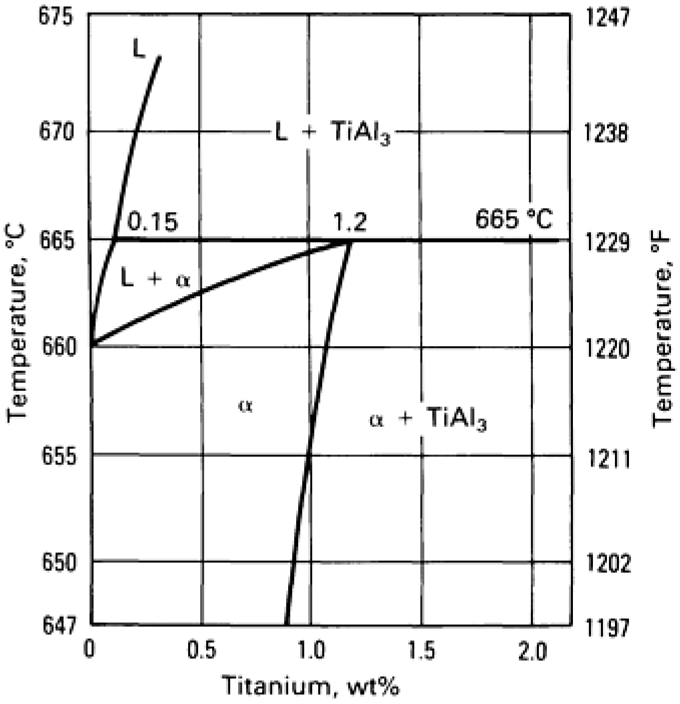

Fig. 2 Aluminum-titanium binary phase diagram.

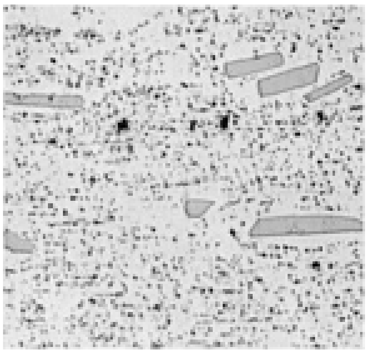

Fig. 3 Micrograph showing large, soluble $TiAl_3$ particles and small, insoluble $(Ti,Al)B_2$ particles in Al-5Ti-1B master alloy. As polished. 250×.

Despite much study over several decades, the mechanism of grain refinement is not completely clear. It is argued that even at low titanium levels the peritectic mechanism is operative because boron, even at very low levels, shifts the peritectic point to the left (Ref 9). Recent studies have shown that commercial aluminum-titanium-boron master alloys contain $(Al,Ti)B_2$ particles that are effective centers for the surface concentration of titanium atoms (Ref 10). Titanium boride (TiB_2) particles are not effective nuclei, and the successful master alloys contain an excess of titanium over that required to form TiB_2 stoichiometrically. Thus, an aluminum-titanium-boron master alloy operates by releasing soluble and insoluble particles in the melt. As the soluble aluminide phase releases titanium into the melt, the $(Al,Ti)B_2$ particles become increasingly active nuclei for α-aluminum.

Grain-Refining Agents. A number of commercial master alloys are available for use as grain-refining agents. Where it is the practice to add titanium above the peritectic level, that is, in the range of 0.1 to 0.2%, aluminum-titanium binary alloys containing up to 10% Ti can be obtained in the form of cast waffles for furnace additions. Also in use are briquettes consisting of titanium powder compacted with salts such as KCl and KBF_4.

For controlling grain structure at lower titanium addition levels, the aluminum-titanium-boron master alloys are available as both cast waffle and chopped rod. The rod form, which is used in the primary industry for continuous addition to the molten metal stream during ingot casting, has a superior metallurgical structure in terms of the constituent particle size and distribution.

Silicon Modification

It is standard practice to refine the eutectic structure as well as the grain structure of aluminum-silicon casting alloys. A moderate improvement in mechanical properties is guaranteed with structural integrity when the silicon eutectic phase is refined with arsenic, antimony, or sulfur (Ref 11). The more usual and more effective treatment is structure modification of the silicon phase, although on occasion there may be an increased susceptibility to porosity. Modification occurs naturally at rapid solidification rates (quench modification), but requires a modifying agent at the slower solidification rates typical of sand casting (impurity modification). Elements in groups I and IIa and the rare earths europium, lanthanum, cerium, praseodymium, and neodymium modify, but only sodium and strontium produce a strong modifying action at the low concentration required for commercial application (Table 4). Both modifying actions transform the flake eutectic silicon into a fibrous form, producing a compositelike structure with increased ultimate tensile strength, ductility, hardness, and machinability.

Table 4 Characteristics of elements used as silicon modifiers in aluminum-silicon alloys

Element	**Atomic radius ratio**[(a)]	**Melting temperature, K**	**Vapor pressure at 1000 K**		**Free energy of oxide formation (ΔG_{oxide}) at 1000 K, kJ/mol**	Comments on modifying capability
			Pa	**atm**		
Barium	1.85	998	5.07	5×10^{-5}	-482	**Moderate modifying power**
Calcium	1.68	1112	26.3	2.6×10^{-4}	-509	**Weak modifying action**
Strontium	1.84	1042	101.3	0.001	-480	**Moderate modifying power; optimal addition: 0.01-0.02%. Good resistance to fade; semipermanent effect; much easier to store and handle than sodium; overmodification not as serious as with sodium, but can increase porosity**
Sodium	1.58	371	2×10^4	0.2	-367	**Very potent modifier with 0.1% addition. Dissolves rapidly; fades rapidly due to evaporation; difficult to store and handle; difficulty in controlling additions can lead to overmodification; can increase porosity**
Cerium	1.56	1071	10^{-11}	10^{-16}	-497	**Can be conveniently added as mischmetal; requires up to 60 min for dissolution; very resistant to fade; modification effect increases up to 2% additions; reduces**

						dendrite arm spacing in hypoeutectic alloys
Aluminum	1.22	933	5.4×10^{-6}	5.3×10^{-11}	-457	. . .

(a) Ratio of atomic radius of element to atomic radius of silicon

Mechanism of Modification

The finer silicon-phase distribution in the modified structure is evident from structures D and E in Fig. 4. Region C in Fig. 4 is the coupled zone. This defines the compositional and growth temperature (velocity) limits within which it is necessary to solidify in order to obtain a completely eutectic structure in aluminum-silicon alloys. The zone retains its shape, but narrows as the temperature gradient in the liquid is reduced (see the article "Solidification of Eutectics" in this Volume). Modification was originally attributed to the repeated nucleation of the eutectic silicon phase at a reduced temperature (Ref 12, 13). It is now established that, although the nucleation temperature is depressed, the silicon phase grows continuously without repeated nucleation at an increased undercooling (Ref 14, 15). The aluminum phase is not affected structurally by modification, and there is evidence that both sodium and strontium are concentrated in the silicon phase. Consequently, modification is now considered to be associated primarily with a change in the silicon-phase growth mechanism. This change is induced either at high growth velocities or by a modifier at all but extremely low velocities, and it results in a change from a faceted to a more isotropic growth morphology.

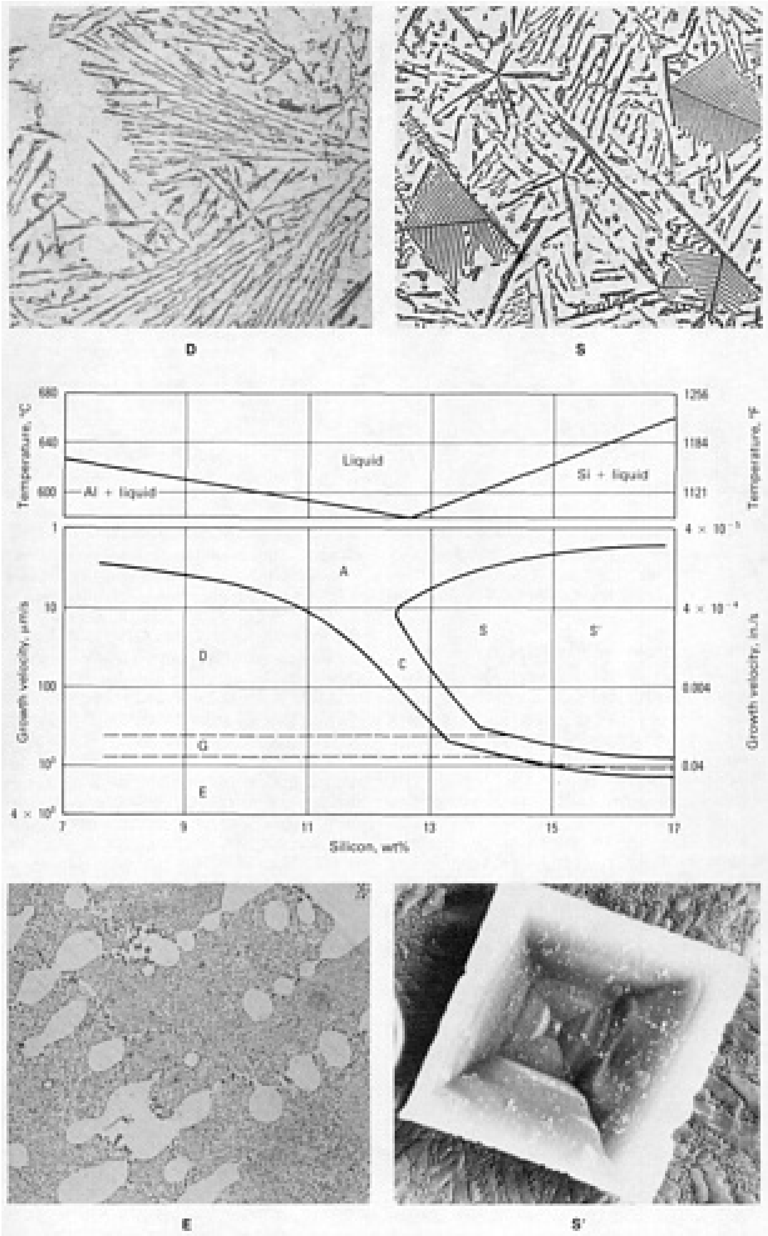

Fig. 4 Coupled zone diagram for aluminum-silicon alloys determined from directional solidification studies with a temperature gradient in the liquid of 125 °C/cm (570 °F/in.). Region A, massive, rod, and angular eutectic silicon and complex regular silicon. Region C, coupled zone (see Fig. 5). Region D, angular and flake eutectic silicon and aluminum dendrites. Region G, flake-to-fibrous eutectic silicon transformation. Region E, fibrous eutectic silicon and aluminum dendrites. Region S, eutectic silicon and complex regular and starlike primary silicon. Region S', eutectic silicon and complex regular, starlike, and polyhedral primary silicon. Micrographs: S, complex regular and starlike primary silicon with flake eutectic silicon; 100×. D, typical unmodified structure of a 413 alloy showing flake eutectic silicon and aluminum dendrites; 100×. E, typical chill-modified structure of a 413 alloy showing fibrous eutectic silicon and a higher volume fraction of finer aluminum dendrites than structure D; 100×. S', scanning electron micrograph showing a (100) section through an octahedral primary silicon particle revealing four {111} planes; 1500×.

Growth Characteristics

Faceted morphologies occur in high-entropy phases and are a consequence of anisotropic growth. The solid/liquid interface of a high-entropy phase is smooth on an atomic scale. Silicon is a borderline case with (111) and possibly (100) interfaces in this category. Growth normal to a (111) silicon interface occurs by the lateral propagation of intrinsic steps across the interface at a rate determined by the rate of step generation. Primary silicon phase often displays a faceted octahedral morphology that is bound by slow-growing (111) faces, as shown in structure S' in Fig. 4. Growth rate anisotropy is increased when growth normal to certain planes is enhanced by such defects as twins and screw dislocations, which create self-perpetuating steps at the growth front (Ref 16). This occurs in silicon when the twin-plane reentrant edge mechanism (TPRE) operates and enhances growth in the <211> directions, resulting in hexagonal plate and starlike primary silicon morphologies (structure S, Fig. 4).

These silicon growth characteristics are in evidence at the duplex solid-liquid eutectic growth front, and the silicon eutectic phase in an unmodified alloy develops several distinct growth habits, depending on the growth velocity and temperature gradient in the liquid at the interface, as shown in Fig. 5. The ratio of temperature gradient *G* to growth velocity *v* (*G*/*v* ratio) in region A is high enough for the eutectic phases to grow independently to produce large, faceted silicon crystals in an aluminum solid-solution matrix. Growth in region B occurs by a more coupled, short-range diffusion process. The silicon phase leads at the interface and develops a [100] preferred growth direction. Its morphology varies from closely packed rods at high-temperature gradients to a variety of faceted forms at lower gradients (structure B, Fig. 5). The angular silicon structure is prominent in the lower areas of region B. Interconnected silicon flakes form between the angular silicon particles in region B + C, and the flake structure predominates in region C + B, which covers the thermal conditions encountered in sand casting. The flakes have {111} habit, and their flat surfaces are parallel to internal {111} twins. They lead the aluminum phase at the nonisothermal growth front and branch by splitting or displacement twinning to achieve the spacing characteristics of the growth velocity. Successive {111} twinning on the surface of a flake permits a direction change through any angle while maintaining growth in a [112] direction. All the active {111} planes are cozonal (Ref 18).

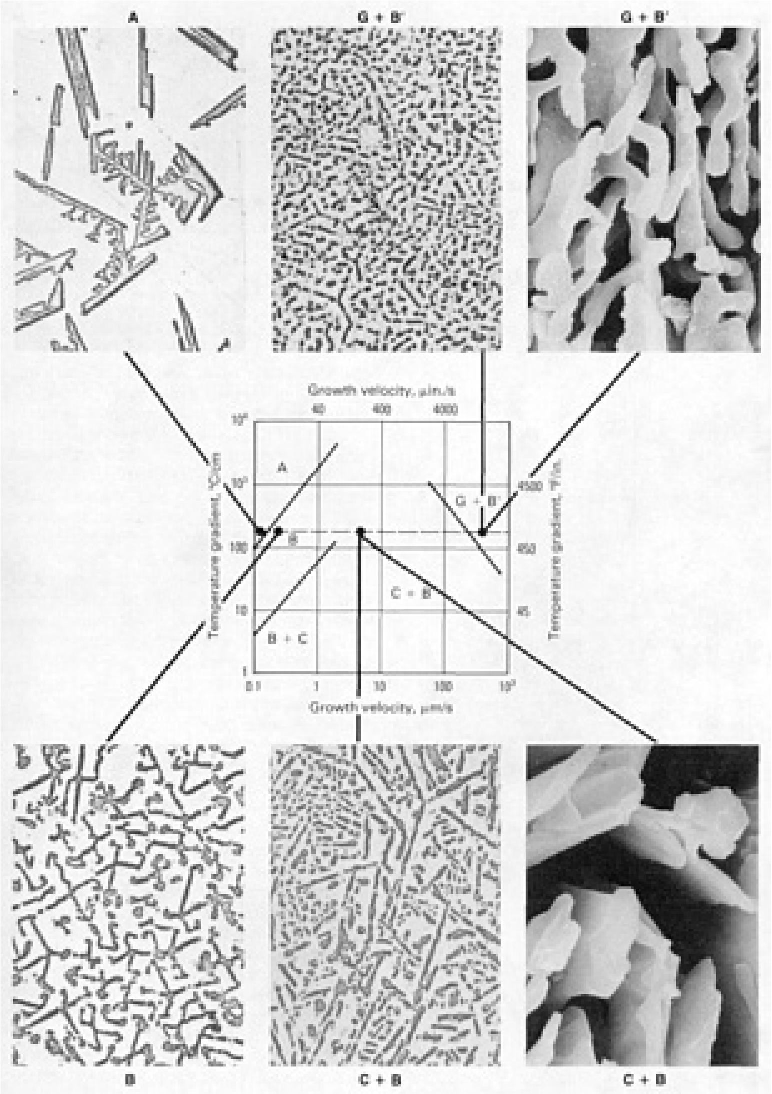

Fig. 5 Eutectic silicon morphologies found in the coupled zone as a function of growth velocity and temperature gradient in the liquid at the growth interface. Region A, massive, faceted eutectic silicon in an aluminum matrix. Region B, rod and rod with faceted sideplate eutectic silicon in an aluminum matrix. Region B + C, angular silicon with some flake eutectic silicon in an aluminum matrix. Region C + B, mainly flake eutectic silicon with some angular silicon in an aluminum matrix. Region G + B', quench-modified fibrous silicon with some modified angular silicon eutectic in an aluminum matrix. Micrographs: A, massive faceted eutectic silicon; 100×. B, rod with faceted sideplate eutectic silicon; 100×. C + B, mainly eutectic flake silicon with some angular silicon, 100×, and scanning electron micrograph (lower right) showing angular silicon and flake eutectic silicon; 1500×. G + B', quench-modified fibrous silicon and modified angular silicon, 100×, and scanning electron micrograph (upper right) showing quench-modified fibrous silicon; 1500×. Source: Ref 17.

Quench Modification

Quench-modified eutectic forms in region G of Fig. 4 and in region G + B' of Fig. 5. Transmission electron microscopy has shown that the silicon fibers have smooth external surfaces and that many are twin free (Ref 19, 20). These features are consistent with isotropic fibrous growth at an atomically rough interface, as shown in Fig. 6. The silicon phase can branch readily and no longer leads at the interface. The fibers are much finer than slowly grown flakes and are finer than impurity-modified fibers. The diffusion process is short range and approximates that of a normal rod structure.

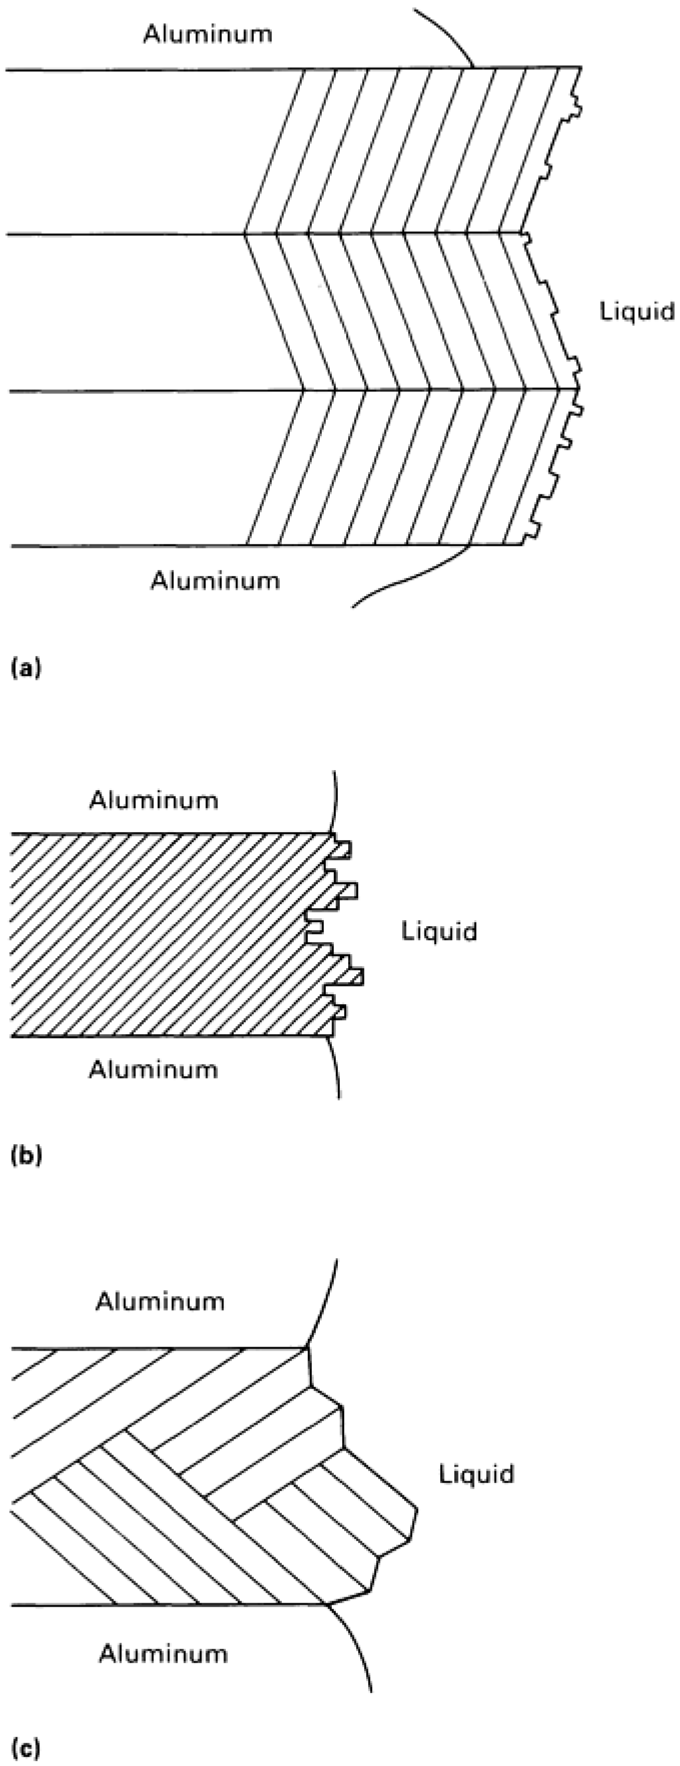

Fig. 6 Schematic of the eutectic silicon growth interface. (a) Unmodified flake silicon. Widely spaced {111} twins probably make the propagation of intrinsic steps across (111) interfaces the significant growth mechanism. (b) Quench-modified fibrous silicon. An atomically rough, twin-free eutectic silicon interface at

which atomic additions are made randomly. Branching occurs readily by overgrowth. (c) Impurity-modified fibrous silicon. Finely spaced {111} twins mean that TPRE is the major step source during silicon growth. If twinning occurs equally on four {111} systems, a [100] fiber growth direction results.

Chemical Modification. The efficiency of impurity modification is evident from Fig. 7, which shows how the structures of directionally solidified aluminum-silicon alloys change with increasing strontium content. Transmission electron microscopy has shown that fibers in impurity-modified alloys are microfaceted to varying degrees and are heavily twinned on up to four {111} systems. Multiple twinning creates many reentrant steps on the silicon interface, facilitating growth by the TPRE mechanism at an isothermal interface, with branching achieved much more easily than with the flake morphology. The change from flake to fibrous growth is a consequence of impurity incorporation into the silicon phase by adsorption at the silicon growth front. A hard sphere model has been used to show how an impurity atom of the appropriate size can force a step propagating across an interface (as occurs in flake growth) to miss one regular close-packed position and, by falling into the next alternative stacking sequence, create a twin. This size factor requirement (atomic radius of modifier/atomic radius of silicon > 1.64) is thought to be the first and principal requirement for impurity modification (Ref 21).

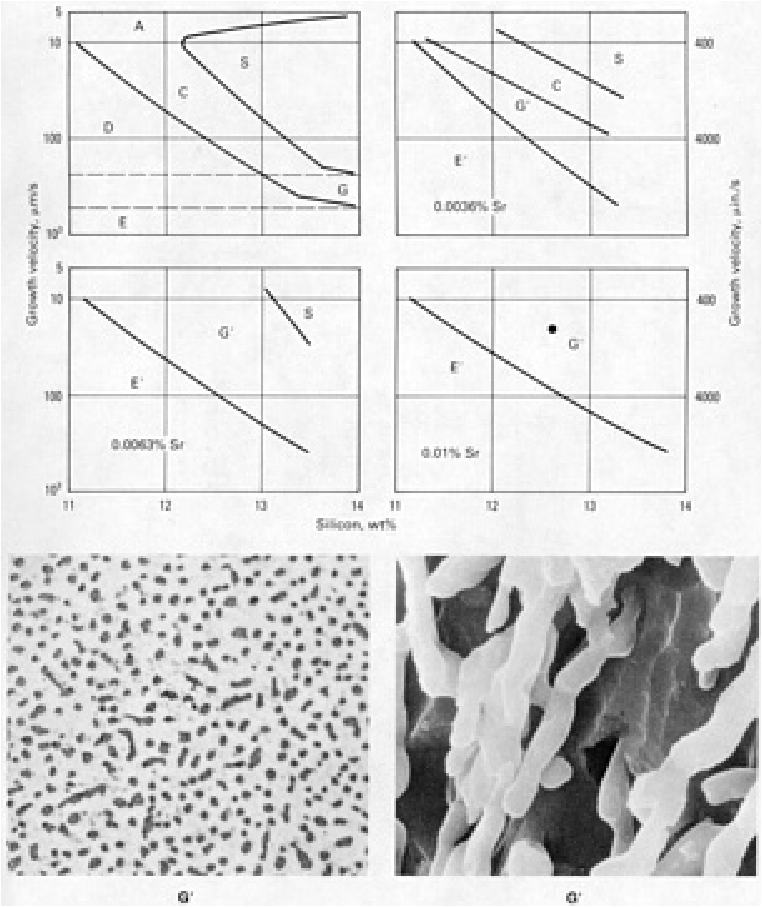

Fig. 7 Change in the coupled zone diagram of aluminum-silicon alloys with increasing strontium additions as determined from directional solidification studies with a temperature gradient in the liquid of 125 °C/cm (570 °F/in.). Regions A, C, D, E, G, and S are shown in Fig. 4. Region G', impurity-modified fibrous silicon; Region E', impurity-modified fibrous silicon and aluminum dendrites. Micrographs: G' strontium-modified fibrous silicon, 300×, and scanning electron micrograph (right) showing strontium-modified fibrous silicon; 2500×.

Modifiers and Their Side Effects

Modifying Agents. The observations recorded in Table 4 show that factors other than atomic size control the efficiency of a modifier. A low melting point and a high vapor pressure promote rapid dispersion of the modifier in the melt, but a high vapor pressure will encourage fade by evaporation. Oxidation loss will be a problem with modifiers having a free energy of oxide formation higher than that of aluminum. A low solid solubility and a wide miscibility gap having a monotectic point at a very low concentration of modifier, as in the aluminum-sodium system, produce a large increase in modifier concentration at the growth front and a powerful modifying effect. Therefore, sodium dissolves and disperses rapidly in the melt without oxidation, but fades quickly (<20 min) and within this time provides a powerful modifying action. Strontium dissolves quickly, and although it oxidizes slightly, it has a greater resistance to fade than sodium, producing a more permanent but weaker modifying action. A sodium addition of more than 0.02 wt% causes the overmodification associated with AlSiNa compound formation and a reduction in mechanical properties. Strontium does not exhibit the same complex overmodification behavior, but undesirable compounds of the Al_2SrSi_2 type in A356 alloys containing more than 0.05 wt% Sr contribute to a decrease in mechanical properties (Ref 22).

Sodium can often be added as a metal in preweighed, sealed aluminum cans or as sodium compounds in cover fluxes. Strontium does not present the same storage and handling problems, and it is usually added as a low-strontium master alloy such as Al-10Sr or Al-14Si-10Sr, a high-strontium master alloy (for example, Al-90Sr), or a pure metal. Master alloys are usually supplied in waffle form, but several aluminum-base master alloys containing 3 to 10% Sr are supplied in rod form for rapid dissolution. Waffles dissolve slowly and require 30 to 45 min for optimum modification. Metallic strontium additions are smaller, dissolve quicker, and introduce less iron into the alloy than master alloy additions. Strontium should be added in the temperature range of 670 to 720 °C (1240 to 1330 °F) in A356 alloys. Low-strontium master alloys should be added at high melt temperatures for rapid dissolution with high recovery. High-strontium master alloys should be added to a melt with minimal superheat (Ref 22).

Hydrogen Pickup and Loss. The subject of hydrogen pickup in aluminum-silicon melts is highly controversial, especially when one considers the effect of modifiers on the rate of hydrogen pickup from moisture in the atmosphere. The literature sometimes presents conflicting reports--for example, sodium and strontium both result in "gassy" melts and that they have no effect. This difficulty can arise because the gas content is often inferred from the amount of porosity formed upon casting rather than from a direct measurement of the hydrogen content of the melt. However, because both sodium and strontium form oxides of strong chemical stability and because numerous foundrymen report commercial problems with gas pickup, there is probably a tendency toward increased hydrogen pickup in modified alloys. The problem apparently becomes more severe at higher melt temperatures and at higher modifier concentrations.

Therefore, the benefits of eutectic modification are offset to some extent by hydrogen pickup, accompanying oxide film formation, and porosity generation. This is particularly true of the most effective chemical modifiers--sodium and strontium. An advantage of the eutectic refiner antimony is that porosity formation can be alleviated by gas fluxing with an inert gas or an inert gas-chlorine mixture to obtain low hydrogen levels without loss of antimony (Ref 23). In contrast, any active gas, such as chlorine or freon, rapidly removes sodium or strontium from a melt.

Whenever a modifying agent is used, there is an increase in hydrogen in the melt. Hydrogen pickup occurs when the oxide film on an aluminum melt is broken and a reaction takes place with moisture in the ambient atmosphere. Therefore, to minimize pickup, modifiers (and refiners) must be added with as little disturbance to the melt surface as possible. The addition of sodium, even when carefully added using the vacuum-packed form, introduces gas to the melt. Similarly, strontium-containing master alloys are a source of hydrogen, but this is reduced by the use of high-purity aluminum-

strontium binary alloys and particularly the strontium-base master alloys, which are melted and cast under conditions that minimize hydrogen contamination.

Excess hydrogen can be removed from modified melts by the use of inert gas fluxing techniques, although it appears more difficult to achieve low levels (<0.10 cm^3/100 g) in strontium-containing melts than in sodium-containing melts. However, in both cases, the very act of molten metal fluxing accelerates the loss of the modifier from the melt.

It is widely reported that hydrogen introduced into a melt by strontium is more difficult to remove than that introduced by sodium. These reports are often based on observations of porosity instead of the hydrogen content of the melt, and this can be misleading. For example, in A356 melts with identical hydrogen contents--one modified with strontium and the other non-modified--the strontium-modified melt will have a higher volume fraction porosity for the same solidification conditions (Ref 5).

Fluidity. One of the principal attributes of the aluminum-silicon alloys is their excellent fluidity, or the ability to fill a mold cavity. Fluidity is a complex characteristic that is influenced by surface tension, viscosity, alloy freezing range, melt cleanliness, superheat, and solidification conditions. Chemical modifiers are generally considered to be detrimental to fluidity despite the fact that all the chemical modifiers commonly in use decrease surface tension. This anomaly is due to the overwhelming influence of the surface oxide film, which can increase the surface tension of pure aluminum threefold. Therefore, the most surface active modifier--sodium--has been found to reduce fluidity by about 10% (Ref 24), while the available evidence on strontium-modified melts indicates that the fluidity is the same as that of the nonmodified melts.

Other Structural Features

Other important structural features are secondary dendrite arm spacing or dendrite cell spacing in hypoeutectic alloys (Ref 25), the size and distribution of primary silicon phase in hypereutectic alloys, and the type and distribution of intermetallic phases. For all practical purposes, the dendrite cell spacing, as defined in Ref 25, is equivalent to the dendrite arm spacing and is controlled by the local solidification time (the time elapsed for the temperature to fall from the liquidus to the solidus at a particular location in the casting).

Dendrite Structure. Aluminum dendrite cells grow as the casting cools through the solidification temperature range after heterogeneous nucleation of the α-aluminum phase. Spacings in aluminum-silicon alloys are shown in Fig. 8. For comparison, Fig. 9 shows dendrite cell sizes as a function of cooling rate for some aluminum-base foundry alloys.

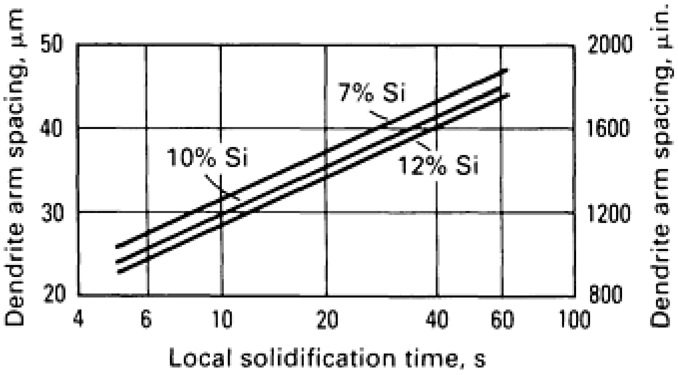

Fig. 8 Variation of dendrite arm spacing with local solidification time for Al-7Si, Al-10Si, and Al-12Si alloys. Local solidification time is defined as the time elapsed for the temperature to decrease from the liquidus to the solidus temperature at a particular location on the casting.

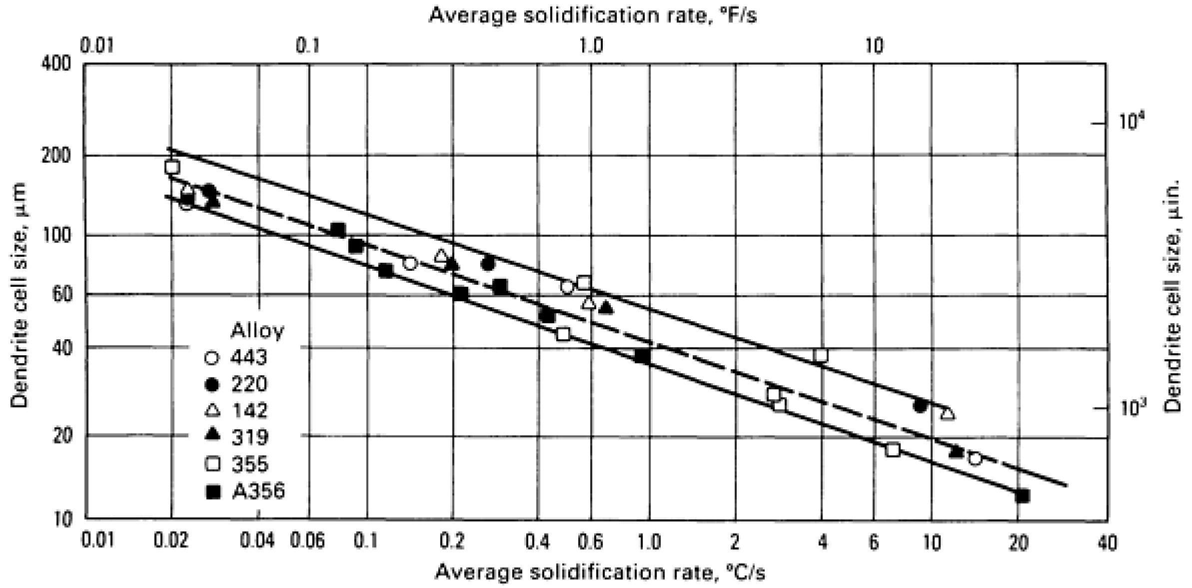

Fig. 9 Dendrite cell spacing as a function of cooling rate for some aluminum casting alloys.

Primary silicon particles impart wear resistance to hypereutectic alloys such as 390. Optimum wear resistance and good machinability with good castability require a fine and uniform distribution of primary silicon particles. This can be achieved with the high rate of solidification in pressure die casting, but it is not good practice. All alloys should be treated to refine the primary silicon phase with phosphorus, usually in the form of copper-phosphorus additions. The phosphorus reacts with aluminum to produce a fine dispersion of AlP, which is a very effective heterogeneous nucleate for silicon. The primary silicon-phase morphology in refined and unrefined 390 alloy is shown in Fig. 10.

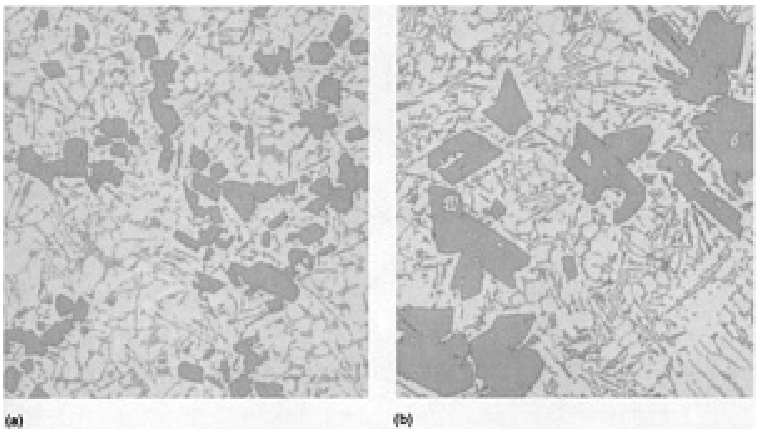

Fig. 10 Micrographs showing structures of phosphorus-refined 390 alloy (a) and unrefined 390 alloy (b). Both 250×.

Intermetallic phases can seriously impair the mechanical properties of aluminum-silicon casting alloys. They form as a result of overmodification, excessive titanium from grain-refining additions, or impurities. They can be controlled by good founding practice and by limiting or neutralizing impurities. Iron in the form of plates of $FeSiAl_5$ (or βphase) is

important in this respect (Ref 26). The sizes of the β plates and their effect on mechanical properties depend on iron content and cooling rate (dendrite arm spacing), as shown in Fig. 11.

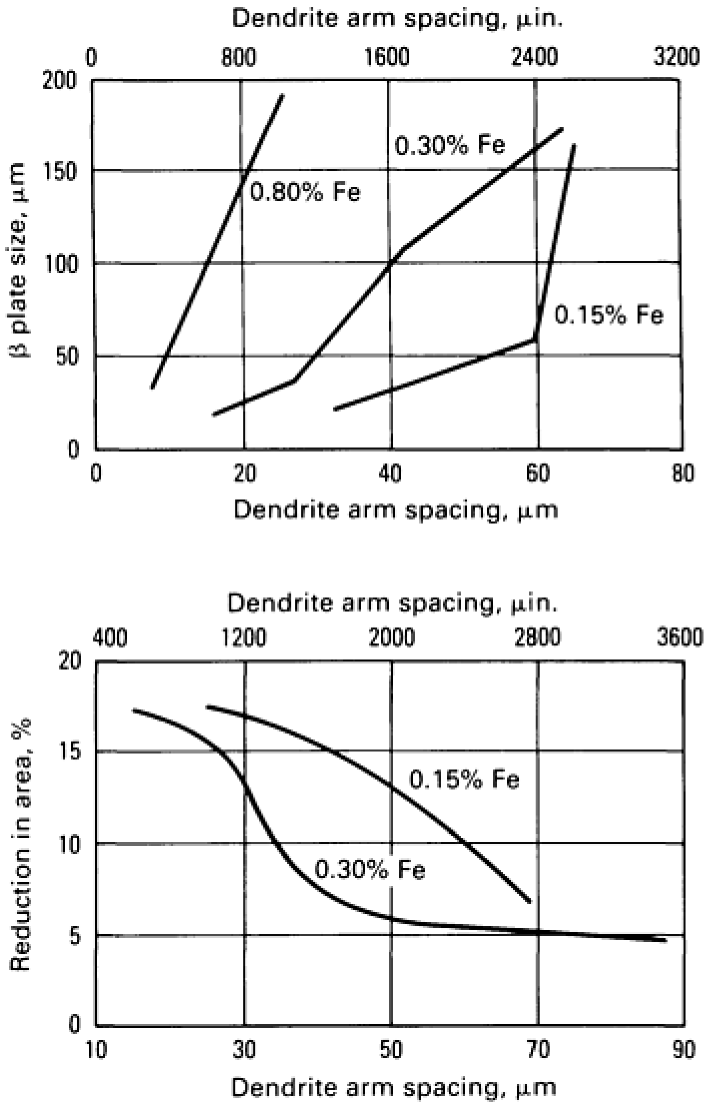

Fig. 11 Maximum β plate length and reduction in area of Al-7Si-0.3Mg alloys containing various amounts of iron as function of dendrite arm spacing.

Structural Assessment

Rapid on-line melt structural assessment for grain refinement and degree of modification is becoming an essential part of quality control. The off-line optical examination of separately cast, polished and etched samples is the traditional method of structural assessment, but the development of microprocessor technology has made possible the introduction of rapid on-line techniques based on electrical resistivity (Ref 27), and in particular, thermal analysis (Ref 28, 29, 30, 31, 32, 33). In the latter, grain refinement is assessed by examining the thermal response at the liquidus temperature and the modification that occurs at the eutectic temperature. Direct, differential, or derived cooling curves and heat-of-solidification measurements can be used.

The instruments currently in use analyze a cooling curve obtained from a small melt sample solidified under standardized conditions in a sand cup. One instrument assesses grain refinement in hypoeutectic alloys in terms of the barrier to nucleation of the aluminum primary phase. A grain size number is computed using an algorithm based on the undercooling for nucleation $\Delta\theta$and the duration of the nucleation event t_1 (Fig. 12a). The relationship among the computed grain size number, the measured grain size, and the ASTM grain size number for an Al-7Si alloy is shown in Fig. 12(b). The shape of the cooling curve at the liquidus in hypereutectic alloys is not as sensitive. Consequently, silicon primary particle refinement is usually assessed by measuring the solidification start temperature and a scale calibrated with similar measurements for refined and unrefined alloys.

(b) Correlation between average grain size determined metallographically and the grain size number displayed by one instrument for an Al-7Si alloy. Source: Ref 29.

The cooling curve parameters sensitive to modification and recorded by an instrument are shown in Fig. 13. The rating system (Ref 28) uses the ΔT value as an index for modification (Fig. 13). Figure 13(c) shows that ΔT does not increase continuously with strontium content and that it differs in magnitude from alloy to alloy. It is now realized that ΔT is not a comprehensive modification parameter, because it reflects not only modification but also the influence of alloying elements and impurities. Recently, revised algorithms based on ΔT, t_2, and t_3 (Ref 29) and on T_E, T_c, $\Delta\theta$, and ΔT (Ref 30) have been shown to be capable of assessing modification in terms of unmodified, undermodified, modified, and overmodified states. The total heat of solidification is sensitive to the degree of modification. For A356 alloys, it is 95 cal/g for an unmodified alloy; it increases to 98 cal/g for an undermodified alloy, reaches a maximum value of 100 to 103 cal/g for a fully modified alloy, and decreases to 98 cal/g when overmodified.

Effect of Structure on Properties

Aluminum-silicon alloys exhibit a highly desirable combination of characteristics, such as castability, weldability, good corrosion resistance, wear resistance, and machinability. Mechanical properties are principally controlled by the cast structure. Therefore, for a given composition (and heat treatment), it is the ability to optimize grain size, eutectic structure, cell size, casting soundness, and the size and distribution of intermetallics that determines the properties.

As discussed earlier, achieving an optimum combination of mechanical properties requires recognition and control of the undesirable side effects of modification and grain refining. The effects of the principal structural modifiers taken singly and in combination are illustrated in the examples outlined below.

The modification of the eutectic phase in hypoeutectic and eutectic aluminum-silicon alloys allows an optimum combination of strength and elongation (Ref 14). Both under- and overmodification result in a degradation of these properties, as shown below for a sodium-modified, sand cast eutectic alloy:

	Ultimate tensile strength		Elongation, %
	MPa	**ksi**	
Specification	160 min	23 min	**5**
Unmodified alloy	77	11	**2**
Partially modified alloy	147	21	**4**
Fully modified alloy	188	27	**8**

Overmodified alloy	**167**	**24**	**6**

The key attributes of strontium, compared to those of sodium, are its greater resistance to loss from a melt and greater tolerance (in terms of amount) to overmodification.

Grain Refinement. There appears to be no strong effect of grain size reduction on mechanical properties in hypoeutectic alloys (Ref 3). Figure 14 illustrates a small loss in tensile properties in permanent mold cast A356 test bars with increasing grain size. The effect is greatest in the modified alloy, in which elongation decreases from $4\frac{1}{2}$ to $2\frac{1}{2}$%, with an increase in grain size from 200 to 1600 μm (0.008 to 0.064 in.).

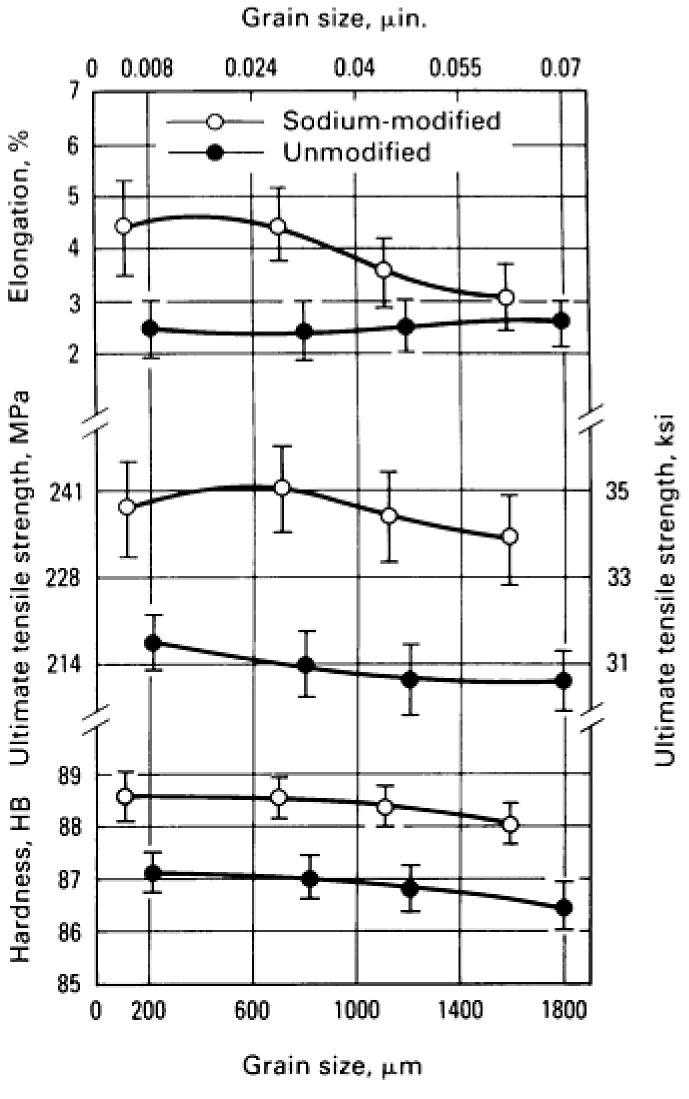

Fig. 14 Mechanical properties of A356 alloy as-cast test bars. Source: Ref 3.

Dendrite cell size, which is controlled by solidification rate, is an important indicator of the mechanical properties of a casting. As shown in Fig. 15, ultimate tensile strength and elongation are enhanced by a reduction in cell spacing. It must be realized that increasing solidification rate (decreasing cell size) also has other beneficial attributes, such as reduction in gas porosity, smaller intermetallic particle size, more refined eutectic structure, and greater solute saturation. Therefore, all improvements in properties cannot be attributed solely to a smaller cell spacing.

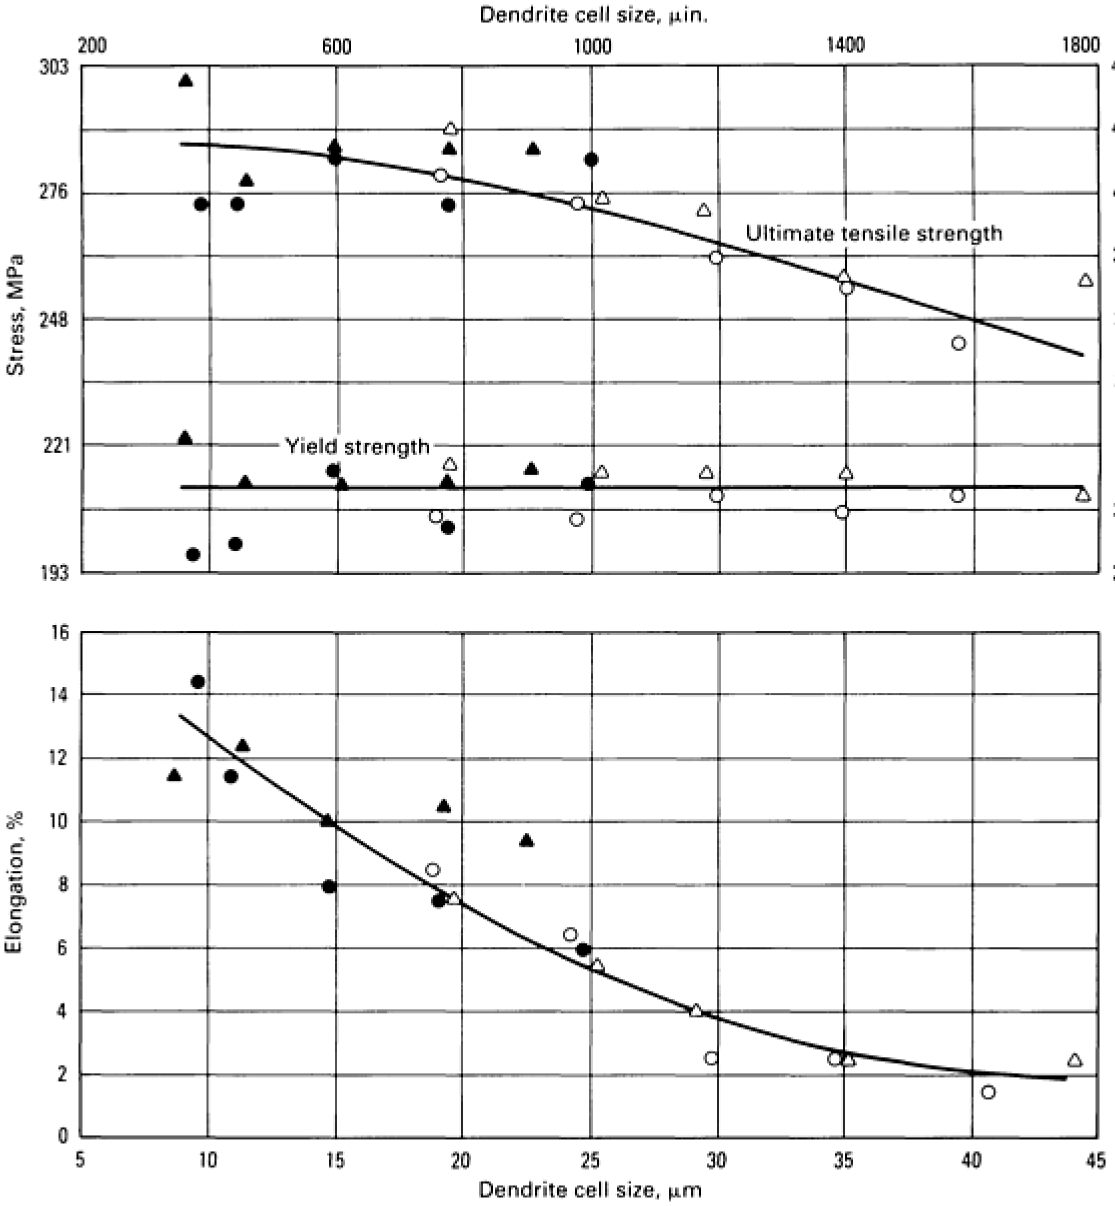

Fig. 15 Relationship between dendrite cell size and tensile properties for alloy A356-T62. The different symbols indicate results from different heats. Source: Ref 25.

Eutectic Structure and Cell Size. Hypoeutectic alloys such as A356 can be considered composites that consist of dendrite fibers, which can be strengthened by heat treatment, and a eutectic matrix strengthened by modification. The mechanical properties of the composite depend on volume fraction and fiber spacing (dendrite arm spacing). The mechanical properties of A356 are often expressed by a quality index *Q*, where:

$$Q = \text{UTS} + 150 \log \text{elongation}$$

where UTS is ultimate tensile strength and elongation is measured in percent.

Figure 16(a) shows the variation of *Q* with strontium for three cooling rates in A356, and Fig. 16(b) shows the effect of Al-5Ti-1B grain refiner on strontium-modified A356 as a function of titanium and boron content. Figures 16(a) and 16(b) show the influence of cooling rate (dendrite arm spacing) and strontium modification on *Q* values and the fact that grain refinement has an effect only at the lowest cooling rates.

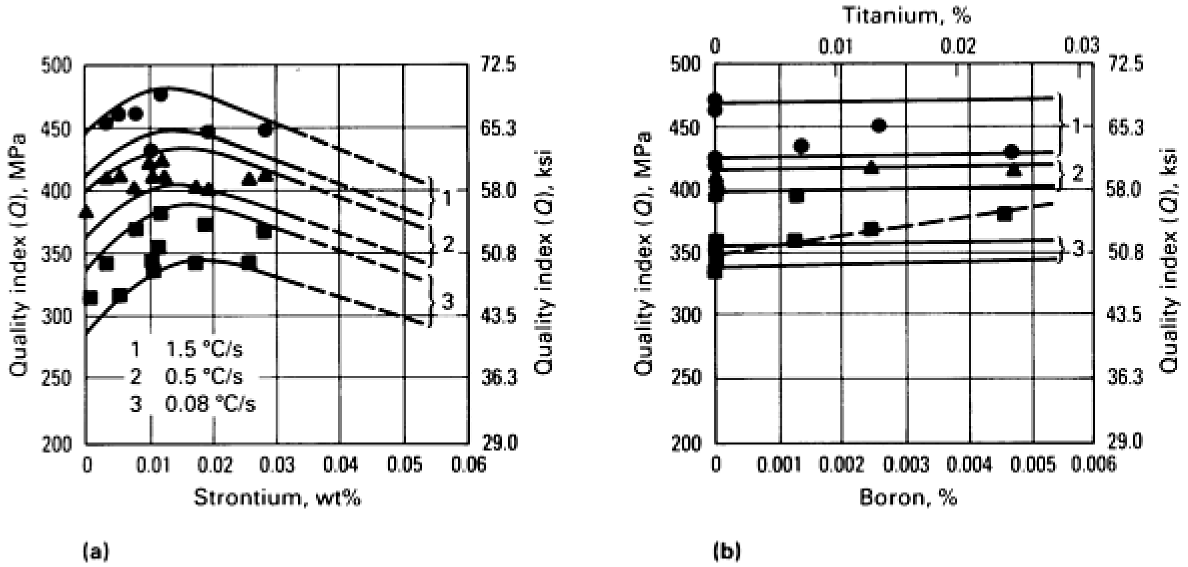

Fig. 16 Variation of *Q* with strontium (a) for three cooling rates in A356 alloy. Property measurements made on cast material after heat treatment to develop T6 temper. (b) Influence of titanium-boron grain refiner on strontium-modified A356-T6 as a function of titanium content. Source: Ref 34.

Solidification of Eutectic Alloys: Cast Iron

D.M. Stefanescu, University of Alabama

Introduction

Cast iron is a binary Fe-C or a multicomponent Fe-C-*X* alloy that is rich in carbon and exhibits a considerable amount of eutectic in the solid state. Two such possible eutectics may result, as follows:

- If solidification occurs according to the metastable diagram, Fe-Fe_3C, the white eutectic or austenitic (γ), iron carbide (Fe_3C) forms
- If solidification follows the stable diagram iron-graphite (a significant amount of silicon is required for this to occur), the gray eutectic, austenite-graphite (Gr), results

Depending on composition, cooling rate, and liquid treatment, it is also possible to produce a mixed white-gray eutectic called mottled structure. The two basic types of eutectic are very different, with mechanical properties such as strength, ductility, and hardness varying over very large intervals as a function of the type and the amount of eutectic formed. To understand the mechanism of the solidification of cast iron, it is necessary first to discuss the structure of liquid iron-carbon alloys.

Structure of Liquid Iron-Carbon Alloys

Observations from x-ray, neutron diffraction, and sound velocity measurements on liquid binary iron-carbon alloys at temperatures approximately 20 °C (35 °F) above the liquidus indicate that for up to 1.8% C the distance between nearest iron neighbors r_I, as well as the number of nearest neighbors N_I in the first coordination sphere, increases (Fig. 1). Above 1.8% C, the distance remains constant, while the number of nearest neighbors continues to grow. Above 3.5% and up to 5.5% C, both the distance and the number of neighbors remain constant. Above 3.5% C, short-range order regions rich in carbon exist in the melt. This means that the melt becomes more dense with the addition of carbon. A maximum packing density is reached at 3% C, and it remains constant at higher carbon concentrations. The excess carbon forms carbon-rich regions (nonhomogeneities) in the melt.

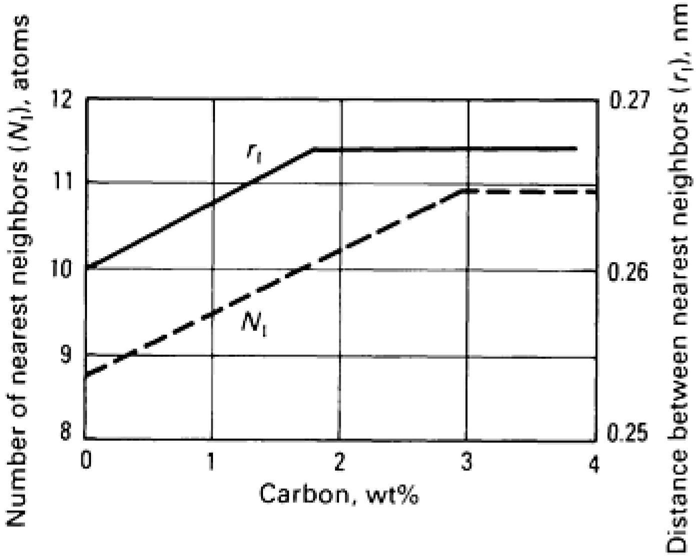

Fig. 1 Variation of distance between nearest neighbors (r_I) and the number of nearest neighbors (N_I) as a function of the percentage of carbon in the iron-carbon alloy. Source: Ref 1.

Viscosity measurements (Fig. 2) show a correlation between viscosity and percentage of carbon. This correlation can be further explained in terms of increased viscosity as the interatomic distance becomes smaller.

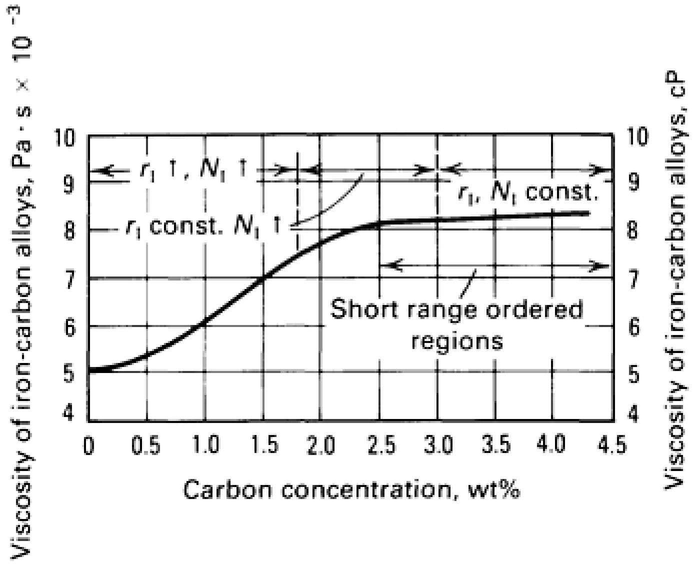

Fig. 2 Viscosity of iron-carbon alloys as a function of carbon concentration at a temperature ≈20° above liquidus. Source: Ref 2.

Liquid iron-carbon alloys with low carbon content (< 3.5% C, that is, steels and cast irons poor in carbon) are microscopically homogeneous. Liquid iron-carbon alloys with high carbon (>3.5% C, that is, cast irons rich in carbon) are colloidally dispersed systems with microgroups of carbon in liquid solution. The nature of these microgroups is not clear. It is hypothesized that they are either Fe_3C clusters (Ref 3) or C_n clusters (Ref 1, 4).

Because the nucleation energy for Fe_3C is smaller than that for graphite, it is thermodynamically possible for the carbon-rich regions to exist as Fe_3C clusters. Other investigators consider the C_n clusters to be stable (Ref 3). Their size is supposed to be in the range of 1 to 20 μm (40 to 800 μin.), and it increases with the carbon equivalent, lower silicon content, and lower holding time and temperature. It is to be expected that the carbon-rich configurations existing in molten iron-carbon alloys are in dynamic equilibrium and that they diffuse within the melt.

Nucleation of Eutectic in Cast Iron

Structure of Graphite in the Austenite-Graphite Eutectic. The graphite phase is a faceted crystal bounded by low index planes. For graphite crystallizing from an iron-carbon melt, the normally observed bounding planes are (0001) and $\{10\bar{1}0\}$, as shown in Fig. 3(a). The crystallographic structure of graphite and the possible growth directions, *A* and *C*, are shown in Fig. 3(b). Because unstable growth occurs on $\{10\bar{1}0\}$ planes, the edges of the platelike graphite crystals are not well defined. Graphite growing out of liquid iron-carbon alloys has a layer-type structure, with strong covalent bonds (4.19×10^5 to 5×10^5 J/mol, or 3.09×10^5 to 3.70×10^5 ft · lbf/mol) between atoms in the same layer. There is a trielectronic bond of each atom with its neighbors, while the fourth electron is common for the layer giving the metallic properties of graphite. Weak molecular forces exist between layers (4.19×10^3 to 8.37×10^3 J/mol, or 3.09×10^3 to 6.17×10^3 ft · lbf/mol). The prism plane is a high-energy plane at which impurities absorb preferentially. Strength and hardness are higher in the *C* direction of the graphite crystal.

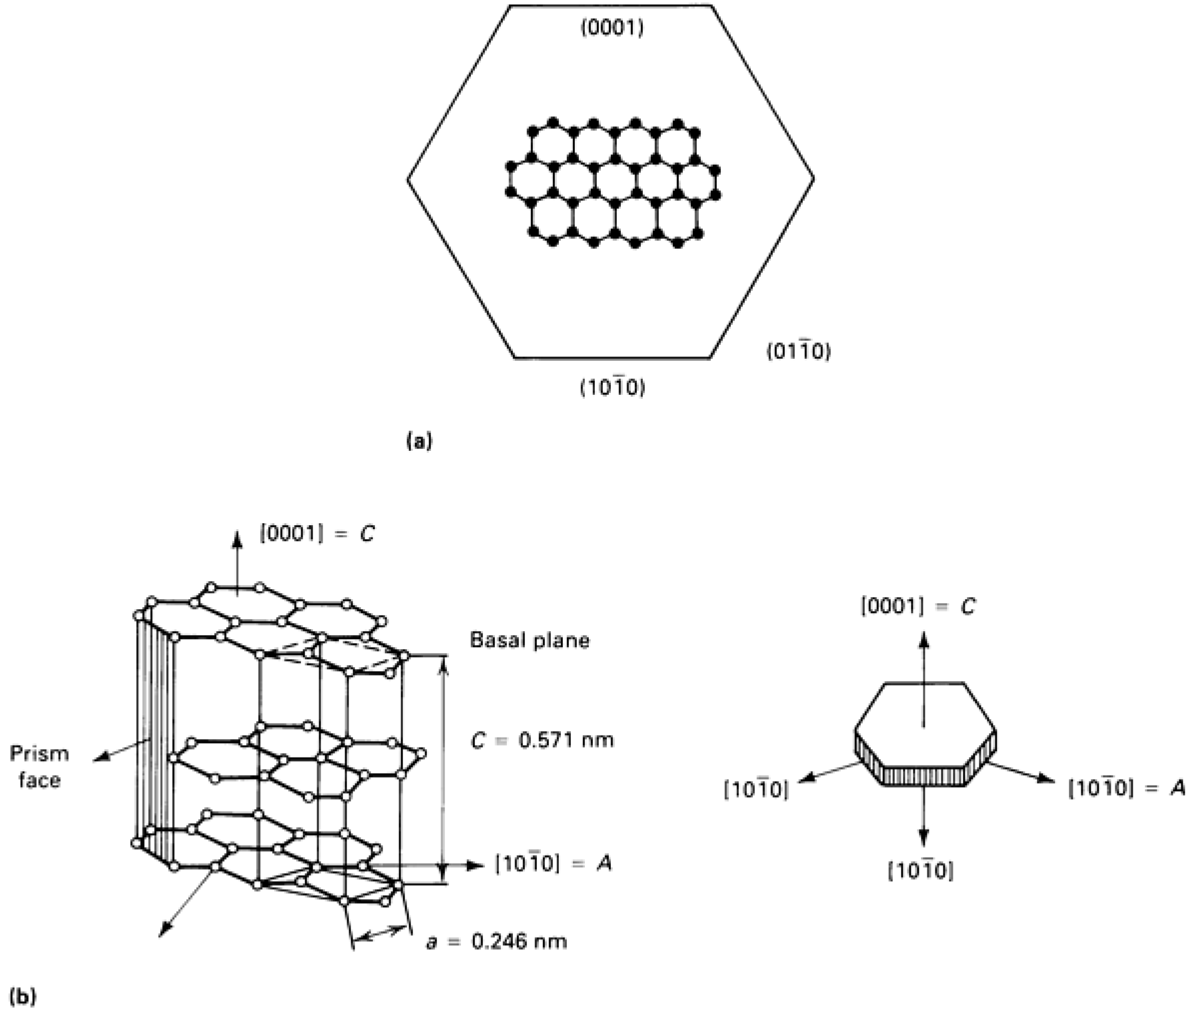

Fig. 3 Crystalline structure of graphite. (a) Crystal of graphite bounded by (0001) and $(10\bar{1}0)$ type planes; the hexagonal arrangement of the atoms within the (0001) plane is shown relative to the bounding $(10\bar{1}0)$ faces. (b) Hexagonal structure of graphite showing the unit cell (heavy lines). Source: Ref 5.

Complete destruction of the graphite structure occurs only at about 4000 °C (7230 °F). This explains the presence of some graphite aggregates in molten iron even at temperatures considerably higher than the liquidus temperature.

Depending on the chemical composition and the temperature gradient/growth rate ratio, G/R, and/or cooling rate, $G \cdot R$, a variety of graphite shapes can solidify as part of the austenite-graphite eutectic. Basically, they are as follows:

- Flake (actually plate) graphite (FG)
- Compacted/vermicular graphite (CG)
- Coral graphite
- Spheroidal (nodular) graphite (SG)

A schematic of these graphite types, showing the traces of the $\{10\bar{1}0\}$ planes, is given in Fig. 4.

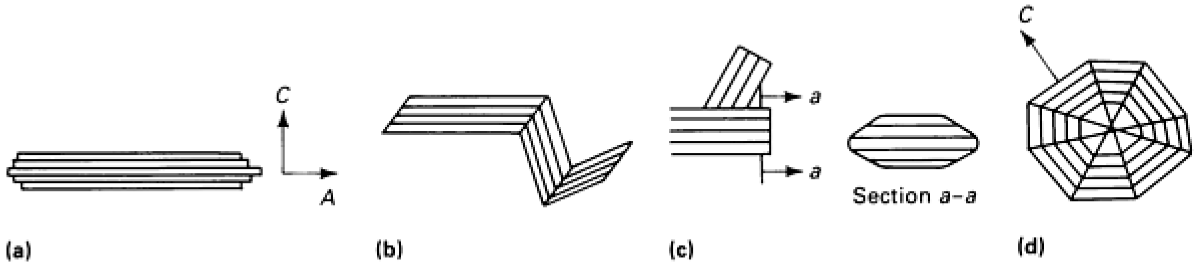

Fig. 4 Schematic of graphite types occurring in the austenite-graphite eutectic. (a) Flake graphite. (b) Compacted/vermicular graphite. (c) Coral graphite. (d) Spheroidal graphite.

Nucleation of the Austenite-Flake Graphite Eutectic. Experimental evidence indicates that various types of nuclei become effective at various temperatures. Indeed, if only one type of nuclei would be active in a cast iron melt, an undercooling-superheating curve will show a single arrest for the temperature region over which the nuclei become effective. However, as shown in Fig. 5, a number of steps are observed in the relationship, suggesting that various foreign nuclei become effective as superheating is increased. Increasing the superheating apparently destroys the effective nuclei. Consequently, the number of eutectic grains (eutectic cells) decreases as the superheating increases, and as a result undercooling increases. However, when undercooling, Δ, is increased at constant superheat by increasing the cooling rate or the growth rate, *R*, the eutectic cell count will increase (Fig. 6). Mathematically, this is shown by $r^* \propto 1/\Delta T$, where r^* is the critical size radius. As Δ increases, r^* decreases, yielding an increasing number of critical size nuclei as well as more eutectic cells.

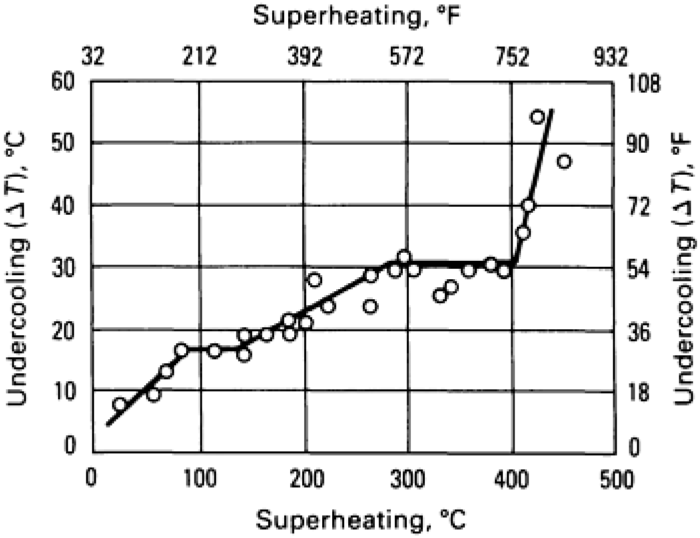

Fig. 5 Relationship between superheating and maximum undercooling in flake graphite cast iron. Source: Ref 6.

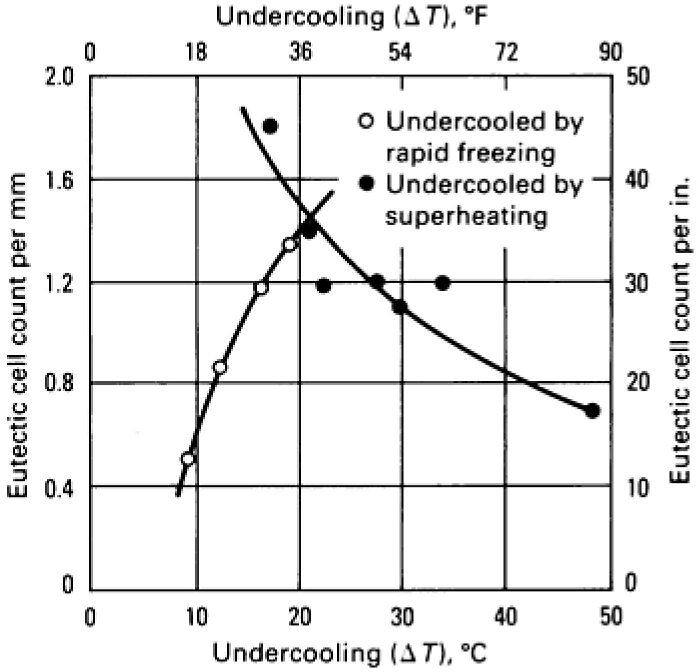

Fig. 6 Influence of undercooling on eutectic cell count in flake graphite cast iron. Source: Ref 7.

Homogeneous nucleation is improbable in cast iron because typical undercoolings are much smaller than required by the theory of homogeneous nucleation (1 to 10 °C, or 2 to 20 °F), as opposed to 230 °C, or 415 °F). Nevertheless, some C_n clusters (as discussed earlier in this section) or undissolved graphite may act as heterogeneous nuclei for graphite formation. When two separate melt charges of similar composition containing white iron and gray iron are compared, the resulting structure provides support for the idea that some type of residual graphite serves as graphite nuclei during solidification (Ref 8). Further, additions of graphite to the melt enhance nucleation because the eutectic cell count is increased while the chilling tendency decreases (Ref 9).

A rather wide variety of compounds have been claimed to serve as nuclei for FG cast iron, including oxides (for example, silicon dioxide) or silicates, sulfides, nitrides (boron nitride), carbides (for example, Al_4C_3), and intermetallic compounds (Ref 8). In addition, a number of metals, such as sodium, potassium, calcium, strontium, barium, and yttrium and the lanthanides, act as inoculants in FG iron and can therefore be considered to play a significant role in the heterogeneous nucleation of the austenite-FG eutectic (Ref 8, 10, 11, 12). High silicon concentrations in the melt can also contribute to the heterogeneous nucleation of graphite.

The heterogeneous nucleation of FG iron occurs mainly on silicon dioxide particles (Ref 13). This assertion is based on experimental results as well as on the following theoretical considerations. If the oxygen dissolved in the iron is in equilibrium with carbon in an iron-acid lining-slag-atmosphere system, Eq 1 can be written:

$$(SiO_2) + 2[C] \rightleftharpoons [Si] + 2\{CO\} \qquad \textbf{(Eq 1)}$$

The equilibrium temperature for Eq 1 can be calculated as:

$$\log\frac{[Si]}{[C]^2} = -\frac{27486}{T} + 15.47 \qquad \textbf{(Eq 2)}$$

where *T* is the temperature in degrees K.

Below the equilibrium temperature, solid silica is formed by precipitation deoxidation; above the equilibrium temperature, silica is decomposed. Silica serves as nuclei for graphite growth. The formation of silica particles in turn

requires nucleation, which can be promoted by inoculation. Therefore, the inoculation of FG iron can be described as a deoxidation process with the following requirements:

- Enough oxygen must be available in the melt
- The addition of elements with high affinity to oxygen, such as calcium, aluminum, and barium, to form nuclei for silicon dioxide precipitation (heterogeneous catalysis)
- Inoculation temperature must be a maximum of 50 °C (90 °F) above the equilibrium temperature to avoid dissolution of the silicon dioxide particles
- The cooling rate after inoculation must be low enough to allow sufficient time for silicon dioxide formation, but high enough to prevent coalescence and segregation of silicon dioxide

A different theory of heterogeneous nucleation in FG iron has also been proposed (Ref 10). Based on the study of the influence of the inoculation of pure iron-carbon and iron-carbon-silicon alloys with pure metals, it was concluded that the addition of elements capable of forming saltlike carbides increases the number of eutectic cells and therefore the number of nuclei in the cast iron. Saltlike carbides are carbides containing the ion C_2^{2-} . Typical saltlike carbides of metals that have been proved to act as nuclei are as follows:

Group I	**Group II**	Group III
$NaHC_2$	CaC_2	**YC_2**
KHC_2	SrC_2	**LaC_2**
	BaC_2	

These carbides have a number of properties that support the hypothesis of their role as nuclei:

- Due to the strong ionic bond between carbon and the metal, they will not dissolve in the melt but will precipitate as insoluble particles
- They are regions of concentration in the melt as compared with the bulk composition of the liquid and can serve as heterogeneous nuclei
- They have carbon planes in their structures that can serve as a basis for the epitaxial growth of graphite from the melt (Fig. 7)

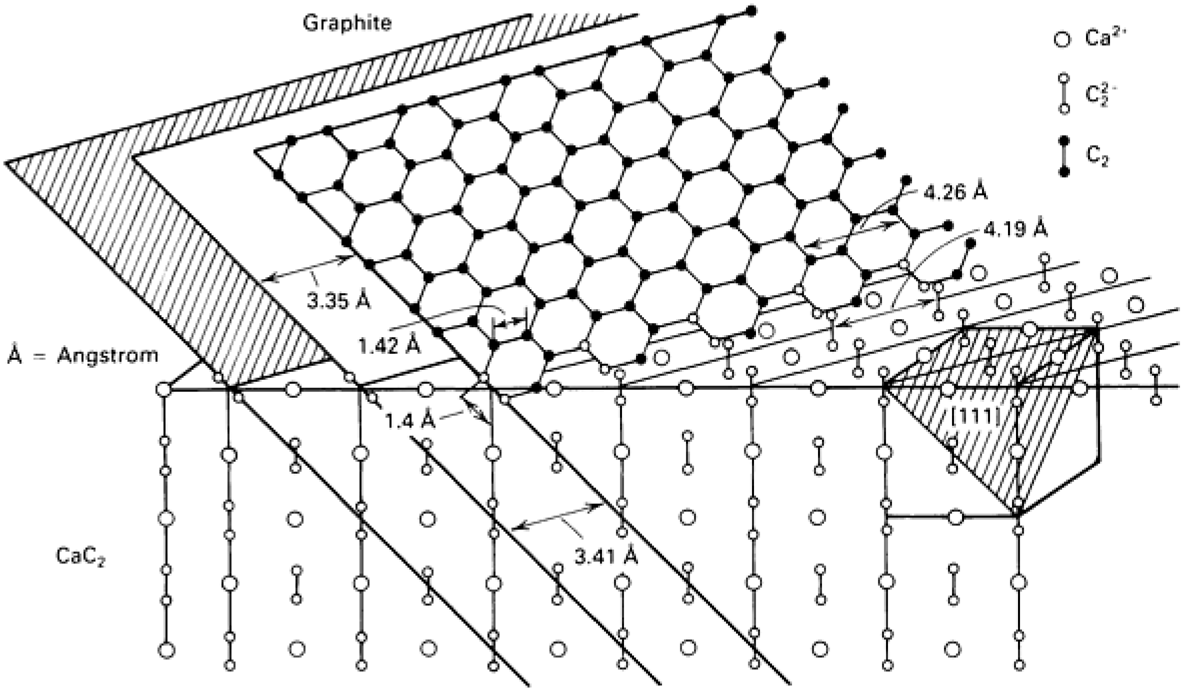

Fig. 7 Epitaxial growth of graphite on a CaC_2 crystal. Source: Ref 10.

A schematic of the mechanism of inoculation by metals forming saltlike carbides is shown in Fig. 8. A metal from the I, II, or III Group in the periodic table is added to the melt and reacts with carbon to form a saltlike carbide, M_zC. Graphite then grows heterogeneously from the melt on the carbon planes of the carbide.

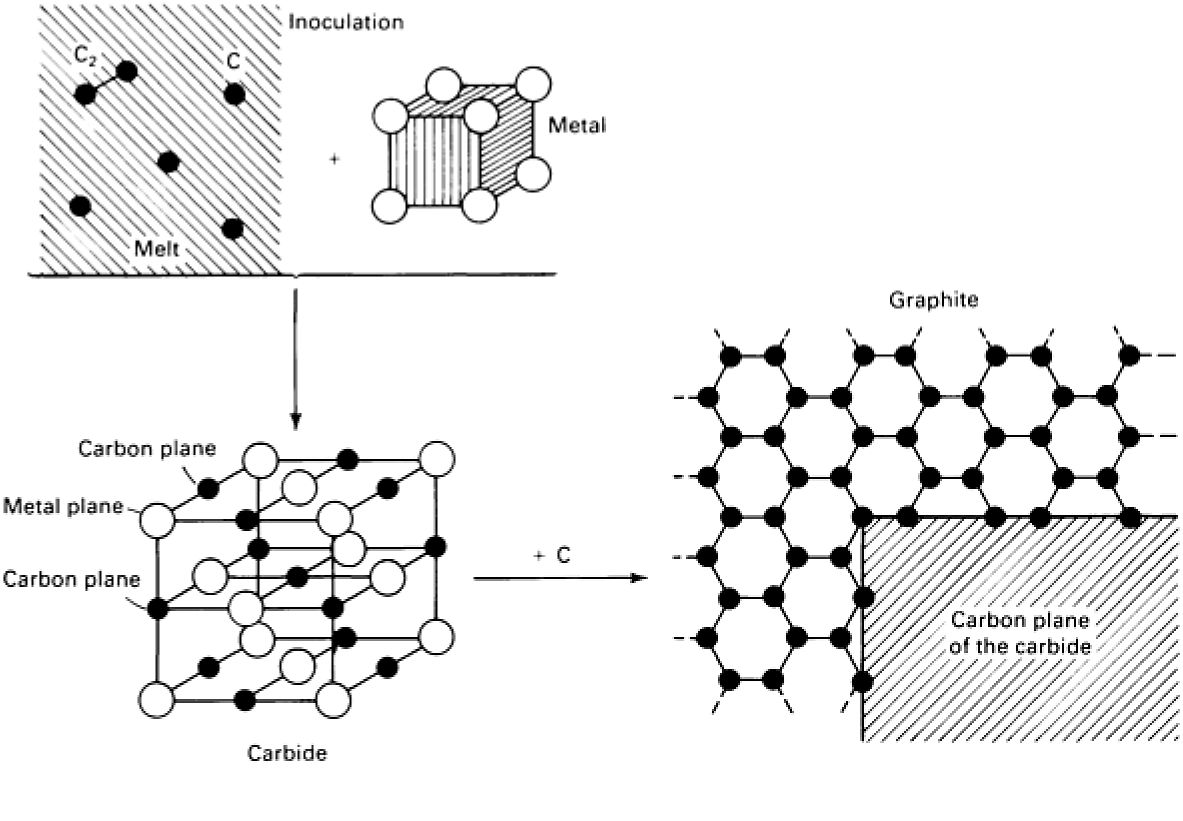

Fig. 8 Schematic of the inoculation of cast iron by metals to form saltlike carbides. Source: Ref 10.

Nucleation of the Austenite-Spheroidal Graphite Eutectic. Because most of the inoculants used in FG iron treatment are also effective for SG irons, it is reasonable to assume that similar mechanisms and substrates are active in both types of irons. Extensive transmission electron microscopy and scanning electron microscopy studies have been done to identify the composition of graphite nuclei in SG irons, with a rather wide variety of results. Numerous types of compounds have been found in the middle of graphite spheroids; therefore, it was hypothesized that they could act as nuclei. Some of these compounds are as follows: $3MgO \cdot 2SiO_2 \cdot 2H_2O$ (cristobalite) (Ref 14), $xMgO \cdot yAl_2O_3 \cdot zSiO_2$, $xMgO \cdot ySiO_2$, $xMgO \cdot ySiO_2 \cdot zMgS$ (Ref 15), MgS (Ref 16), Te + Mn + S (Ref 17), and lanthanide sulfides (Ref 18).

A rather extensive work on what appeared to be substrates for spheroidal graphite in chilled ductile iron concluded that the substrates are duplex sulfide-oxide inclusions with a diameter of 1 μm (40 μin.). The core is probably made of Ca-Mg or Ca-Mg-Sr sulfides, while the outer shell is made of complex Mg-Al-Si-Ti oxides with a spinel structure (Ref 19) .

The orientation relationships were established as follows. For the nucleus core/nucleus shell:

$$(110)\ \text{sulfide} \parallel (111)\ \text{oxide}$$
$$[10\bar{1}0]\ \text{sulfide} \parallel (2\bar{1}\bar{1})\ \text{oxide}$$

For the nucleus shell/graphite:

$$(111)\ \text{oxide} \parallel (0001)\ \text{graphite}$$
$$[1\bar{1}0]\ \text{oxide} \parallel [10\bar{1}0]\ \text{graphite}$$

The x-ray diffraction data showed that the first few graphite layers, adjacent to the (111) oxide, had a dilated lattice (0.264 nm, or 2.64 Å, instead of 0.246 nm, or 2.46 Å). It was suggested that the spacing within the graphite layers decreases away from the oxide until unconstrained spacing is reached. Dislocations were frequently observed in the matrix, and it was suggested that these were generated to relieve some of the elastic strain in the graphite layers adjacent to the oxide.

These observations allow for a theory of nucleation of spheroidal graphite similar to the catalytic theory of nucleation of flake graphite on silicon dioxide, as discussed previously. It can be assumed that the nucleation process begins with the formation of complex sulfides that serve as nuclei for complex oxides, which in turn serve as nuclei for spheroidal graphite.

Structure of Iron Carbide in the Austenite-Iron Carbide Eutectic. The iron carbide (cementite) consists of an orthorhombic unit cell with 12 iron atoms and 4 carbon atoms per cell and therefore has a carbon content of 6.7 wt%. Its density is 7.6 g/cm^3.

Nucleation of the Austenite-iron Carbide Eutectic. Very little information is available on the nature of the nuclei of the white eutectic. Nevertheless, it is accepted that the nucleation of Fe_3C occurs at lower undercooling than that of graphite (Ref 7). This is supported by the slopes of the solubility lines in the phase diagram, which shows that the supersaturation of cementite increases faster than that of graphite, resulting in an increased probability for the nucleation of cementite as the temperature is lowered. Cooling curve data also show that the solidification of white iron begins at a lower temperature than that of gray iron. There is some evidence that silicon dioxide and aluminum oxide can serve as substrates for the growth of the Fe-Fe_3C eutectic and that the nature of the substrate can influence the morphology of the eutectic (Ref 20).

Nucleation of Primary Phases in Cast Iron

Depending on the carbon equivalent (or saturation degree), the primary phase can be either austenite for hypoeutectic cast iron or graphite for hypereutectic cast iron.

Primary Austenite. The formation and growth characteristics of austenite dendrites have received considerably less attention from investigators than eutectic cell count and morphology simply because dendrites are not readily discernible in the structure. Nevertheless, it has been demonstrated that inoculants that are effective in increasing the cell count (such as calcium-titanium, strontium, and 75% FeSi) have little effect on the solidification pattern of primary austenite dendrites (Ref 21).

A number of elements, such as titanium, vanadium, and aluminum, were proved to increase the number of dendrites and their length when compared with the base iron. For titanium and vanadium, this was attributed to the formation of carbides, nitrides, and carbonitrides, which then act as substrates for austenite solidification. The influence of aluminum was not explained. Other elements, such as cerium and boron, although being instrumental in increasing the number and length of dendrites, were not considered to be nucleants for austenite. It was suggested that these elements restrict the growth of the eutectic cells, which subsequently results in larger undercooling for eutectic solidification. This means that more time (a larger temperature interval) is available for the nucleation and growth of austenite (Ref 21).

Primary Graphite. It is reasonable to assume that nuclei that are active in the solidification of eutectic graphite also serve as nuclei for hypereutectic primary graphite. Nevertheless, it must be noted that inoculation does not seem to increase significantly the number of eutectic cells in hypereutectic FG iron. On the other hand, inoculation is quite effective in hypereutectic SG iron.

Growth of Eutectic in Cast Iron

Coupled Zone in Cast Iron

The degree and type of eutectic growth that occurs in cast iron can be determined by using tools such as growth rate curves to locate coupled zone regions, isothermal time-temperature diagrams to gage susceptibility to carbide formation, and growth rate-composition plots to ascertain parameters that affect both directional and multidirectional solidification. As shown in Fig. 14 in the article "Solidification of Eutectics" in this Volume, the coupled growth region of the eutectic in cast iron is asymmetric. It is possible to construct a theoretical coupled zone for gray iron from the condition of equal growth rate of the austenite (γ) and graphite (Gr) phases (Ref 22). First one must consider the growth rate curves for γ and Gr in the Fe-C system (Fig. 9). For FG iron, the growth rate of austenite, R_γ, and that of graphite along the [10$\bar{1}$0] direction, R_{Gr}[10$\bar{1}$0], intersect; therefore, a coupled zone can be constructed. For SG iron, where the predominant growth direction is along [0001], the two rates, R_γ and R_{Gr}[0001], do not intersect, which means that coupled growth is impossible.

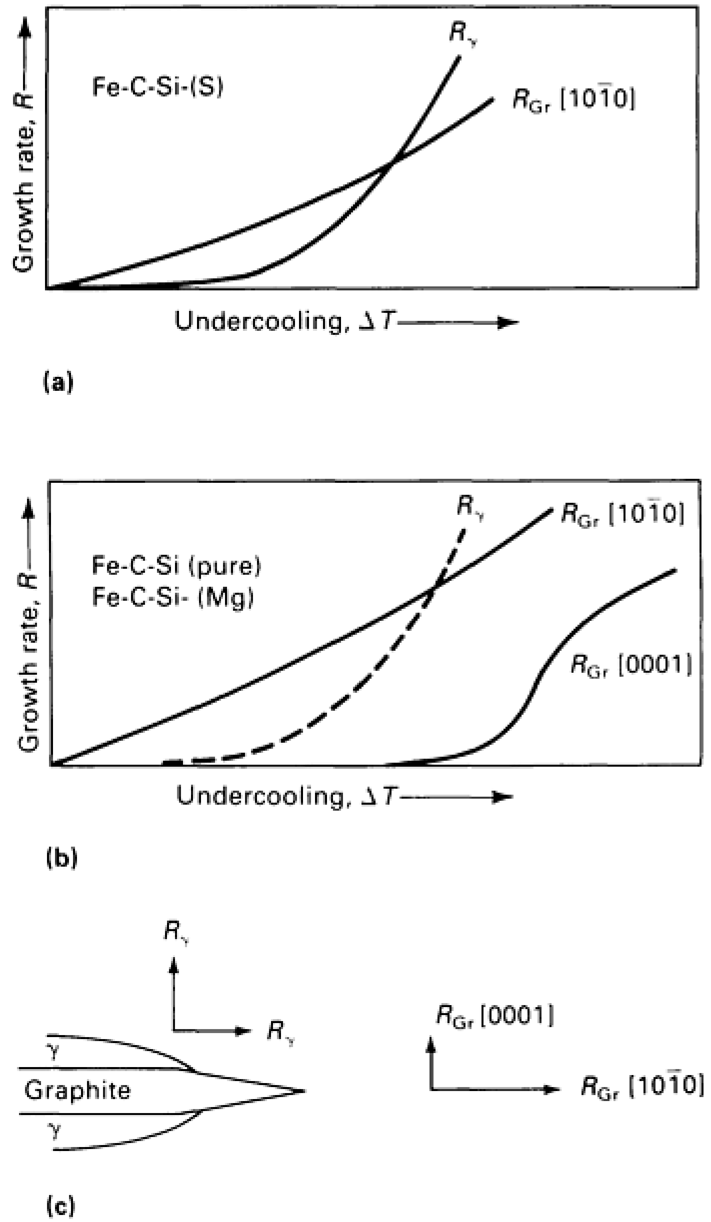

Fig. 9 Suggested growth rate curves for austenite and graphite in the iron-carbon-silicon alloys. (a) Austenite-FG eutectic. (b) Austenite-SG eutectic. (c) Different graphite growth rates in lamellar growth. R_{Gr} [10$\bar{1}$0] determines the lamellar habits of graphite flakes, while R_{Gr} [0001] gives the rate of thickening for the flake.

Source: Ref 5.

Figure 10(a) shows the point at which the graphite and γ growth curves for gray iron cross and are equal ($\Delta T\gamma$/Gr); at points 1 and 2 on the curves, the growth rates are the same, but the undercooling differs. Figure 10(b) shows the phase diagram in the vicinity of the eutectic point, with $\Delta T\gamma'$ and $\Delta T\gamma''$ drawn for growth conditions represented by the points of Fig. 10(a). Point Q in Fig. 10(b) corresponds to $\Delta T\gamma$/Gr where $R\gamma = R_{Gr}$. At the left of the $R_{Gr} = R\gamma$ line, primary γ dendrites will form, while at the right of this line, graphite will be the leading phase. Coupled eutectic growth can only occur for combinations of undercoolings and compositions on the dotted line $R_{Gr} = R\gamma$.

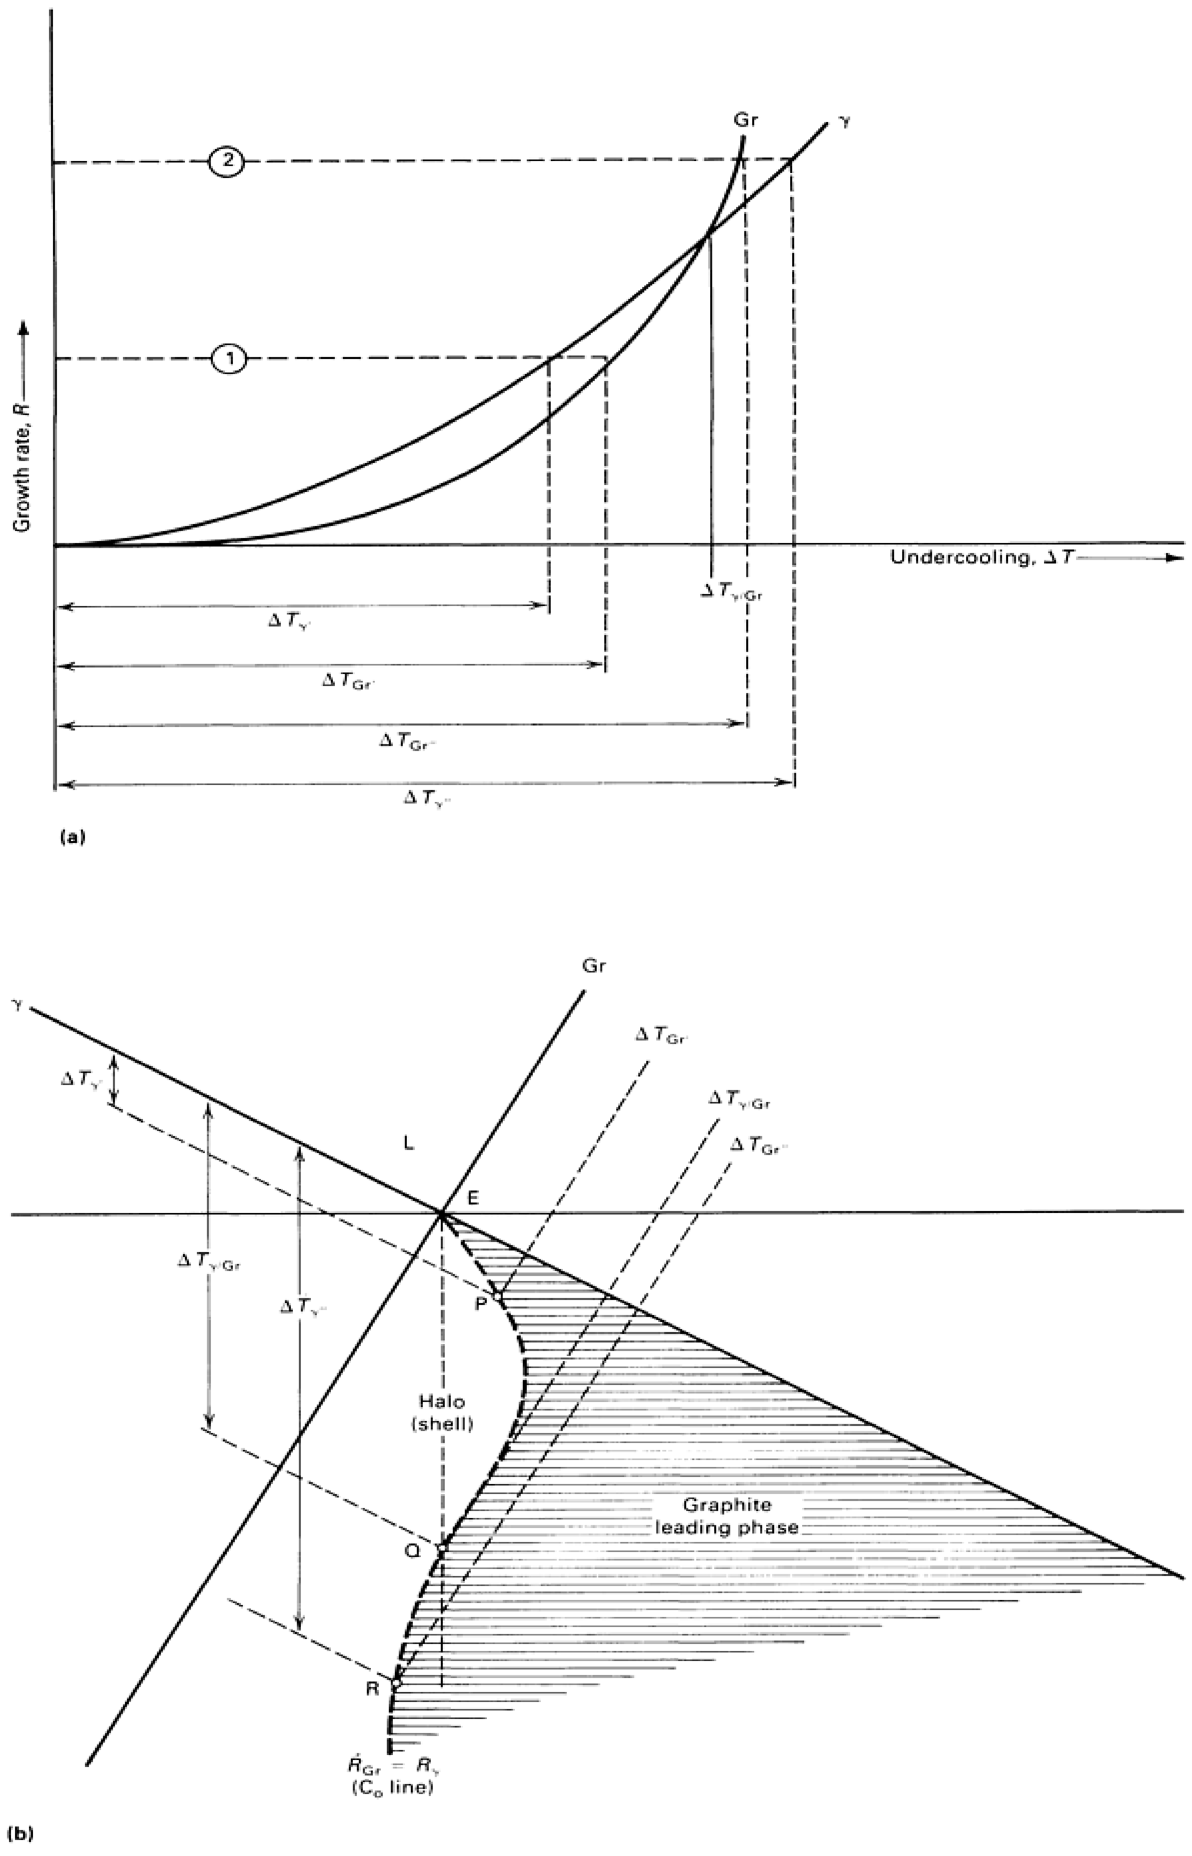

Fig. 10 Constructions of coupled growth line in iron-carbon-silicon alloys. (a) γ and Gr growth curves. (b)

Construction of the equal growth rate curve $R\gamma = R_{Gr}$. Source: Ref 22.

The transition from a fully eutectic to a eutectic plus dendrite structure in pure iron-graphite alloys of eutectic composition has been determined, and the γ-iron and graphite-iron eutectic boundaries have been calculated (Fig. 11).

(b) Temperature-composition diagram with superimposed phase diagrams, stable (Eu_1) and metastable (Eu_2). Au, austenite dendrites; Gr, primary graphite plates; Ce, primary

cementite plates. Source: Ref 23.

Isothermal Solidification

Solidification studies are usually performed athermally because of the high rate of the liquid-solid transformation. Nevertheless, useful information can be extracted from the isothermal time-temperature-transformation diagrams shown in Fig. 12. It is apparent that SG iron is more susceptible to carbide formation than FG iron. Graphite precipitates earlier in SG iron than in FG iron at all undercoolings, although the time interval for complete gray solidification is smaller in FG irons.

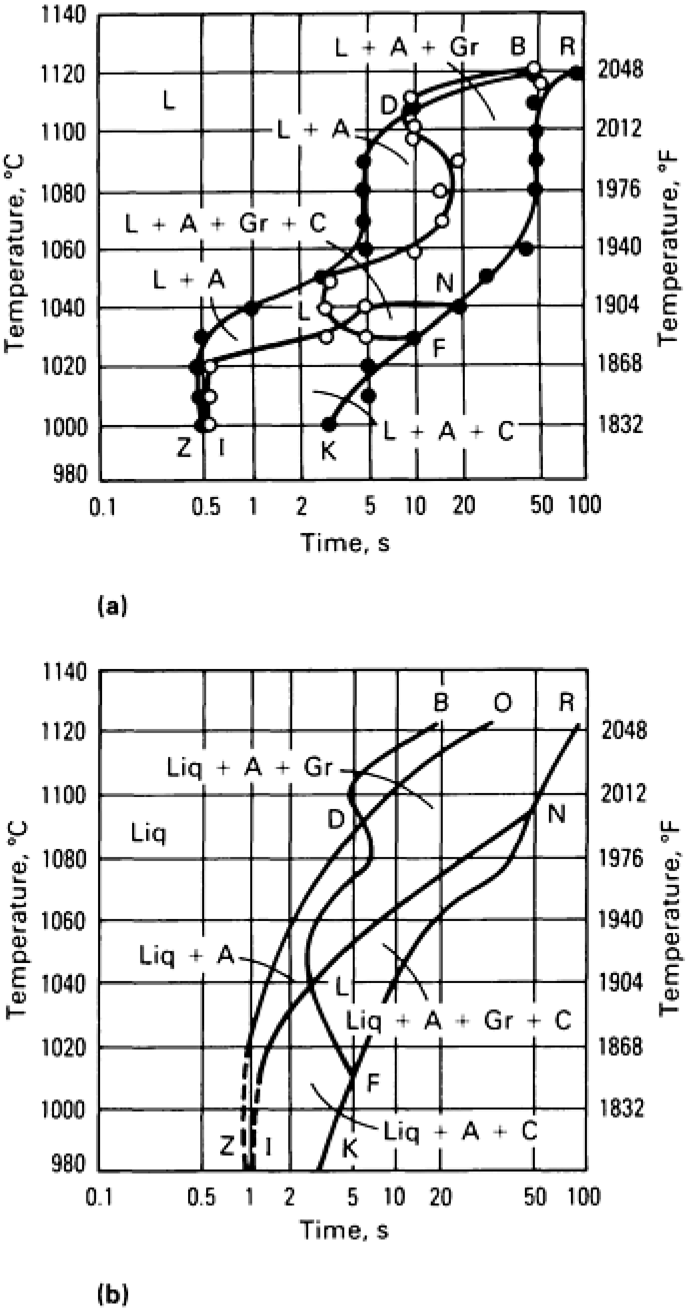

Fig. 12 Time-temperature-transformation diagrams for isothermal solidification of eutectic cast iron. (a) FG cast iron. (b) SG cast iron. L, liquid; A, austenite; C, cementite; Gr, graphite. Source: Ref 7.

Growth in Directional Solidification

It is quite obvious from the previous discussion that undercooling and composition must be carefully selected to achieve coupled growth of the eutectic in cast iron. The γ-FG eutectic is a coupled irregular eutectic of the faceted (Gr)/nonfaceted (γ) type. The γ-SG eutectic is a divorced eutectic.

The basic parameters affecting the morphology of the eutectic are the *G*/*R* ratio and composition. As shown in Fig. 13, it is possible to achieve a variety of structures in cast iron when varying *G*/*R* and/or the level of impurities (for example, cerium). The gray eutectic can solidify with a planar interface. The theoretical relationship $\lambda^2 R$ = constant (Jackson and Hunt), where λ is the spacing, is not obeyed in the growth of the γ-FG eutectic. Different experimental results are compared with the theoretical behavior in Fig. 14.

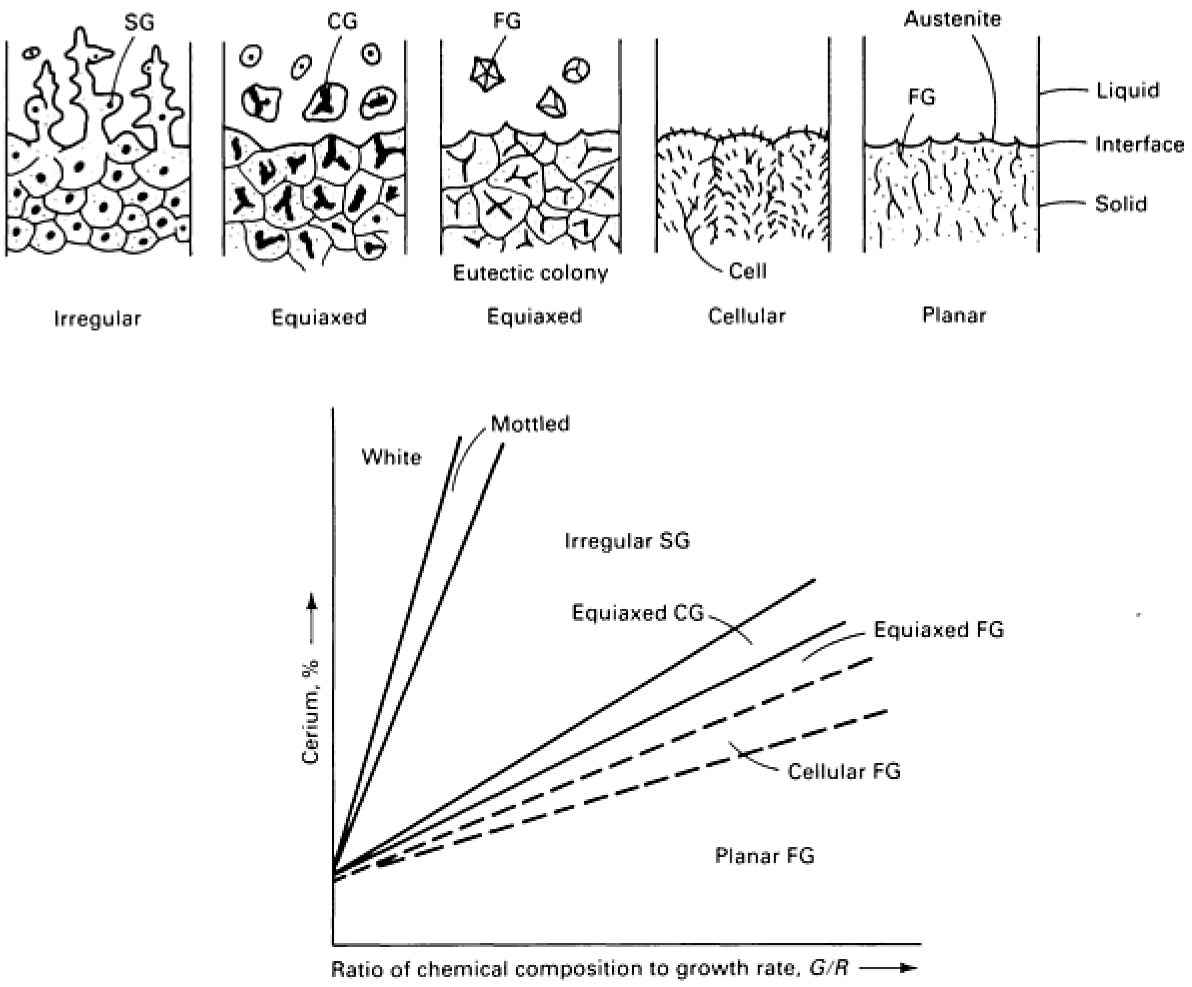

Fig. 13 Schematic showing the influence of composition (% cerium), *G*, and *R* over the eutectic morphology of iron-carbon-silicon alloys. Source: Ref 24.

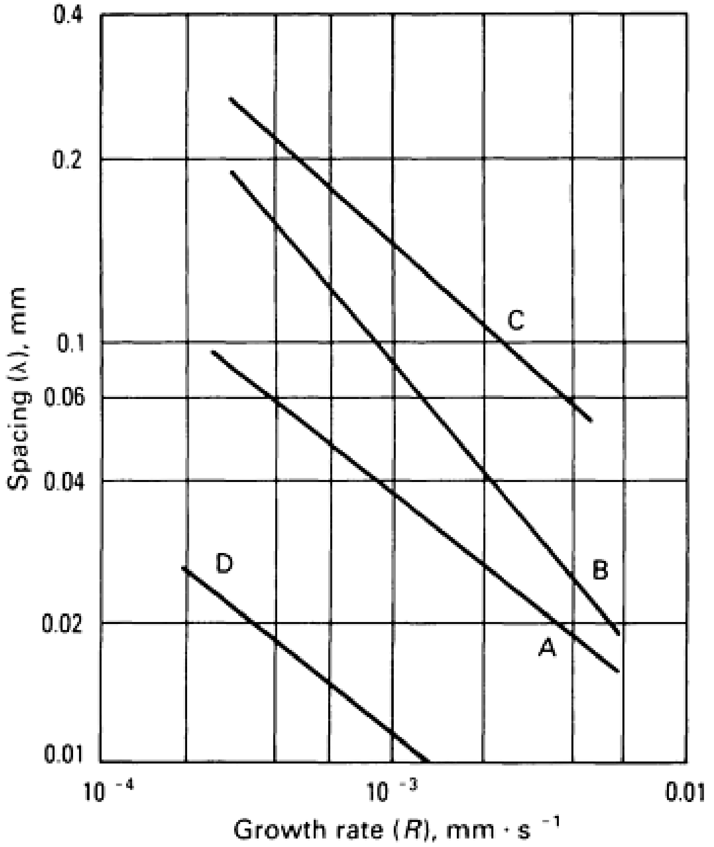

Fig. 14 λ-*R* relationships in FG cast iron. A, Lakeland l= 3.8 × 10^{-5} · $R^{-0.5}$ cm; B, Nieswaag and Zuithoff λ= 0.56 × 10^{-5} · $R^{-0.78}$ cm (0.004% S); C, Nieswaag and Zuithoff λ= 7.1 × 10^{-5} · $R^{-0.57}$ cm (>0.02% S); D, Jackson and Hunt λ= 1.15 × 10^{-5} · $R^{-0.5}$ cm (theoretical). Source: Ref 5.

The departure of experimental values from the theoretical line is a clear indication of irregular rather than regular cooperative growth in FG cast iron. For *G*/*R* ratios selected to produce a planar interface during the directional solidification of FG iron, it has been measured that the growth constant in the $R = \mu \cdot \Delta T^2$ equation is $\mu = 8.7 \times 10^{-8}$ m · s^{-1} · K^{-2} (Ref 23).

In the case of SG iron, even for hypereutectic irons, the graphite spheroids do not grow in independent austenite envelopes, but rather are associated with austenite dendrites (Fig. 15). The eutectic austenite is dendritic and cannot be distinguished from the primary austenite. Spheroidal graphite precipitates directly from the melt, becomes enveloped in an austenite shell that is very soon incorporated into the dendrites, and then grows together with the dendrites (Ref 25, 26).

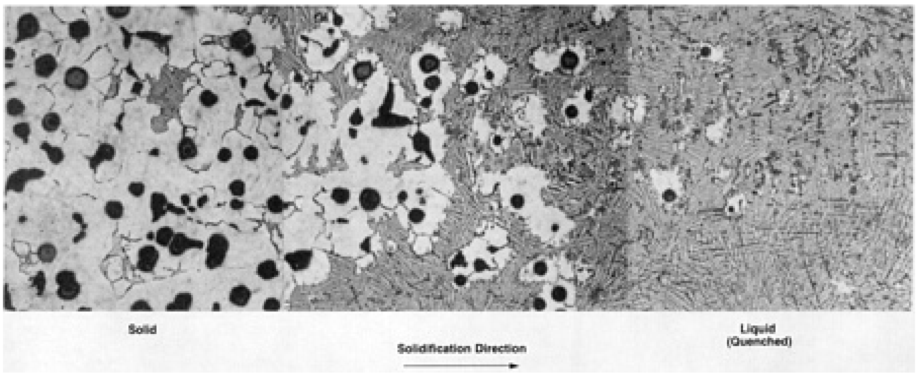

Fig. 15 Microstructure of the solid/liquid interface for a directionally solidified hypereutectic cerium-treated spheroidal graphite cast iron. Source: Ref 25.

Growth in Multidirectional Solidification

Flake (Lamellar) Graphite Eutectic. The austenite-FG eutectic solidifies with the formation of eutectic colonies (cells) that are more or less spherical in shape. It is generally thought that each eutectic cell is the product of a nucleation event. The eutectic cell is made of interconnected graphite plates surrounded by austenite. The degree of ramification of graphite within the cell depends on undercooling, with higher undercooling resulting in more graphite branching (Fig. 16). The leading phase during the eutectic growth is the graphite. Graphite spacing is determined by the same parameters as for regular eutectics (see the article "Solidification of Eutectics" in this Volume), with branching occurring as a response to interface instability. In turn, interface instability is determined by localized changes in composition, convection currents, crystallographic orientation different from the heat extraction direction, and a change in temperature gradient.

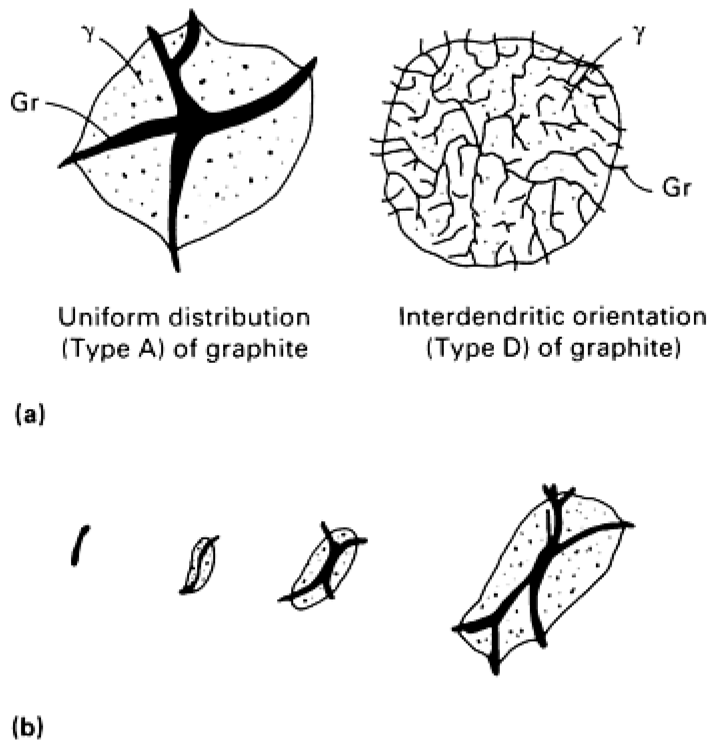

Fig. 16 Schematic of solidification of flake graphite. (a) Typical eutectic colonies (cells). (b) Growth sequence for a eutectic colony.

Figure 17 shows a scanning electron microscopy (SEM) photomicrograph of graphite eutectic cell and prior austenitic dendrite structures in gray cast iron.

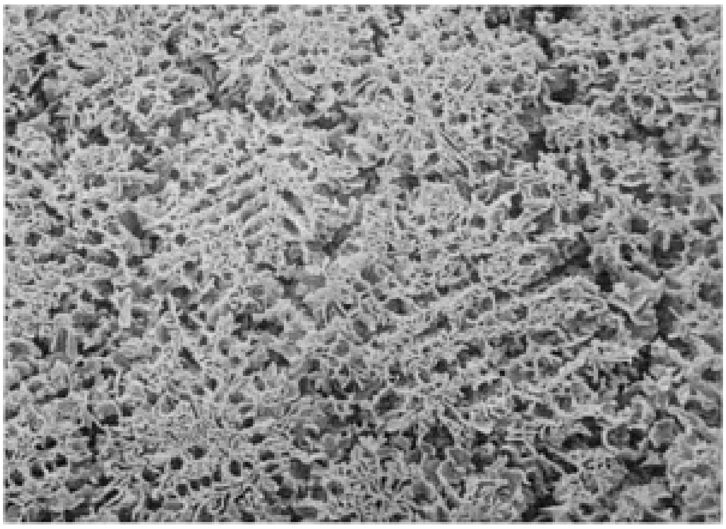

Fig. 17 SEM photomicrograph showing graphite, eutectic cell, and prior dendrite structure in gray cast iron. 200×. Courtesy of Gary F. Ruff, CMI International.

The variations in graphite structures have been classified, together with the length of the flakes, by standards that have been utilized for many years. Flake graphite in gray cast iron can be designated as:

- Type A, uniform distribution, random orientation
- Type B, rosette grouping, random orientation
- Type C, superimposed flake sizes, random orientation
- Type D, interdendritic segregation, random orientation
- Type E, interdendritic segregation, preferred orientation

The formation of the eutectic flake graphite (Types A, B, C, and D) is greatly influenced by the amount by which the iron melt cools below the equilibrium temperature for the austenite-graphite eutectic before appreciable solidification occurs. Gray iron with Type A graphite undergoes only small amounts of undercooling, whereas that with Type D graphite undercools significantly below this equilibrium temperature. The undercooling that occurs with Type B graphite is intermediate between the two, producing fine graphite flakes, like Type D, in the center of the eutectic cells or rosette and a coarser type like Type A at the outer cell boundaries. Type E graphite occurs in strongly hypoeutectic gray irons with carbon equivalents well below 4.3%. Figure 18 shows examples of Type A, B, D, and E flake graphite structures in gray cast irons at various magnifications.

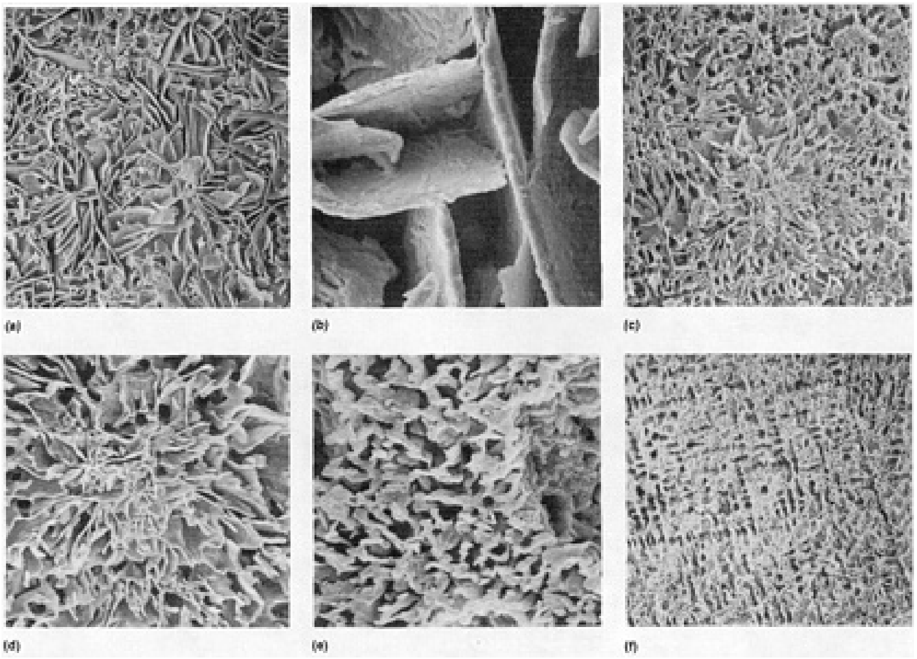

Fig. 18 SEM photomicrographs illustrating variety of flake graphite structures present in gray cast iron: Type A structure at (a) 100× and (b) 430×; Type B structure at (c) 100× and (d) 430×; (e) Type D at 2100×; and (f) Types D (fine) and E (coarse) at 100×. Calculations using data from continuous cooling experiments given in Ref 27 allowed estimation of the growth constant η in the range of 7.25×10^{-8} to 9.5×10^{-8} m · s^{-1} · K^{-2}, which is of the same magnitude as the values given previously for the case of directional solidification.

The solidification of off-eutectic FG iron will start with the nucleation and growth of a primary phase, which is austenite dendrites for hypoeutectic iron or primary graphite plates for hypereutectic iron. It is not unreasonable to assume that the primary phases may play a role in the nucleation of the eutectic, with further growth of the eutectic occurring, as experimental evidence shows, on the primary phases.

Spheroidal Graphite Eutectic. Growth of the austenite-SG eutectic is more complicated and less understood than that of the γ-FG eutectic, although a good number of theories have been proposed. As discussed previously in this section, the γ-SG eutectic is a divorced eutectic. It has been rather widely accepted that the growth of this eutectic begins with nucleation and the growth of graphite in the liquid, followed by early encapsulation of these graphite spheroids in austenite shells (envelopes). A schematic of the process is shown in Fig. 19. Graphite nucleation and growth deplete the melt of carbon in the vicinity of the graphite; this creates conditions for austenite nucleation and growth around the graphite spheroid. Once the austenite shell is formed, further growth of graphite can occur only by solid diffusion of carbon from the liquid through the austenite.

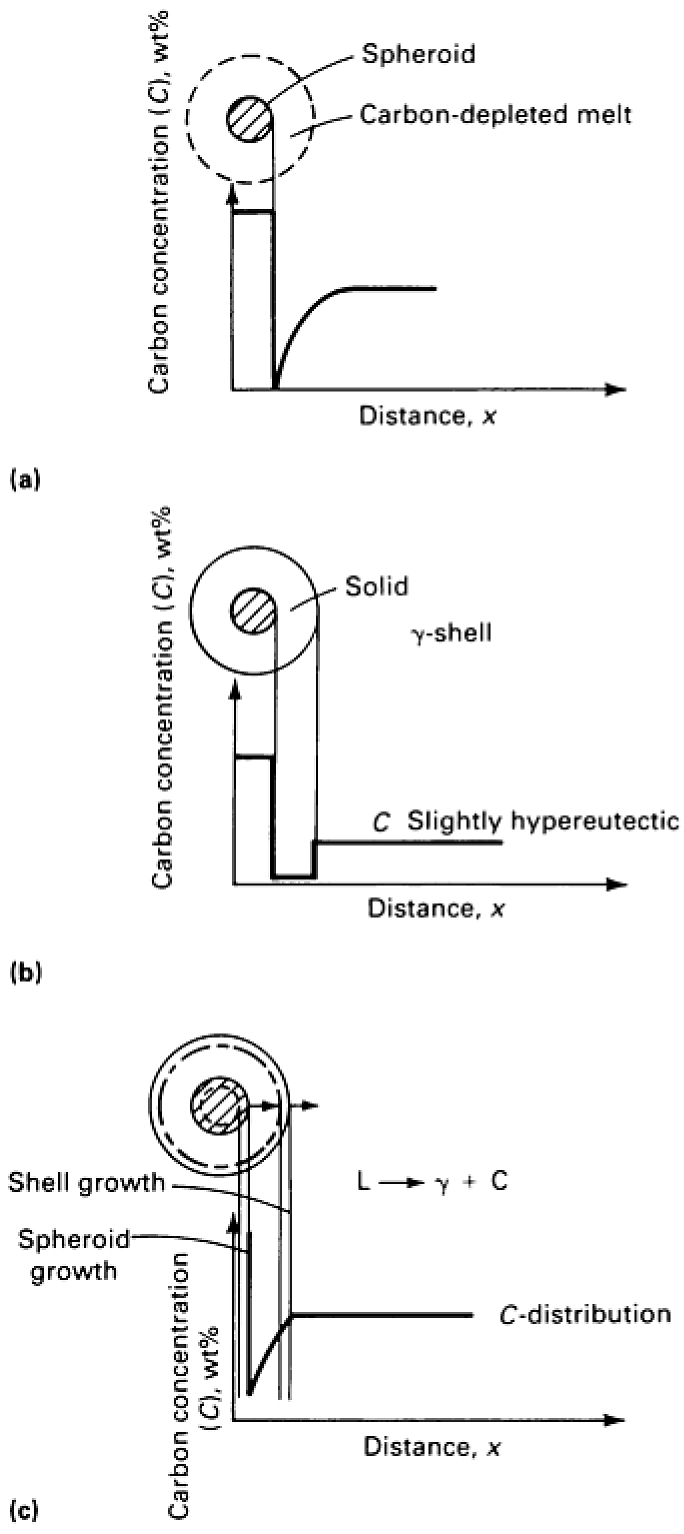

Fig. 19 Isothermal growth of a graphite spheroid within an austenite shell and growth of the shell with a smooth interface. (a) Growth of spheroidal graphite in contact with melt. (b) Envelopment by austenite. (c) Growth of spheroidal graphite within the austenite shell. Source: Ref 22.

Calculations of the diffusion-controlled growth of graphite through the austenite shell were originally made based on Zener's growth equation for an isolated spherical particle in a matrix of low supersaturation (Ref 28). Equation 3 was derived:

$$R_{Gr} = \frac{V_m^{Gr}}{V_m^g} D_c^g \frac{r_g}{r_{Gr}(r_g - r_{Gr})} \frac{X^{g/L} - X^{g/Gr}}{X^{Gr} X^{g/Gr}} \quad \textbf{(Eq 3)}$$

where R_{Gr} is rate of growth of graphite; V_m^{Gr} and V_m^g are the molar volumes of graphite and austenite, respectively; D_c^g is the diffusivity of carbon in austenite; r_{Gr} and $r\gamma$ are the radii of graphite and austenite, respectively; $X\gamma/L$ and $X\gamma/Gr$ are the molar fractions of austenite at the austenite/liquid and austenite/graphite boundaries, respectively; and X^{Gr} is the molar fraction of carbon in graphite. It has also been shown that $r\gamma = 2.4\ r_{Gr}$. A slightly different approach, based on a steady-state diffusion model of carbon through the austenite shell (Ref 29), also allowed derivations for R_{Gr} and $r\gamma$.

However, recent research has shown that the solidification mechanism of SG iron is more complicated and that austenite dendrites play a significant role in eutectic solidification (Ref 25, 26). The eutectic austenite is dendritic and can scarcely be distinguished from primary austenite dendrites. The sequence of solidification is as follows:

- At the eutectic temperature, austenite dendrites and graphite spheroids nucleate independently in the liquid
- Limited growth of spheroidal graphite occurs in contact with the liquid
- Flotation or convection then determines the collision of spheroidal graphite with the austenite dendrites
- Graphite encapsulation in austenite can occur before or immediately after the contact between graphite and austenite dendrites
- Further growth of graphite occurs by carbon diffusion through the austenite shell

This sequence is illustrated schematically in Fig. 20.

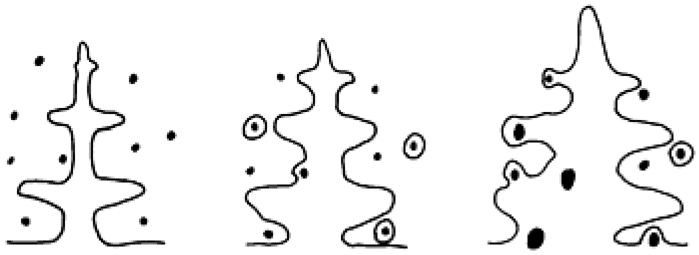

Fig. 20 Schematic illustrating the progression of growth in austenite-SG eutectic.

Graphite shape in SG iron is not perfectly spheroidal. Depending on cooling rate and chemical composition, significant deviations from the true spheroidal shape can be obtained (various nodularities) (Fig. 21).

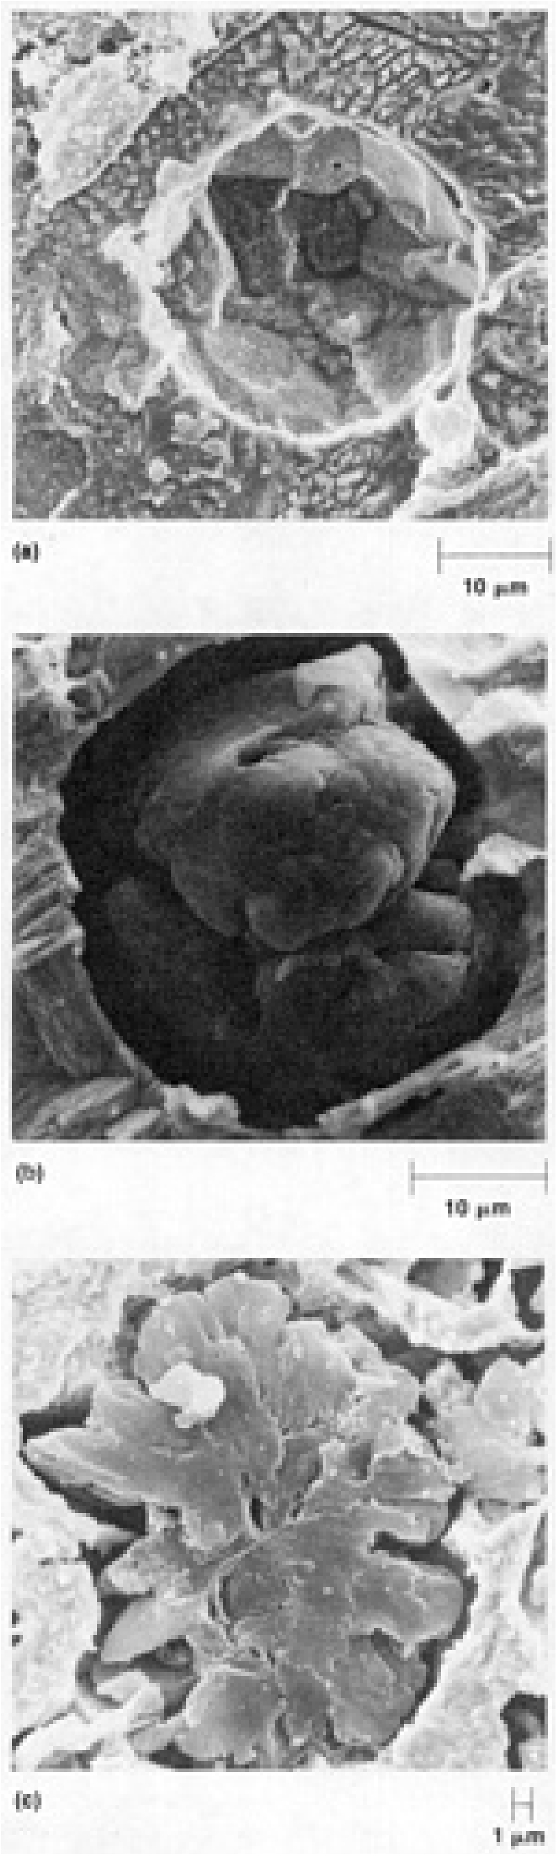

Fig. 21 SEM micrographs of deep-etched spheroidal graphite samples showing a fractured graphite spheroid

(a). Nodularity decreases from (a) through (c).

It remains now to explain the reasons for the change of the habits of graphite from lamellar to spheroidal. Many theories have been proposed (see, for example, review works in Ref 5 and 8), but because of space limitations, only a few will be discussed in this section.

Many theories capitalize on the observation that the graphite/liquid surface energy is higher in SG iron than in FG iron. These theories explain spheroidal graphite formation by either simply implying that a sphere will have less free surface energy than a lamella with the same volume above a certain critical interface energy (Ref 30) or by suggesting that the high interface energy will curve the growing crystal in order to decrease the energy/volume ratio, resulting in spheroidal rather than lamellar graphite (Ref 31).

The defect growth of graphite theory explains spheroidal graphite formation based on the possible growth mechanisms of faceted crystals such as graphite (Ref 32). Three growth mechanisms are considered: two-dimensional nucleation (Fig. 22a), step of a defect (twisted) boundary (Fig. 22b), and screw dislocation. The first two mechanisms are governed by exponential laws and apply to the $(10\bar{1}0)$ surface, but the third is governed by a parabolic law and applies to the (0001) surface of the graphite crystal.

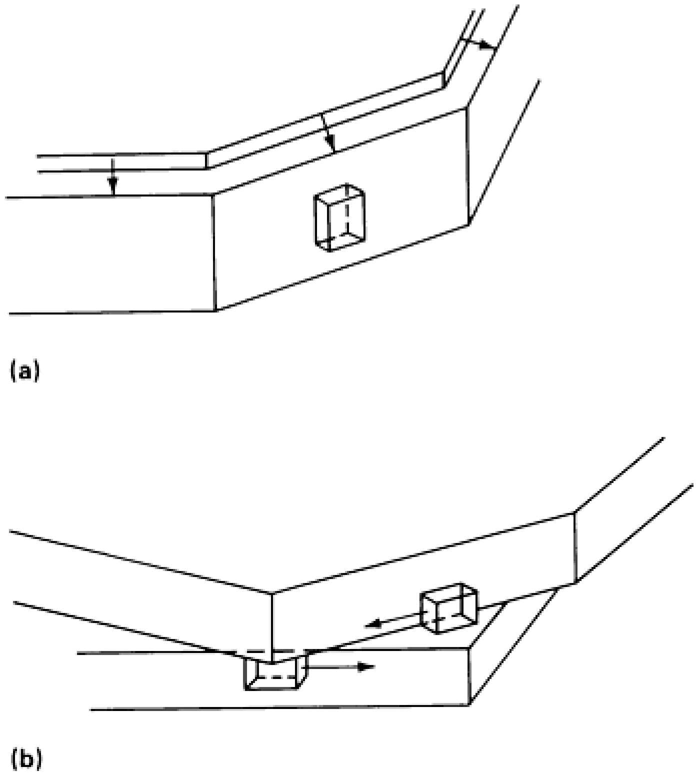

Fig. 22 Growth of graphite in the <10$\bar{1}$0> direction. (a) Growth by two-dimensional nucleation on $(10\bar{1}0)$ faces illustrates that steps on (0001) surfaces will advance only as far as bounding crystal edges. (b) Growth from step to twist boundary illustrates that the (1010) faces grow by nucleation of planes at the step. Source: Ref 32.

When weak, reactive impurities such as sulfur are present in the melt, a contaminated environment occurs. These elements change the edge energy of steps, resulting in a relative position change of the growth rates involved, as shown in Fig. 23(a). The curve for growth on the step of a defect boundary, R_{step}, is at a lower undercooling than those for growth by two-dimensional nucleation, R_{2D}, or by screw dislocation, R_{screw}.

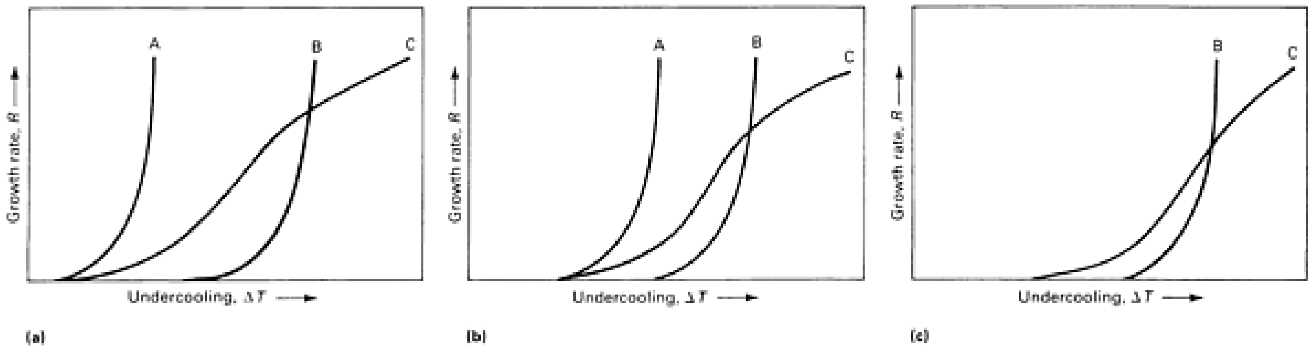

Fig. 23 Suggested Δ*T*-*R* correlation for (10$\bar{1}$0) and (0001) crystal faces of graphite growing in various environments. (a) Contaminated environment (for example, sulfur-containing iron-carbon-silicon alloy). (b) Pure environment (for example, iron-carbon-silicon alloy). (c) Environment with reactive impurities (for example, magnesium-containing iron-carbon-silicon alloy). Three growth mechanisms are discussed: A, on the step of the defect boundary (R_{step}); B, two-dimensional nucleation (R_{2D}); C, screw dislocation (R_{screw}). Source: Ref 32.

In a pure environment such as an iron-carbon-silicon alloy with no sulfur contamination, the growth rate curves are displaced to higher undercooling (Fig. 23b). In a melt of sufficient purity, or when increasing cooling rate, the higher degree of undercooling may allow growth with R_{screw} so that graphite spheroids can form. This has been achieved experimentally for pure nickel-carbon alloys by increasing the cooling rate of the melt, or for ultrapure iron-carbon alloys by cooling slowly in a vacuum.

In an environment with reactive impurities (for example, magnesium), the impurity will react with the surface, and the growth at a step of a twist boundary will be neutralized. Only the curves for R_{2D} and R_{screw} are left, and they are displaced to greater undercoolings (Fig. 23c).

Another theory relates graphite shape in cast iron with undercooling (kinetic plus constitutional) during solidification (Ref 5). As shown in Fig. 24, each graphite form has its own temperature for growth, which is achieved by a specific cooling rate and composition. Steps on surfaces can change graphite morphology from plate to rod. With an increase in undercooling, pyramidal instabilities will occur on the faces of the graphite crystal. At undercoolings of 29 to 35 °C (50 to 65 °F), instabilities occur on the (10$\bar{1}$1) faces of the pyramid, and it is suggested that graphite spheroids form at these undercoolings. Finally, at large undercoolings of 40 °C (70 °F), the growth form noted is a pyramidal one, bounded by (10$\bar{1}$1) faces. These pyramidal crystals are part of the series of imperfect forms observed particularly in thick-wall SG iron castings.

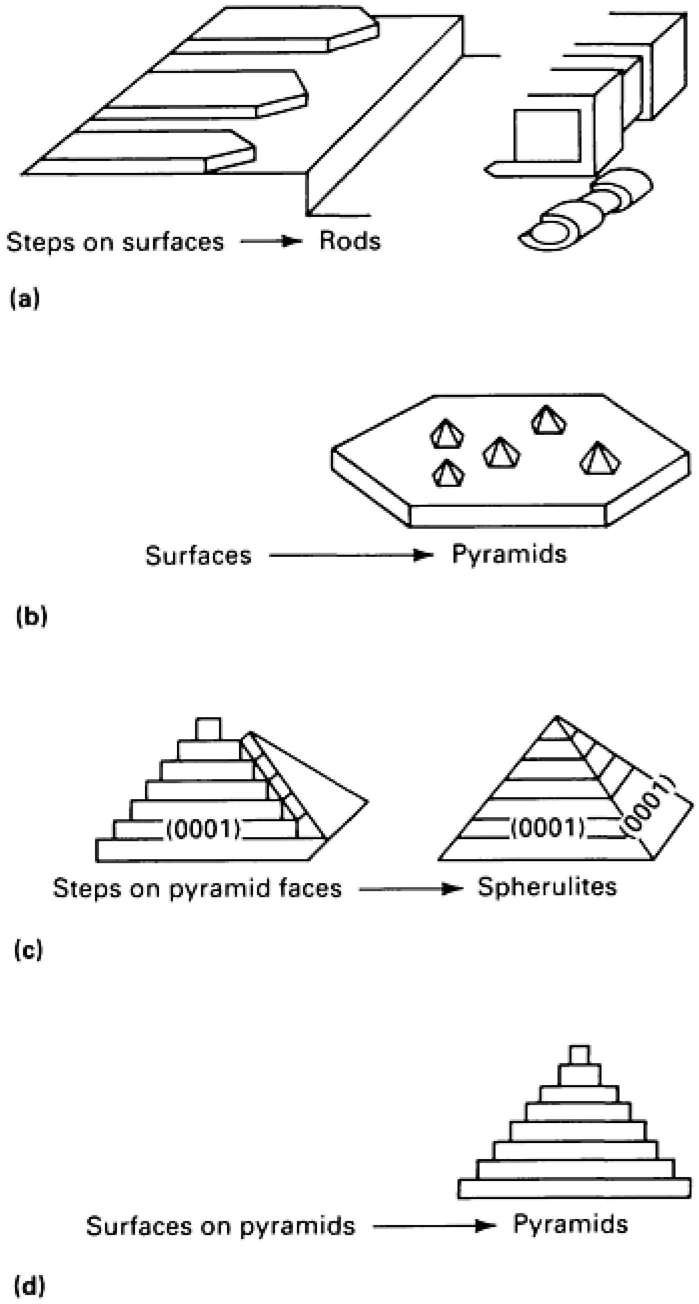

Fig. 24 Correlation among the different types of instability observed in graphite growth and growth morphologies with increasing undercooling, Δ*T*. (a) Δ*T* = 4 °C (7 °F). (b) Δ*T* = 9 °C (16 °F). (c) Δ*T* = 30 °C (54 °F). (d) Δ*T* = 40 °C (72 °F). Source: Ref 5.

Imperfect spheroidal graphite shapes, such as those in Fig. 21(b) and 21(c), are due to incorrect kinetic undercooling and an imbalance of impurities influencing constitutional undercooling. An insufficient amount of impurities influencing kinetic undercooling (for example, magnesium) will favor the formation of intermediate graphite shapes, such as compacted/vermicular, while an insufficient amount of impurities influencing constitutional undercooling (for example, lead) will perturb the surface of the spheroid and promote the formation of protuberances.

Surface Adsorption Theory. This somewhat older theory of graphite growth postulates that the change from lamellar to spheroidal graphite occurs because of the change in the ratio between growth on the $(10\bar{1}0)$ face and growth on the (0001) face of graphite (Ref 33). For equilibrium conditions, the Gibbs-Curie-Wulf law states that the crystalline phase with the higher interface energy has a slow rate of growth in the normal direction. Bravais's rule stipulates that the growth rate in the direction normal to a plane is inversely proportional to the density of atoms located on the plane.

Accordingly, it follows that under equilibrium conditions the crystallographic plane with the highest density of atoms has the lowest interface energy and the minimum growth rate in a direction perpendicular to the plane. Nevertheless, under the nonequilibrium conditions prevailing during the solidification of cast iron, kinetic considerations become important. Assuming growth by two-dimensional nucleation, the highest rate of growth will be experienced by the face with the higher density of atoms, where the probability for nucleation is higher.

Therefore, in a pure environment, the highest growth rate will be in the (0001) direction of the graphite crystal (Fig. 25), resulting in the formation of unbranched single crystals (coral graphite). In a contaminated environment, surface-active elements such as sulfur or oxygen are absorbed on the high-energy plane $(10\bar{1}0)$, which has fewer satisfied bonds. Subsequently, the $(10\bar{1}0)$ plane face achieves a lower surface energy than the (0001) face, and growth becomes predominant in the $(10\bar{1}0)$ direction, resulting in lamellar (plate) graphite. Finally, the reactive impurities (such as magnesium, cerium, and lanthanum) in an environment scavenge the melt of surface-active elements (sulfur, diatomic oxygen, lead, antimony, titanium, and so on), after which they also block growth on the $(10\bar{1}0)$ prism face. A polycrystalline spheroidal graphite results.

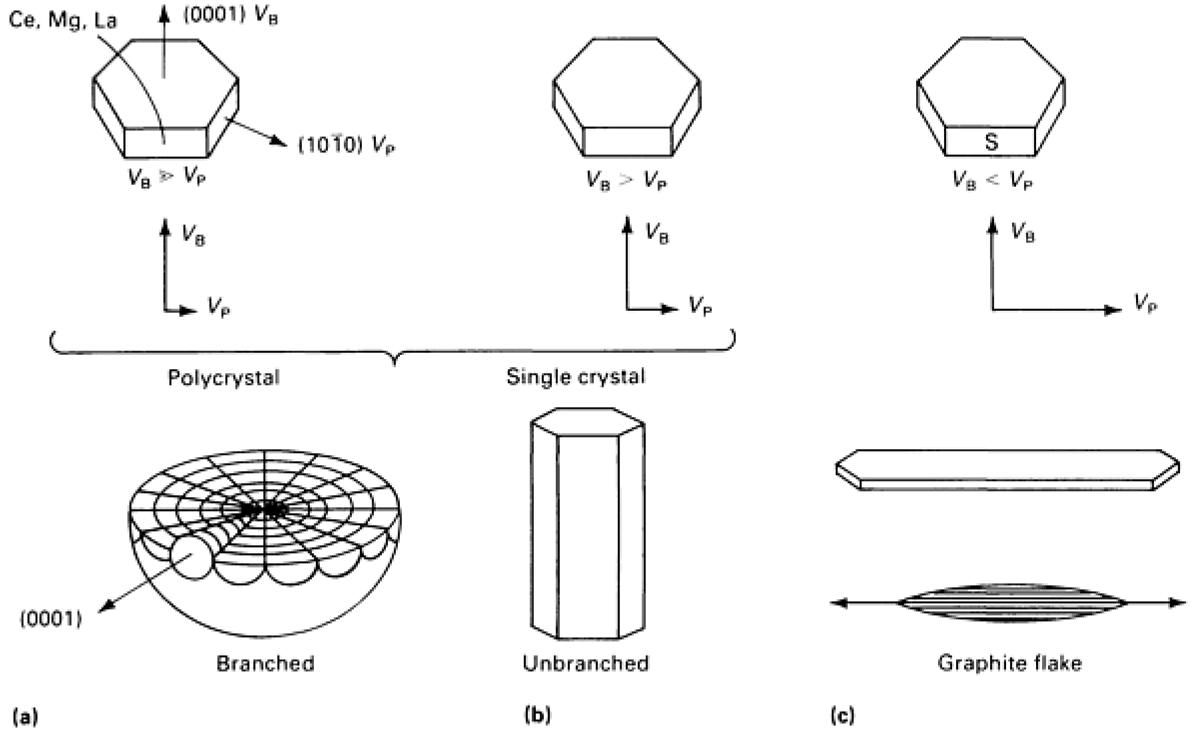

Fig. 25 Schematic of the change in the growth rate of graphite due to the absorption of foreign atoms in spheroidal graphite eutectic. Three variations of an iron-carbon-silicon cast iron are as follows. (a) With nodularizer added as reactive impurity environment. (b) Pure environment. (c) Contaminated environment in which surface-active elements such as oxygen and sulfur are absorbed into system. For (a) and (b), density in the basal plane, V_B is greater than the density in the prism face, V_P, and either branch polycrystalline or unbranched single crystals result. For (c), $V_B < V_P$. Sulfur adsorption makes prism faces the most densely packed, and graphite flakes are subsequently formed.

Compacted/Vermicular Graphite Eutectic. The sequence of growth of compacted/vermicular graphite during the eutectic transformation is shown schematically in Fig. 26, based on experimental data from Ref 34 on rapidly quenched samples from successive stages during the solidification process. It can be seen that at the beginning graphite precipitates as spheroids, which then degenerate during growth and subsequently develop into compacted graphite. Compacted graphite develops as interconnected segments within an austenitic matrix. Typical compacted graphite is shown in Fig. 27.

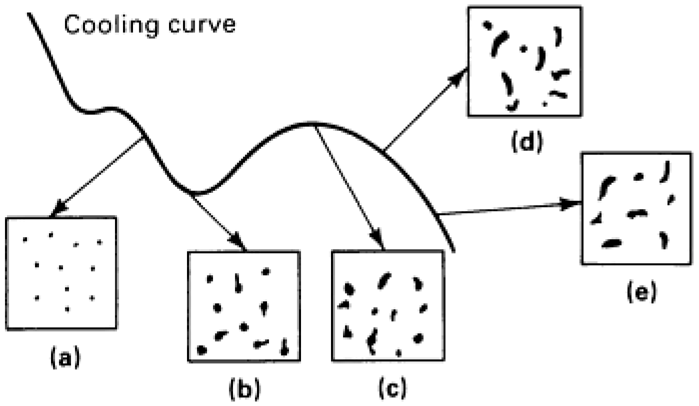

Fig. 26 Schematic of the sequence of development of compacted/vermicular graphite: (a) small spheroids; (b) and (c), some spheroids have tails; (d) compacted graphite plus spheroidal graphite; and (e) compacted graphite.

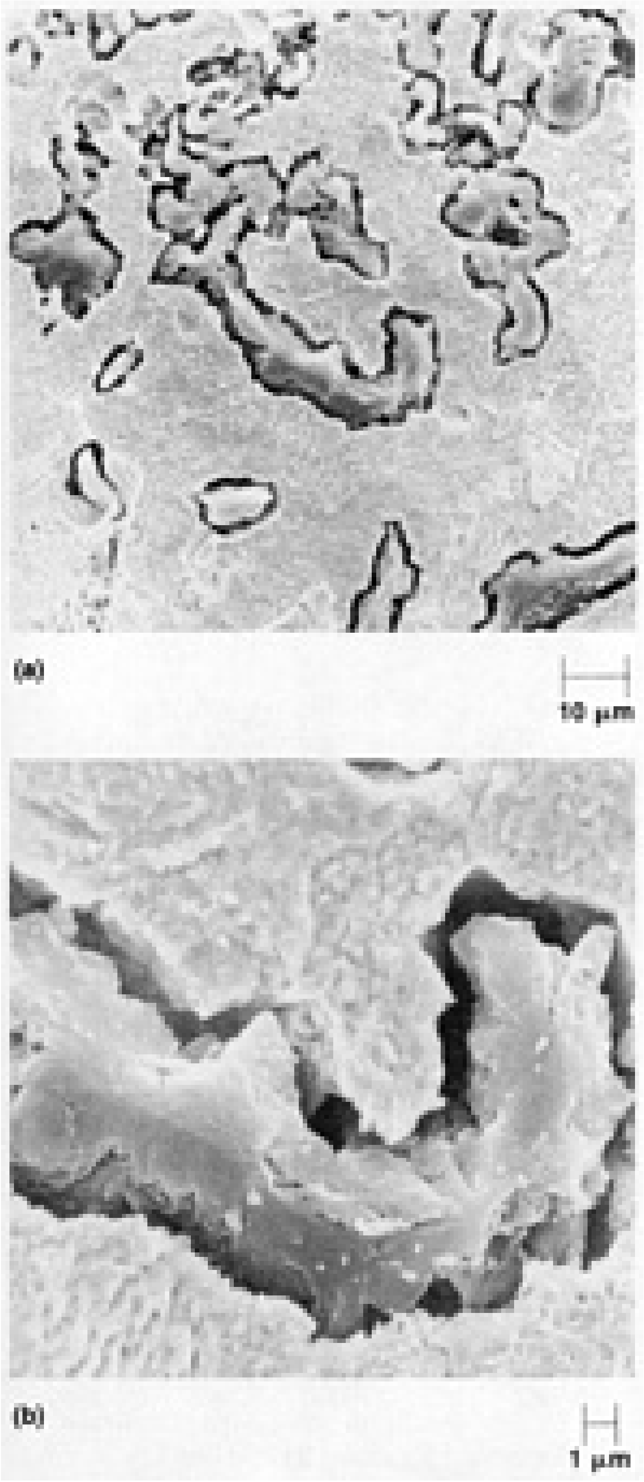

Fig. 27 SEM micrograph of deep-etched CG iron samples. (a) 560×. (b) 2800×.

It was proposed that the growth of compacted graphite occurs by the twin/tilt of boundaries (Ref 35). The initiation of a twin/tilt is related to the unstable growth of the $(10\bar{1}0)$ interface, which can be induced by the presence of some-reactive elements. The formation of a $(10\bar{1}2)$ twin/tilt plane is shown in Fig. 28. It was further hypothesized that when insufficient reactive element is present, the tilt orientation of twin boundaries can alternate, resulting in typical compacted graphite (Fig. 29a). On the other hand, when there is enough impurity in the melt, the tilt orientation is singular, and spheroidal graphite may occur (Fig. 29b).

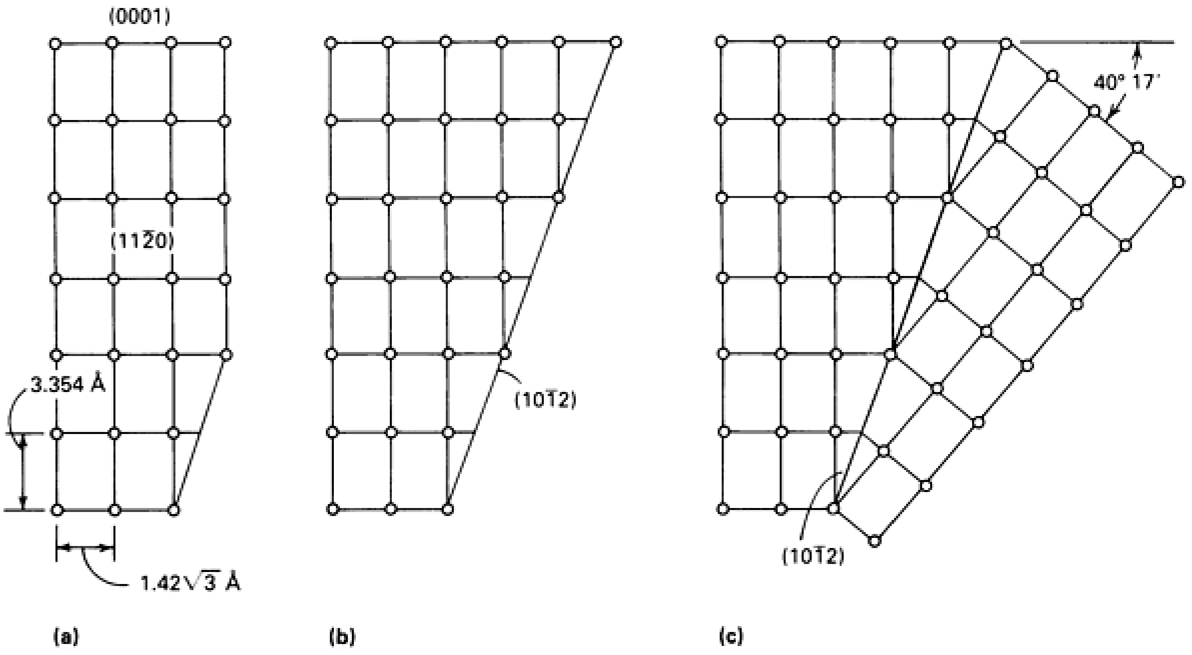

Fig. 28 Diagram of sequences (a) through (c) involved in the formation of a twin/tilt plane for graphite growing in the [1010] direction. Source: Ref 35.

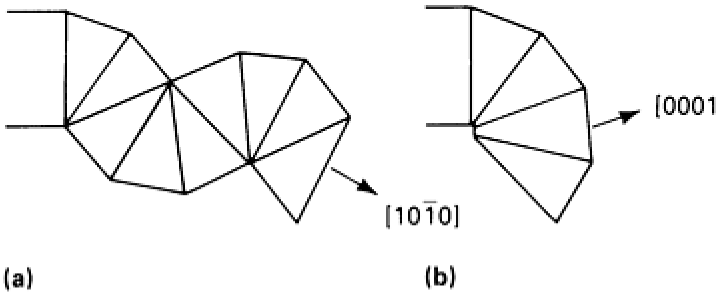

Fig. 29 Change of direction of the tilt of the boundary due to the amount of reactive impurity. (a) Insufficient spheroidization. (b) Sufficient spheroidization. Source: Ref 35.

Based on this growth mechanism, compacted graphite can be considered to grow either by transition from flake graphite (Fig. 30a) or by degeneration of spheroidal graphite (Fig. 30b). The degree of interconnection of the compacted graphite within the eutectic cell is also apparent from Fig. 30. Based on cooling curve configuration, it is reasonable to assume that the growth rate of compacted graphite is similar to that of spheroidal graphite, which is not surprising because the growth direction is supposedly in the [0001] direction of the graphite crystal (see the article "Compacted Graphite Irons" in this Volume).

Austenite-Iron Carbide Eutectic. Growth of the austenite-iron carbide (ledeburite) eutectic begins with the development of a cementite plate on which an austenite dendrite nucleates and grows (Fig. 31). This destabilizes the Fe_3C, which then grows through the austenite. As a result, two types of eutectic structure develop: a lamellar eutectic with Fe_3C as the leading phase in the edgewise direction, *a*, and a rodlike eutectic in the sidewise direction, *c*.

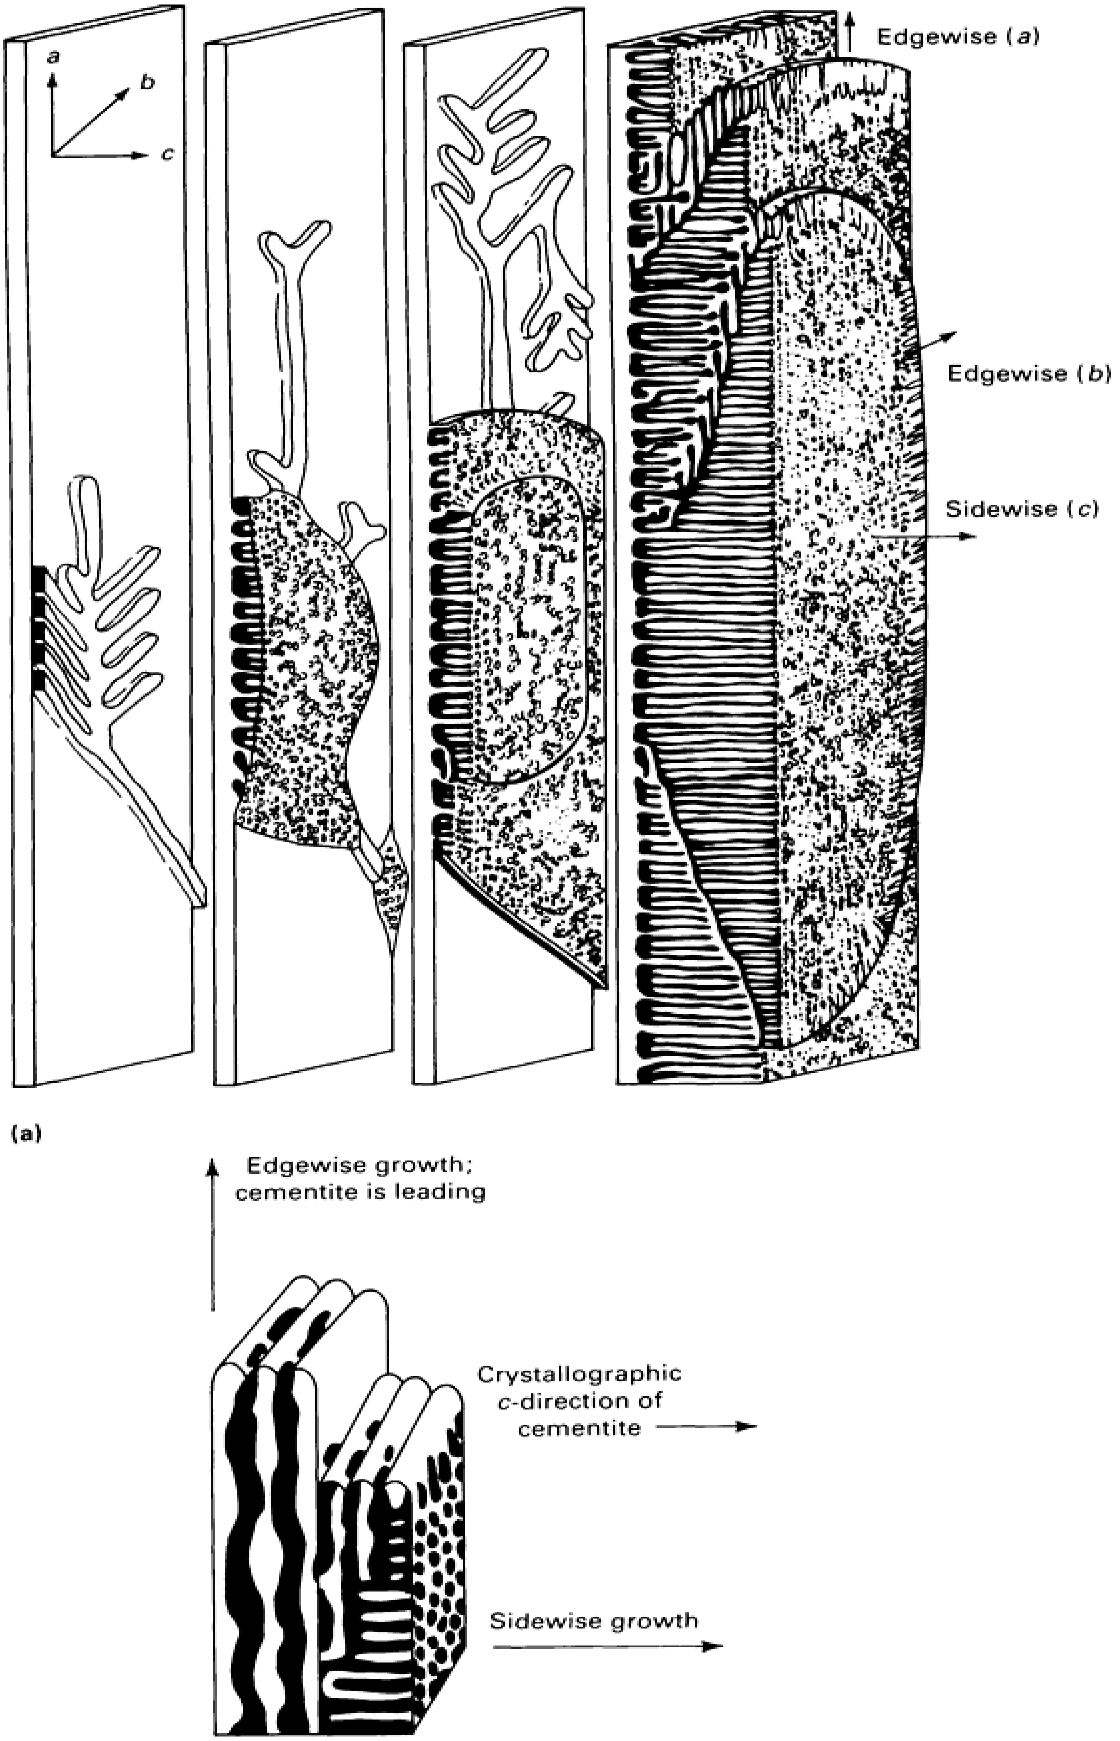

Fig. 31 Schematic illustrating growth of ledeburite (austenite iron carbide) eutectic. (a) Lamellar eutectic with cementite as the leading phase in the edgewise, *a*, direction. (b) Rodlike eutectic in the sidewise, *c*, direction.

Source: Ref 37.

Cooling rate has a significant influence on the morphology of the γFe_3C eutectic. At moderate undercoolings, ledeburite structure is expected. High cooling rates, as obtained in quenching experiments, produce a degenerated eutectic structure dominated by Fe_3C plates. A coarse mixture of Fe_3C and γ lls the spaces between the Fe_3C plates. This structure obviously does not result from cooperative growth (Ref 7). A platelike carbide structure associated with equiaxed eutectic grains can be obtained by increasing the undercooling by superheating, by decreasing the silicon content, or by adding chromium or magnesium.

The gray or white solidification mode of cast iron apparently depends on the relative nucleation probability and the growth rates of the graphite and Fe_3C phases. In turn, this will be a function of the cooling rate and chemistry of the alloy. As shown in Fig. 32, only the graphite eutectic can nucleate and grow between the eutectic temperature for the gray eutectic (1153 °C, or 2107 °F) and that for the white eutectic (1148 °C, or 2098 °F). Below 1148 °C (2098 °F), both eutectics can occur. The growth rate of the γFe_3C eutectic rapidly exceeds that of the γGr eutectic, and at a temperature of approximately 1140 °C (2085 °F), the gray-to-white transition occurs (Ref 5, 38).

Cooling Curve Analysis

Cooling curves have been extensively used in the experimental study and production control of cast irons. The history of solidification can be traced on the cooling curve. A detailed description of the principles involved in this analysis and its application in cast iron technology is given in the articles "Interpretation and Use of Cooling Curves (Thermal Analysis)" and "Compacted Graphite Irons" in this Volume.

Interpretation and Use of Cooling Curves (Thermal Analysis)

H. Fredriksson, The Royal Institute of Technology, Sweden

Introduction

THERMAL ANALYSIS is a classical method of determining phase diagrams. By melting and cooling an alloy of known composition and registering the temperature-time curves, the liquidus temperature for the respective alloy can be determined. Figure 1 shows an idealized view of the relationship between the cooling curves and the phase diagram for an alloy A-B. The starting point for solidification is given by a change in the slope of the cooling curve due to the evolution of the heat of solidification. This starting point is normally used to define the liquidus temperature. The method is described more fully in Ref 1.

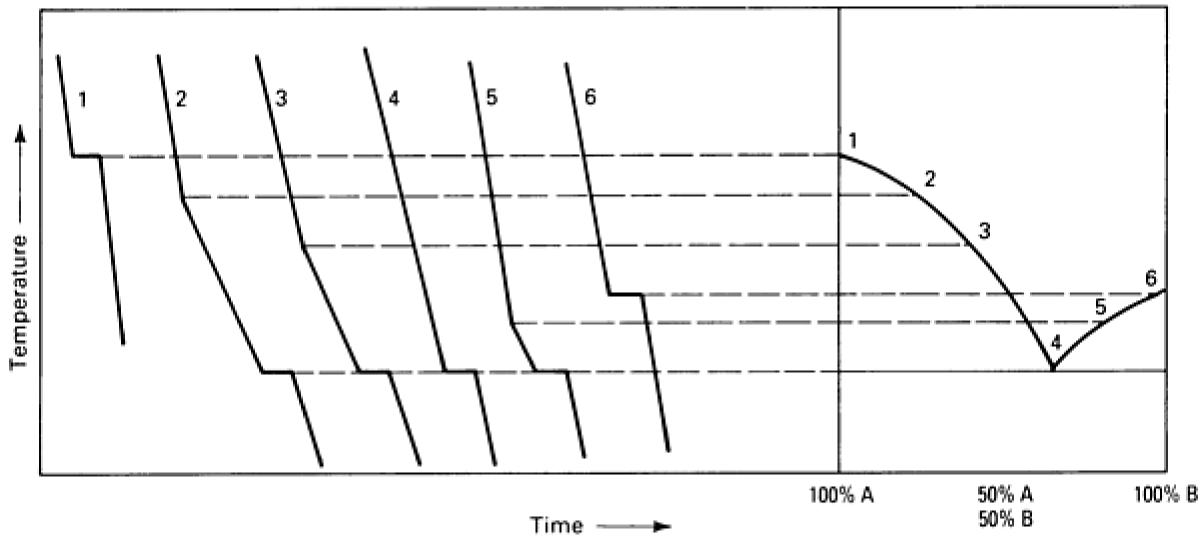

Fig. 1 Relationship between a cooling curve and phase diagram for alloy A-B.

The idealized behavior illustrated in Fig. 1 is not seen in experimentally determined temperature-time curves. For example, Fig. 2, an experimentally determined cooling curve for an iron-carbon alloy with 3.2% C, shows that the formation of austenite and the eutectic reaction occur at a temperature well below the liquidus and the eutectic temperatures, respectively. The reason for this depends on the nucleation and growth of the crystals in the liquid. In this article, this effect will be analyzed, and the use of thermal analysis in industrial processes and in research will be discussed.

Quantitative Thermal Analysis

Cooling curves describe a balance between the evolution of heat in the sample and the heat transport away from the sample. It is often easiest to describe this in a mathematical form. However, heat transport away from the liquid is often very complex and can be described in many different ways because of the experimental conditions. Currently, heat transport is often described by numerical methods. In the following discussion, only the expression dQ/dt will be used to define the heat transport away from the experimental setup. This heat transport must be equal to the evolution of heat in the sample. Before and after the solidification process, this is balanced by a loss of heat capacity. Before the start of the solidification process, this can be written in analytical form as:

$$\frac{dQ}{dt} = V.r.C_p \frac{dT}{dt} \qquad \textbf{(Eq 1)}$$

where V is the volume of the sample, ρ is the density of the liquid, C_p is the heat capacity, and dT/dt is cooling rate of the liquid.

From a cooling curve similar to that shown in Fig. 2, dT/dt is the slope of the curve before solidification begins. By evaluating the slope as a function of time in an experiment, dQ/dt can be determined if ρ and C_p are known. This can later be used in the analysis of the temperature-time curve.

When the liquid cools to the liquidus temperature, crystals are nucleated and begin to grow. The heat balance from Eq 1 will now be:

$$\frac{dQ}{dt} = \left(V.r.C_p + r\Delta H \frac{df}{dT} \right) \frac{dT}{dt} \qquad \textbf{(Eq 2)}$$

where ΔH is the heat of solidification and df/dT is the volume fraction of solid formed at a changing temperature. The change in shape of the temperature-time curve now depends on the volume fraction of solid formed. The larger the rate of increase of volume fraction of solid, the smaller the slope (dT/dt) of the temperature-time curve. The volume fraction of solid formed is related to the number of crystals and their growth rate.

Crystals are normally nucleated when the temperature of the liquid reaches the liquidus temperature as well as the eutectic temperature. In spite of this, the temperature of the liquid will decrease further and initially the curve can be extrapolated to show where no crystals are growing. After a certain time, the slope of the curve begins to decrease, slowly at first and then more rapidly. In the early stages of crystal formation, the growing crystals are small (as is heat development) and therefore have no effect on the bulk liquid temperature.

The growth rate is also low because of the low supercooling close to the liquidus temperature. The supercooling increases when the temperature decreases; therefore, the growth rate will increase as the area of the crystal increases. The result is that more heat is given off and the slope of the temperature-time curve begins to decrease. The change in the slope will begin earlier and will proceed faster. The more crystals there are in the liquid, the earlier the change in slope starts, and the faster it will proceed. When the temperature increases, the growth rate of the free crystals decreases again, but they are so large by this time that the volume solidifying per unit of time will also be large. As such, the temperature will continue to increase until the growth rate and the growth area of the crystals offset the heat extraction. The larger the area of the growing crystals, the lower the growth rate and the closer the temperature of the bulk liquid to the liquidus or eutectic temperature.

Deviation From Equilibrium

The solidification process illustrated by the cooling curve in Fig. 2 begins with a primary precipitation of austenite, followed by a eutectic reaction. In this case, the liquid was cast into a sand mold. The heat extraction from the liquid can be described by Chvorinov's law and follows the expression:

$$\frac{dQ}{dt} = \frac{k}{\sqrt{t}} \qquad \textbf{(Eq 3)}$$

where t is the time and K the so-called modulus constant. The value K can be determined by using Eq 1 and the slope of the cooling curve before solidification begins. The fraction of solid can be determined by using Eq 2 and 3 and the data given in Fig. 2. The results of these calculations are shown in Fig. 3(a). This type of analysis has been performed and is discussed in Ref 2, 3, and 4; it can be used to analyze the deviation from solidification under equilibrium conditions.

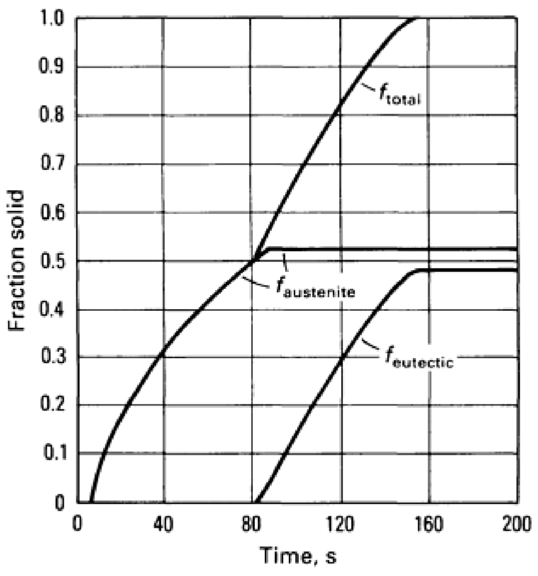

Fig. 3(a) The fraction of solid phases as a function of time for the alloy with a cooling curve shown in Fig. 2.

The Fe-3.2C alloy discussed earlier in this article can be used as an example to illustrate this analysis. According to the iron-carbon phase diagram, the liquidus temperature for this alloy is 1268 °C (2314 °F). At this temperature, dendritic crystals of austenite are formed. Because carbon has a very high diffusivity in austenite, the lever rule* can be used to determine the fraction of solid as a function of temperature. The rule is derived with respect to temperature, and the derivate df/dT is obtained. This derivate is inserted into Eq 2. The temperature-time curve is then easily calculated. The result is shown in Fig. 3(b) as a dashed line. The deviation from the real curve and that calculated under equilibrium conditions is greatest at the beginning of the precipitation of austenite. After the initial stage during the cooling down to the eutectic temperature, the lever rule will describe the fraction of solid formed. The eutectic reaction for the equilibrium case occurs without any undercooling. This derivation from equilibrium will be interpreted below.

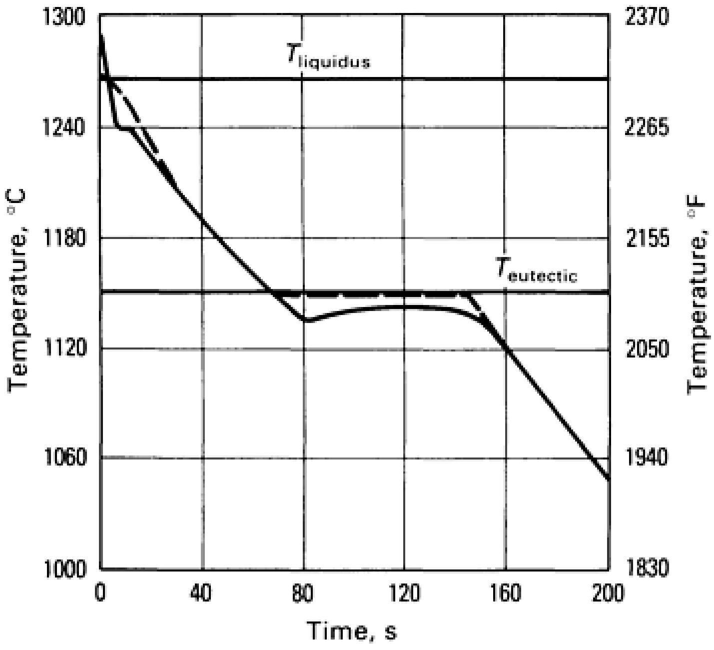

Fig. 3(b) Deviation of the cooling shown in Fig. 2 resulting from equilibrium solidification condition (see dashed line).

The austenite dendrites can be assumed to nucleate randomly in the liquid. They grow in leading tips in a starlike fashion. The secondary dendrite arms form behind the tips. The growth of the dendrite tips is dependent upon undercooling. This undercooling is determined by the growth rate, and it increases with increasing growth rate. The growth rate of the tips is determined by the heat extraction and by the number of growing crystals. When the dendrite crystals have collided, a network of dendrite arms is formed.

The solidification now proceeds by a thickening of the dendrite arms. Similarly, eutectic colonies are randomly nucleated in the liquid; they grow spherically and collide with each other. When the collision occurs, the growth area decreases, and the temperature of the liquid decreases.

Theoretical models that combine growth equations, statistical laws for the collision of crystals, and heat extraction laws have been developed in recent years to describe the above discussion (Ref 2, 3, 4, 5, 6). In the future, these models will probably be used to predict the structure formed during the solidification process and the resultant properties of the material.

Note cited in this section

* The lever rule can be applied to any two-phase field of a phase diagram to determine the amounts of the different phases present at a given temperature in a given alloy. A horizontal line, referred to as a tie line, represents the lever, and the alloy composition represents its fulcrum. The intersection of the tie line with the boundaries of the two-phase field fixes the compositions of the coexisting phases, and the amounts of the phases are proportional to the segments of the tie line between the alloy and the phase compositions.

Differential Thermal Analysis

Thermal analysis has a long history of use in research. To increase accuracy, the experiments are normally carried out by so-called differential thermal analysis.

Simplified Thermal Analysis. Before discussing the theoretical basis of differential thermal analysis, a simplified experimental setup will be considered. This setup consists of a crucible with a melt placed inside a furnace. A thermoelement is placed in the center of the melt to measure the temperature of the sample T_s. Another thermocouple is placed at the wall of the furnace; the purpose of this thermocouple is to regulate the temperature of the furnace T_f as a function of time. The furnace is assumed to cool at a constant rate in degrees Kelvin per minute.

Figure 4 shows the temperature-time cycle for an aluminum-copper alloy that contains 5% Cu. The furnace has cooled during the experiment at a rate of 10 K/min (~285 °C/min, or 510 °F/min). Figure 4 shows that the temperature of the sample is somewhat higher than that of the furnace. This divergence increases slightly with time. A stationary condition, that is, the same cooling rate for the sample and the furnace, never occurs; the cooling rate of the sample is always somewhat lower than that of the furnace. The melt begins to solidify at the point designated t_{start}. Heat is emitted by the sample and the temperature difference between the sample and the furnace increases. A hump sometimes appears in the

temperature-time curve of the sample. The maximum point, or the deviation point, on the cooling curve is usually used to establish the liquidus temperature.

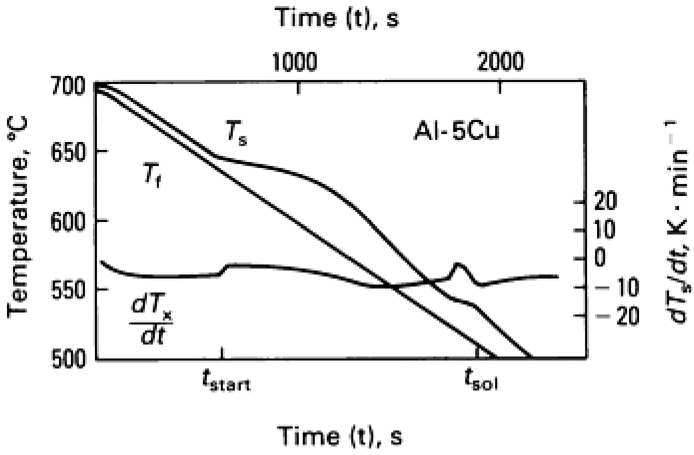

Fig. 4 Thermal analysis of an Al-5Cu alloy cooled at a rate of 10 K/min (~285 °C/min, or 510 °F/min). Source: Ref 6.

The solidification rate, or the reaction rate, decreases after the initial period, and the cooling rate of the sample increases. Toward the end of solidification, or when everything has solidified, the cooling rate of the sample becomes greater than that of the furnace. This is a result of the large temperature difference that exists between the sample and the furnace when a considerable amount of solidification heat is given off. Afterward, the cooling rate of the sample approaches that of the furnace.

It is often very difficult to determine the end of the solidification process and to determine the solidus temperature t_{sol} during the experiment. To facilitate evaluation of the liquidus and solidus temperatures, the temperature-time curve of the sample is derived in most cases.

In general, the derivation of the temperature-time curve for the sample shows a discontinuity when the heat of solidification ceases to develop. The solidus temperature is generally defined by this discontinuity. This discontinuity becomes less pronounced in cases in which the solidification interval is large and the reaction rate is low toward the end of solidification.

The reaction rate is normally evaluated by a simple mathematical analysis. This is described by:

$$\frac{dQ}{dt} = \frac{k}{\sqrt{t}} C_P^S \quad \left(\frac{dT_s}{dt} \right) r . C_p^S . V_S + \Delta H . r . V_S . \frac{df}{dt} = h (T_s - T_f) \qquad \textbf{(Eq 4)}$$

where dT_s/dt is the cooling rate of the sample, C_P^S is the specific heat of the sample, V_s is the volume of the sample, ΔH is the heat of solidification, df/dt is the volume fraction of solid formed per unit time, T_s is the sample temperature, T_f is the furnace temperature, and η is the heat transfer coefficient.

The second term on the right-hand side in Eq 4 is 0 before solidification begins. The heat transfer coefficient η can be evaluated at this time by measuring dT_s/dt, T_s, and T_f. The reaction rate df/dt can be determined by using that value and by remeasuring the temperature and its first-time derivate during solidification.

Differential Thermal Analysis. Figure 5 shows a schematic setup for differential thermal analysis. The sample to be analyzed and the standard sample, with a thermocouple in each, are placed in a furnace. The temperature of the furnace and the cooling rate are controlled and measured with a separate thermocouple. The standard sample and the analysis sample must have the same temperature at the beginning of the experiment. During the cooling cycle, the samples will undergo one or more phase transformations that give off heat. This emission of heat implies that, during the time of

reaction, the temperature of the analysis sample differs from that of the standard sample. The temperature difference between the analysis sample and the standard sample is recorded at the same time the furnace temperature is recorded.

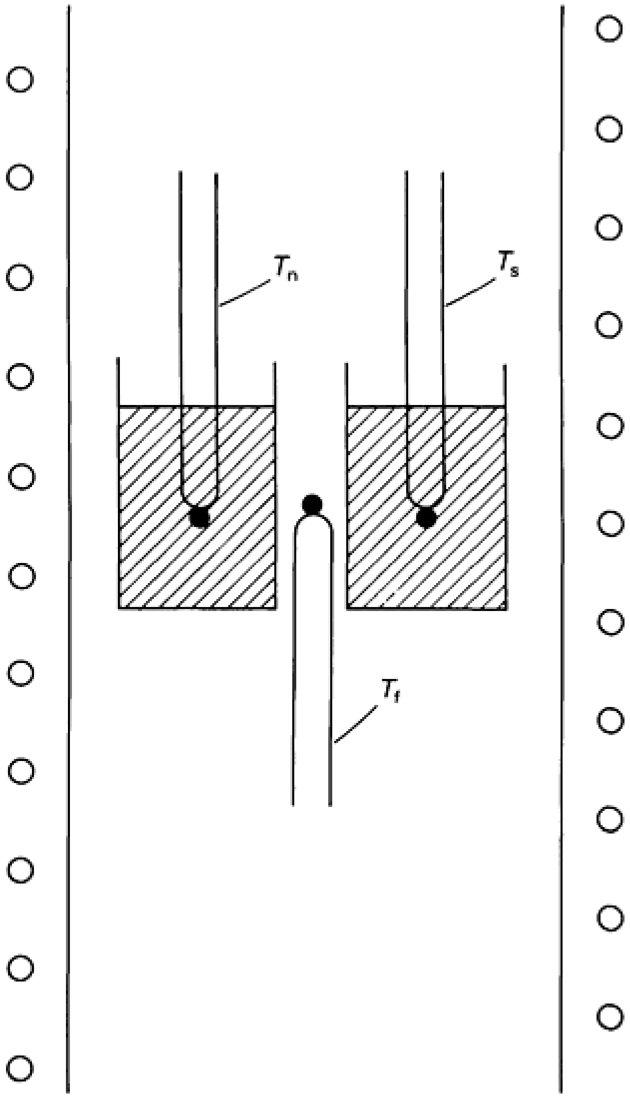

Fig. 5 Schematic of principal setup for differential thermal analysis equipment. T_n is the standard temperature, T_s is the sample temperature, and T_f is the furnace temperature.

Using the experimental setup shown in Fig. 5, one normally registers the difference in temperature between the standard sample and the analysis sample, not the difference between the sample and the furnace. Therefore, only (T_s - T_n) and T_s are known, where T_n is the temperature of the standard sample. In order to be able to calculate the reaction velocity, the term (T_s - T_f) in Eq 4 is replaced with the term (T_s - T_n) + (T_n - T_f). For the standard sample, it is true that $\eta(T_n - T_f)$ is equal to:

$$r.C_p^S.V_n \frac{dT_n}{dt} \qquad \textbf{(Eq 5)}$$

where dT_n/dt is the cooling rate of the standard sample. Replacing this in Eq 4 gives:

$$r.C_p^S.V_s \frac{dT_s}{dt} + (\Delta H).rV_S \frac{df}{dt} = h(T_s - T_n) + r.C_p^n.V_n \frac{dT_n}{dt} \qquad \textbf{(Eq 6)}$$

If the heat of solidification ΔH is known, the reaction rates can be calculated by measuring the temperatures and the cooling rates. If the heat transfer coefficient is known, the heat of solidification can also be determined by integrating Eq 6 over the entire solidification interval (from $f = 0$ to $f = 1$).

Simplifications of Eq 6 are often found in the literature when the reaction rate and the heat of solidification are determined. It is assumed that the first term on the left-hand side is equal to the last term on the righthand side, which leads to the following approximate relationship:

$$\frac{df}{dt} = \frac{h}{(\Delta H)V_S}(T_s - T_n) \quad \textbf{(Eq 7)}$$

Equation 7 shows a direct proportionality between the measured temperature difference and the reaction rate.

In Eq 7, $\eta/\Delta H V_s$ can be considered constant. The difference in temperature between the sample and the normal (T_s - T_n) is measured and is thus known as function of time. The constant can be determined by integrating Eq 6 from $f = 0$ to $f = 1$. This integration is often done graphically.

Equation 7 is also often used in interpretating differential thermal analysis data. However, one should keep in mind that doing so introduces many faults. This can be demonstrated by a comparison between Eq 6 and 7. For example, it is assumed that C_p^S, V_s, V_n, and C_p^n are equal. This is often not the case. To avoid this problem, the sample itself can be used as an imaginary standard sample. The temperature difference can then be determined by a simple computer analysis (Ref 6). To determine the heat of solidification, the heat transfer coefficient η must be determined by a series of reference experiments such as that described for the simple type of experiment in Eq 4.

Determining Liquidus and Solidus Temperature

Cooling curves can be used in many different ways and are often used to determine the liquidus and solidus temperatures. In such applications, the plateau temperature shown in Fig. 2 is often used. However, as indicated earlier, this temperature does not correspond to the liquidus temperature, because of the kinetics during crystal growth. To increase the accuracy, the cooling curve is often derived. In this case, the temperature at which the derivate changes is used as the liquidus temperature. As indicated earlier, this will not provide the correct liquidus temperature. The only way to obtain the correct liquidus temperature is to perform a series of experiments at different cooling rates. The plateau temperature can then be plotted as a function of the cooling rate. The liquidus temperature is determined by extrapolating the line to zero cooling rates. An example of this method is shown in Fig. 6.

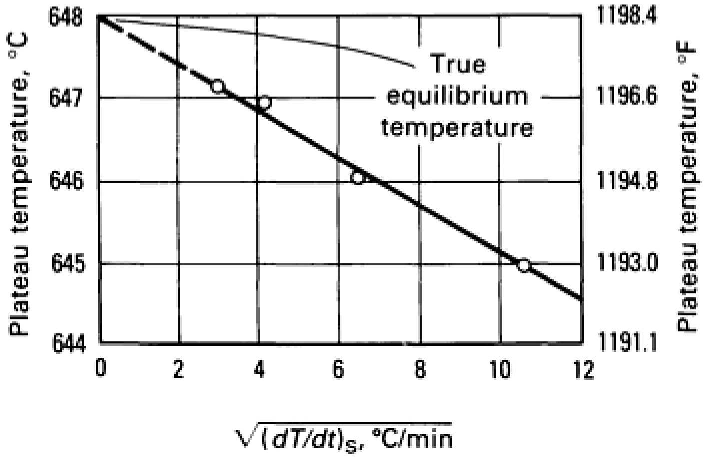

Fig. 6 Liquidus temperature determined for an aluminum-copper alloy. Source: Ref 7.

It is more difficult to determine the solidus temperature than the liquidus temperature. Toward the end of the solidification process, the derivative of the cooling curve often shows a discontinuity (Fig. 7). The solidus temperature is defined in general by this discontinuity. However, the temperature evaluated in this way varies with the cooling rate much more than the liquidus temperature does. This is due to the microsegregation that occurs during solidification. This microsegregation is very much influenced by the cooling rate (Ref 9). Therefore, thermal analysis by cooling is nearly useless for determining the equilibrium solidus temperature. This temperature can be determined only by analyzing the melting process on heating curves.

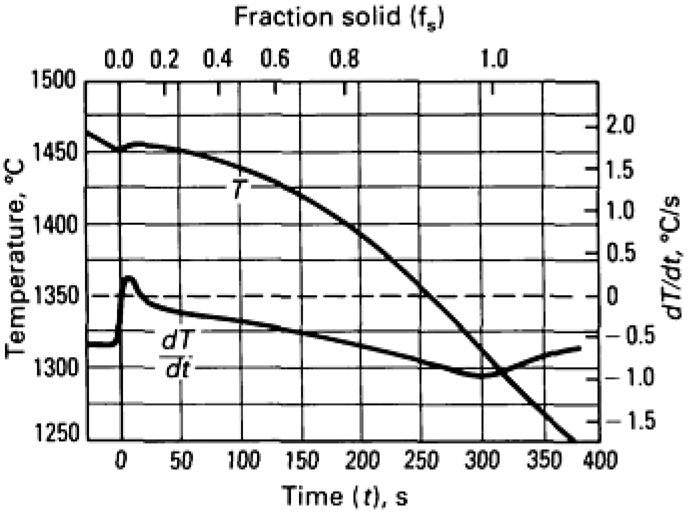

Fig. 7 Temperature-time curve for an iron-base alloy with 1.01% C, 0.25% Si, and 0.46% Mn. The dashed line represents the cooling rate *dT/dt* = 0. Source: Ref 8.

Thermal analysis is often used in industrial processes. One of the most common applications is determination of the chemical composition of cast iron. In this case, a linear relationship has been found between the liquidus temperature and the carbon equivalent, CE, which is defined as:

$$CE = \%C + \frac{\%Si}{3} + \frac{\%P}{3} \qquad \textbf{(Eq 8)}$$

An example of the use of thermal analysis or determining the chemical composition of cast irons is shown in Fig. 8.

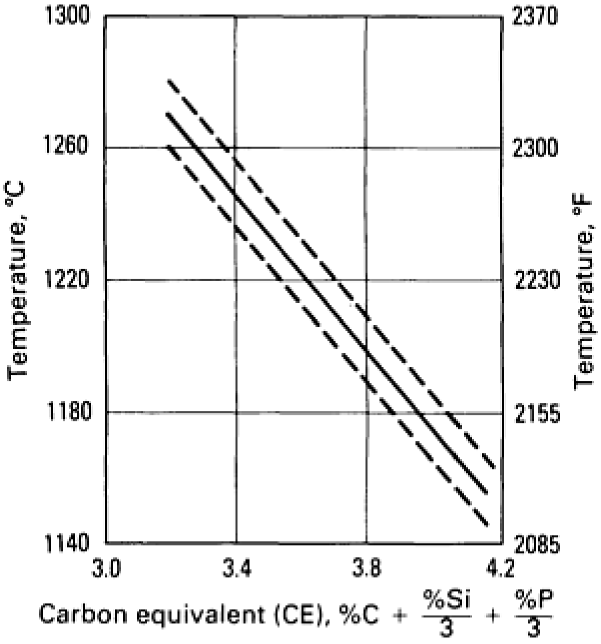

Fig. 8 Thermal analysis used for determining the chemical composition of cast irons.

Given the present knowledge of thermal analysis, it should be noted that these diagrams can be used with accuracy only if the same conditions are prevalent every time. This is due to the influence of the cooling rate and the nucleation frequency on the plateau temperature. Casting temperature, for example, can influence the results. It is well known that the superheat of the liquid influences the number of crystals. The higher the temperature, the lower the number of growing crystals. The result will be a lower liquidus temperature. However, in most cases, a foundry will use the same melting procedure consistently and can therefore determine chemical composition easily and accurately by thermal analysis, provided a curve similar to the one shown in Fig. 8 is developed for their specific conditions.

Patterns and Patternmaking

Robert C. Voigt, University of Kansas

Introduction

A PATTERN is a form made of wood, metal, plastic, or composite materials around which a molding material (usually prepared sand) is formed to shape the casting cavity of a mold. Most patterns are removed from the completed mold halves and used repeatedly to make many duplicate molds. Expendable patterns of such materials as wax or expanded polystyrene are made in quantity and are used only once to produce an individual mold (see the articles "Investment Casting" and "Replicast Process" and the discussion on the evaporative foam process in the article "Sand Molding" in this Volume). The pattern equipment (tooling) needed to make a casting includes the pattern and may also include one or more core boxes. Core boxes are used to make refractory inserts or cores that are placed within a mold cavity to form internal cavities or passageways within the casting. The selection of the type of pattern equipment used to make a casting depends on many factors, including the number of castings to be produced, the size and shape of the casting, the molding or casting process to be used, and other special requirements such as the dimensional accuracy required.

Patternmaking begins with the dimensions of the casting required; however, the design and dimensions of the resultant pattern equipment must incorporate other features and take into account various pattern allowances (Ref 1, 2). Patterns must be oversized to correct for the contraction of the metal upon cooling and any extra metal to be removed from the machined surfaces of a casting. A mold parting line must be selected, and taper or draft must be included on the vertical faces of the pattern to permit the removal of reusable patterns from the mold. Patterns also incorporate provisions for gating and risering (rigging), which facilitate the flow (feeding) of metal into the mold cavity. For castings to be made with cores, the pattern and core boxes must include projections called core prints, which are used to support and locate the cores in the mold cavity. Figure 1 illustrates a typical pattern and mold configuration.

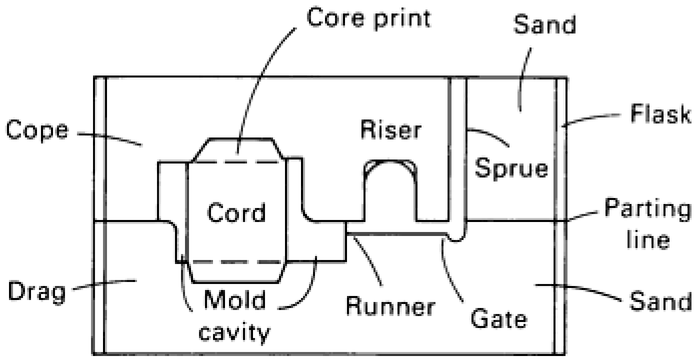

Fig. 1 Schematic of a sand mold. The pattern is used to form the mold cavity, the core print for locating the core, the gate, the runner, the riser, and the sprue. A separate core box is used to make the sand core that is inserted into the parted mold before pouring.

The cost of pattern equipment for a given casting can vary greatly, depending on pattern material, type of pattern, and sometimes the dimensional accuracy required. However, because the pattern equipment is only a part of the moldmaking process, the least expensive pattern is not necessarily the most economical. Additional pattern cost and quality often lead to lower end costs by a reduction in molding costs and pattern repair costs and by an improvement in overall casting quality.

The patterns and patternmaking techniques described in this article are for patterns used to make expendable molds (primarily sand molds). However, the principles described also apply to the dies used for other metal casting processes such as die casting and permanent mold casting (see the articles "Die Casting" and "Permanent Mold Casting" in this Volume).

Types of Patterns

The type of pattern used for a specific application depends primarily on the number of castings required, the molding or casting process to be used, the size of the pattern, and the casting tolerances that are required. The stage of development of a casting design is also a factor. If the casting (or its rigging) is likely to be redesigned, an inexpensive prototype pattern is often used first.

The choice of pattern material is also closely tied to the molding or casting process and the type of pattern to be used. Figure 2 illustrates the most commonly used basic reusable pattern types for a simple pattern shape--a loose pattern, a match plate pattern, and cope and drag patterns. Also indicated are the typical materials and service lives for each pattern type. It should be noted that many factors affect the number of molds that can be made from an actual production pattern before it must be reworked. The pattern lives indicated in Fig. 2 are intended only as general guidelines. Actual pattern life can vary considerably.

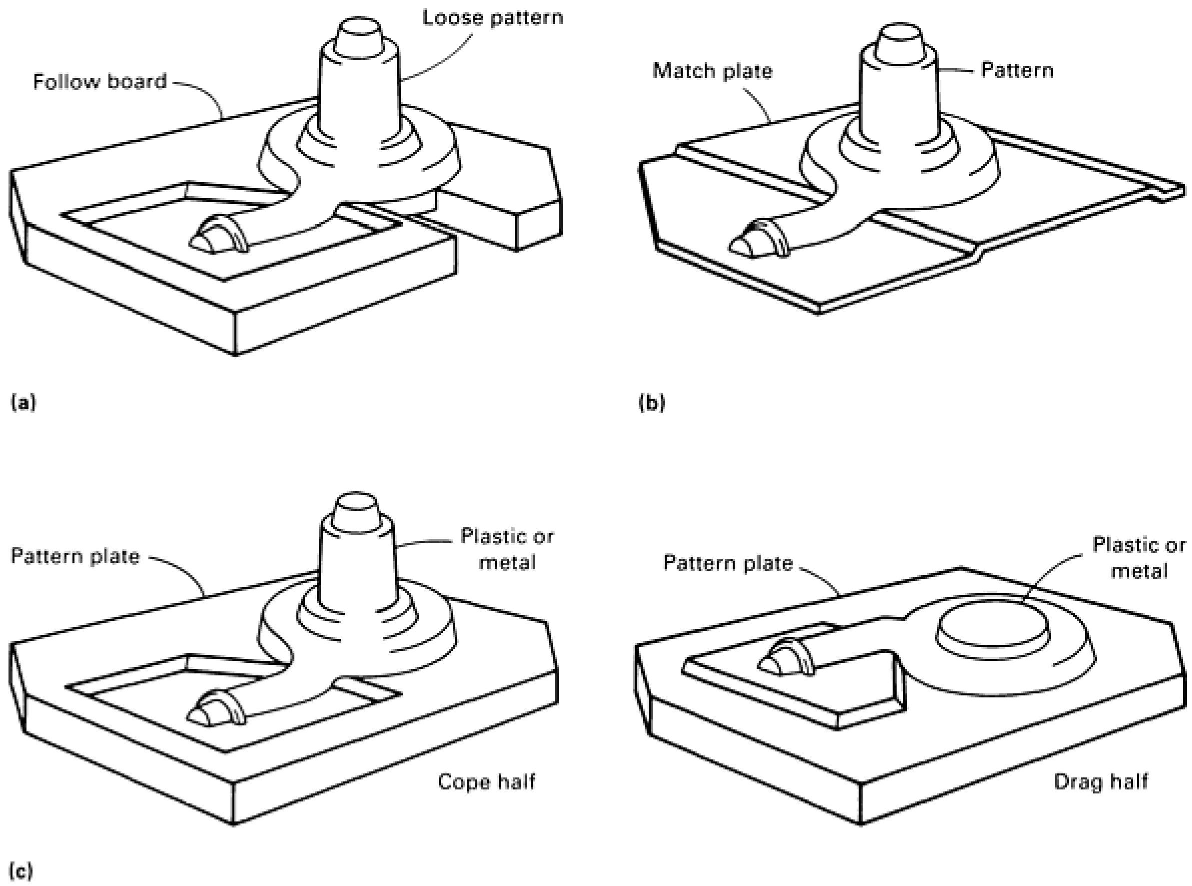

Fig. 2 Three types of patterns used to produce a water pump casting in various quantities. (a) Wood pattern on a follow board, good for 20 to 30 castings. (b) Match plate pattern for up to 50,000 castings depending on material. (c) Cope and drag plastic (up to 20,000 castings) or metal (100,000 or more castings) pattern

Loose patterns, also called one-piece patterns or solid patterns, are the simplest, least expensive type of reusable pattern and are suited only to very low-quantity production. This type of pattern (Fig. 2a) is most appropriate for experimental or prototype castings and is only rarely used for short-run production castings. Molding with a loose pattern requires more manual operations and a much higher degree of molder skill than molding with other pattern types. Many foundry molding departments are not set up to use loose patterns. This increases the cost per mold and results in variations in casting quality from mold to mold compared to moldmaking with other pattern types. A loose pattern can be

made in one piece or in two pieces (split patterns). The split in the two-piece pattern corresponds to the parting line in the pattern. One-piece loose patterns are often used when one side of the pattern is a flat plane that can serve as the parting line, while two-piece loose patterns are more commonly used when the shape to be cast is more complex. Gates and risers for loose patterns can be molded by hand or can be constructed with loose pieces and molded with the pattern.

Molding with one-piece loose patterns often requires considerable time and skill on the part of the molder. The pattern is placed or mounted on a flat mold board or a shaped follow board to support the pattern during molding and to define the parting line. The drag, or bottom, half of the mold is molded first, the mold is turned over, and the mold board is removed. Next the cope, or top, half of the mold is made on top of the drag, the cope is removed, and the pattern is removed from the drag. The gates and risers are then manually cut into the sand mold, and the completed mold is closed. The riser contact can be attached to the pattern so that the mold cavity surface is not damaged when cutting the gates and risers. A flask is usually placed around the completed mold to ensure alignment of the mold halves and to prevent the escape of molten metal during pouring. Two-piece loose patterns are molded in a similar manner except that the split pattern usually incorporates a flat parting plane that simplifies the molding of the cope and drag. Cope and drag mold halves can be made separately, and the split pattern can be removed from the respective mold halves. In this case, care must be taken to ensure alignment of the mold cavities at the parting line.

Match plate patterns (Fig. 2b) are split patterns in which the cope and drag portions are mounted on opposite sides of a plate, called the match plate, conforming to the parting line. The pattern, as well as the associated gating and risering system, is usually made separately and then mounted on the match plate, but can be cast integrally with the plate. The size of the match plate corresponds to the size of the flask used to make the final mold. Flask pin guides are used to ensure accurate alignment of the match plate pattern in the flask and to assist in pattern removal from the mold. Multiple patterns of small parts can be mounted on a single match plate. Common gates and risers on the match plate can often be shared by the multiple patterns on the match plate. Interlocking features can be added to the cope and drag sides of the match plate to ensure accurate alignment of the cope and drag mold halves after removal of the pattern.

Match plate patterns are used for moderate to high-volume production of small- and medium-size castings with considerable dimensional accuracy. The molding operation is simplified considerably by the use of match plate patterns. The decrease in molding costs and increased mold quality offset higher pattern costs for higher-volume castings. Large patterns are usually not match plate patterns, because of the limitations on flask sizes and the difficulties of molders or molding machines in handling large match plate patterns. Because significant pattern wear may occur over the life of a high-production match plate pattern, the selection of pattern material with adequate wear resistance is important. The match plate pattern design often must be rigid enough to withstand high squeeze pressures during automated molding (Ref 3, 4).

If the pattern has a flat parting surface, cope and drag halves can be made separately and fastened to the plate. However, most metal match plate patterns, whether they have a flat parting surface or not, are cast integrally with the plate. In integral casting, the cope and drag mold halves are shaped from a master pattern and then aligned so that the mold cavities face each other but remain separated by a distance equal to the thickness specified for the metal plate. When molten metal is poured, it fills the pattern halves of the mold (usually a plaster mold) and the space that separates them. The resulting pattern is a metal plate with the cope half of the pattern on one side and the drag half on the other. Even when precision molding methods are used to cast a match plate pattern, considerable straightening, machining, and polishing are usually necessary before a metal match plate pattern is ready for use.

Cope and drag patterns (Fig. 2c) are similar to match plate patterns except that the cope and drag portions of a split pattern are mounted or integrally cast on separate plates. Cope and drag patterns are preferred over match plate patterns for high-volume production or for the production of large castings. Pattern cost is higher than for match plate patterns, but the total molding cost per casting may be lower because the cope and drag mold sections can be made simultaneously. Automated vertical parting line molding machines require cope and drag pattern plates because a cope and drag impression is simultaneously made on opposite faces of the same block of sand. Successive blocks of sand are then pushed together side by side. The mold cavity is formed from the cope impression from one block of sand and the drag impression from the next block of sand. Thus, the equivalent of one mold cavity can be made for each block of sand (see the article "Sand Molding" in this Volume). Because the cope and drag are mounted on separate plates, accurate alignment of the two patterns is essential. The design and manufacture of cope and drag patterns are identical to those of match plate patterns.

Special Patterns. A wide variety of special pattern types and special patternmaking techniques can have specific uses in the foundry. Master patterns are used for casting metal patterns and for making plastic patterns. Multiple patterns are cast from the master to make match plate or cope and drag patterns. Special dimensional allowances must be made when

making master patterns (see the section "Pattern Allowances" in this article). A wide variety of techniques and pattern materials can be used to create the master pattern and to form the production patterns from the master pattern. Reverse master patterns (negative patterns) are also used with certain pattern materials to create production patterns. The basic steps for producing production patterns from master patterns are illustrated in Fig. 3.

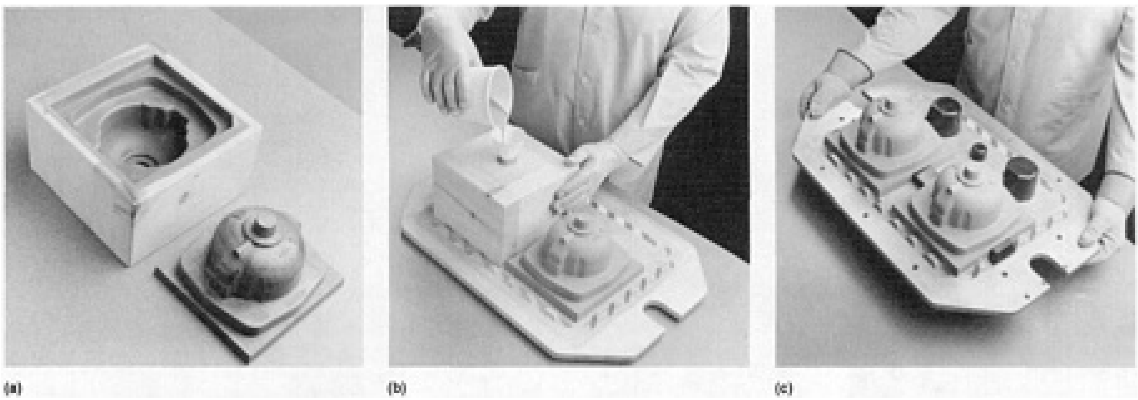

Fig. 3 Steps in producing a match plate pattern from a master pattern. (a) Wood master pattern is constructed with appropriate shrinkage factors included. A reverse from the master pattern. (b) Reverse mold is used to cast the polyurethane pattern on the aluminum match plate. (c) Reverse mold is removed, and a wood gating system is added. Gating can also be cast on with the pattern or made from aluminum stock. Courtesy of W. Allen, Allen Pattern of Michigan

A pattern need not always be a complete replica of the final casting. Molds for very large castings are often made from an assembly of chemically bonded sand mold sections (cores) made in numerous core boxes. This is referred to as an all-core mold. In this case, a single pattern is not required; rather, the pattern is made up of a core box for each section of the mold. These large mold assemblies are made on the foundry floor or in large pits built into the foundry floor (Ref 5). For example, the mold for a large gear can be made from a sectional pattern or core box that is a wedge-shaped segment of the hub, spokes, rim, and teeth. The complete gear mold is assembled from successively made wedge segments. In rare cases, molds can be made by template-shaped patterns that are rotated around a spindle to form a mold surface (called a sweep) or translated along an edge (called screeding) to form an irregular shape. Both sweeping and screeding are manual moldmaking techniques that have been largely replaced by molds that are assembled from core sections produced in core boxes.

Core Boxes. Cores are primarily used to form internal passageways or cavities in castings. Cores can also be used to form sections of the mold for a cast shape that has external projections or negative draft, which would prevent the pattern from being withdrawn from the mold. Core boxes are the reverse patterns or reverse molds used to make the cores that become part of the final mold assembly. The term pattern equipment refers to the pattern itself and to all of the core boxes needed to produce the cores that will be part of the final mold assembly. Because a given casting may have a complex internal shape or many internal passageways, the cost of producing core boxes may exceed that of the associated mold pattern. An example of an intricate full split aluminum core box used in a core blowing machine is shown in Fig. 4. Because many coremaking processes require the use of a gas catalyst to cure the core and binder, special venting considerations must be included in the core box design. Ejection pins can also be included to aid in removing the core from the core box halves.

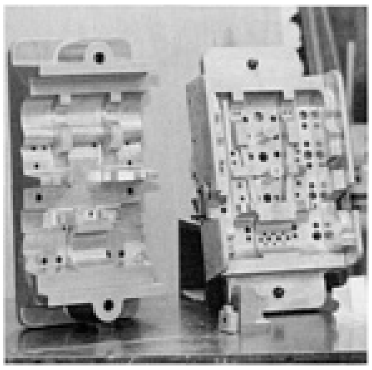

Fig. 4 Full split aluminum core box designed to eliminate pasting of core halves. From *Steel Castings Handbook,* 5th ed., Steel Founders' Society of America, 1980

The type of core box used and the material used to make a core box can vary greatly, just as for patterns. Core box construction depends on the type of coremaking process used and the number of cores required. Sand cores that develop strength during the high-temperature curing of thermal-setting binders (shell hot box and warm box cores) require heat-conducting metal core boxes. (Core sand binder systems and coremaking machines are discussed in the article "Coremaking" in this Volume.) Core boxes can also be subjected to considerable abrasive wear and pressure when core blowing machines deliver sand into the boxes at high air pressures. If cores are symmetrical, they can be pasted together from two core halves produced in a less expensive single half-core box. However, if higher tolerances and higher production rates are required, full split core boxes are used. As for patterns, the lowest cost core box is not necessarily the most economical. Proper casting design to minimize the use of cores is important not only for minimizing core box cost but also for decreasing molding costs and the overall cost of a casting. Casting design to minimize or eliminate cores is discussed in the Section "Design Considerations" in this Volume.

Expendable Patterns. One-piece patterns made of low-melting-temperature materials such as wax or materials that readily vaporize such as expanded polystyrene (EPS) can also be used as inexpensive expendable patterns. One such pattern is needed for each casting to be made.

Two common casting techniques that use expendable patterns are investment casting and evaporative process casting. In investment casting, a wax pattern is made in metal dies and coated with multiple layers of a ceramic or plaster slurry that hardens to form a thin rigid mold. The mold is heated to fire the ceramic and to melt out the wax, leaving an empty mold cavity of the desired shape.

Close-tolerance precision castings can be made using the investment casting process (see the article "Investment Casting" in this Volume).

In evaporative process casting, an EPS pattern is coated with a thin refractory slurry and placed in an unbonded sand mold. When molten metal is poured into the mold, the advancing metal vaporizes the polystyrene and fills the resulting cavity (see the discussion on evaporative foam casting in the article "Sand Molding" in this Volume). Evaporative process casting can be used for prototype or one-of-a-kind castings as well as for high-production castings. Prototype patterns are fabricated from stock foam pieces that are shaped and glued together. Production patterns are made by expanding polystyrene beads to final shape in multiple-piece metal dies. Expanded polystyrene has also been used to anchor multiple cores together in complex core assemblies prior to placement in a mold cavity (Ref 6). During pouring of the mold, the EPS pattern vaporizes, leaving the multiple sand cores in their proper position. This helps to ensure accurate placement of the cores.

Even though a new pattern is necessary for each casting made using expendable pattern processes, there are unique advantages to these processes. Casting design flexibility is greatly increased because the pattern does not have to be designed with parting lines, draft allowances, cores, or other features that are necessary when reusable patterns have to be removed from the mold to create the mold cavity. Complex multiple-piece patterns and sometimes the attachment of gates, risers, and runners are usually accomplished with the aid of adhesives.

Specialized molding presses and auxiliary molding equipment are used to make both wax and EPS patterns. The molds, or negative patterns, are usually machined from cast aluminum. The parting lines for wax and EPS pattern molds must be machined to closer tolerances than those generally required for green sand patterns in order to minimize parting line flash on the pattern. It is difficult to compare overall costs between EPS patterns and reusable patterns. Expanded polystyrene pattern costs are often offset by reduced molding and coremaking costs. A further discussion of wax and expendable polystyrene pattern materials can be found in the section "Expendable Pattern Materials" in this article.

Dies and permanent molds are reusable reverse patterns into which molten metal is poured to make a casting. They have much in common with core boxes and with the reverse patterns or dies used to make wax or EPS expendable patterns. Many of the pattern characteristics described in this article for sand casting with reusable patterns also apply to the design and manufacture of permanent and semipermanent mold and dies used in the permanent mold casting process and the die casting process. These casting processes are discussed in the article "Permanent Mold Casting" in this Volume.

Additional Features of Patterns

The primary purpose of the pattern is to produce a mold cavity of the desired shape. However, to produce successful castings, additional pattern features and pattern design considerations are also important. These include parting line considerations, patterns for gates and risers, core prints, and locating points. Pattern allowances for ensuring a dimensionally correct final pattern are discussed in the next section of this article.

Parting Line. It is necessary to separate (part) the completed mold halves and to withdraw the pattern from the mold for most sand casting processes. Selection of the most convenient and economical pattern parting line (mold parting surface) and design of the pattern so that it can be readily removed from the mold are important pattern design considerations. On a flat pattern plate, the parting surface is a simple plane. Many complexly shaped castings, however, require irregular parting surfaces to facilitate mold parting. The pattern match plate or cope and drag plates are used to establish the parting surface. Irregular parting surfaces can be readily incorporated with these types of patterns. (The term parting line is also used to refer to the very small fin (flash) or line left on the final casting at the parting surface where the two mold halves join.) Some complex pattern shapes cannot be readily removed from the parted mold halves unless the casting is redesigned or cores are used. By selecting the best parting line for a given casting to facilitate pattern removal from the mold, the use of cores to modify the external shape of the casting can be minimized (see the Section "Design Considerations" in this Volume).

These important considerations of mold parting surface and pattern withdrawal from the mold are of concern only when using reusable patterns. Expendable pattern molding processes use one-piece molds for which parting lines and pattern withdrawal are not of concern. This can result in additional casting design flexibility when using the expendable pattern casting process or investment casting techniques.

Gates and risers (rigging) are important factors in the production of quality castings and should be fully considered in the design and construction of patterns. Gating provides for the efficient flow of the molten metal into the mold cavity. Risers are large reservoirs of molten metal attached to the casting. They provide sufficient liquid metal to the casting as it solidifies to prevent internal shrinkage cavities or shrinkage defects in the casting. Gates and risers are commonly attached directly to the pattern and pattern plate and are molded with the pattern. For prototype castings, gates and risers can be made from loose pieces or cut into the molding sand by hand. On production match plate patterns, the gates and risers can be integrally cast on the pattern plate. The proper design of pattern gates and risers depends on the casting shape, the type of metal to be poured, and the molding and casting processes to be used. The location, size, and shape of gates and risers should be determined by an experienced foundry engineer, possibly with computer software design assistance. This is often a trial-and-error process, especially for complexly shaped castings. Pattern gating and risering is often modified after initial castings are made and evaluated, not only to produce sound, dimensionally accurate castings but also to increase casting yield efficiency.

Core Prints. When the production of a cast shape requires cores, provision must be made on the pattern for core prints. Core prints are portions of the pattern that locate and anchor the core in the proper position in the mold. The core print is added to the pattern (and removed from the core box), but does not appear on the final casting, because it is filled with the core itself. Core prints are illustrated in Fig. 1.

Locating Points. The foundry, the pattern shop, and the machine shop all use locating points or locating surfaces on the casting to check casting dimensions. Subsequent machining operations can also use the locating points in establishing the position of the machined surfaces relative to the rest of the casting.

Pattern Allowances

Although a pattern is used to produce a casting of desired dimensions, it is not dimensionally identical to the casting. A number of allowances must be made on the pattern to ensure that the finished casting is dimensionally correct, to ensure that the pattern can be effectively removed from the mold, and to allow for cores to be firmly anchored.

Shrinkage allowance is the correction factor built into the pattern to compensate for the contraction of the metal casting as it solidifies and cools to room temperature. The pattern is intentionally made larger than the final desired casting dimensions to allow for solidification and cooling contraction of the casting. This allowance for contraction is sometimes called patternmaker's shrinkage. The total contraction is volumetric, but is usually expressed linearly. Table 1 lists commonly used pattern shrinkage allowances for various casting alloys. Because different shrinkage allowances must be used for the individual types of metals cast, it is not possible to use the same pattern equipment for different cast metals without expecting dimensional changes. It must be emphasized that these shrinkage allowances are only guidelines and can only be applied with considerable knowledge of the actual casting design and the foundry molding techniques to be used.

Table 1 Typical pattern shrinkage allowances for various casting materials

Patternmaker and foundry should be consulted before shrinkage is specified.

Alloy being cast	Allowance	Approximate shrinkage, %	Shrinkage allowance	
			mm/m	in./ft
Steel	1 in 64	1.6	15/7	3/16
Gray cast iron	1 in 100	1.0	8/4	1/10
Ductile cast iron	1 in 120	0.8	7/8	3/32
Aluminum	1 in 77	1.3	13/1	5/32
Brass	1 in 70	1.4	14/4	11/64

The patternmaker's shrink rule is a special scale that eliminates the need to compute the amount of the shrinkage allowance that must be provided on a given dimension. For example, on a 10.5 mm/m ($\frac{1}{8}$ in./ft) patternmaker's shrink rule, each meter (foot) is 10.5 mm ($\frac{1}{8}$ in.) longer, and each graduation on the shrink rule is proportionately longer than its conventional length. Double shrinkage allowances must sometimes be made if a master pattern is first made in wood and then used to make a metal match plate or cope and drag production pattern. For example, an aluminum pattern made from a wood master pattern would require a double shrinkage allowance on the wood pattern if a steel casting is to be made. The total shrinkage allowance on the wood pattern would then provide for the shrinkage of the aluminum pattern casting and of the steel casting made from the aluminum production pattern.

However, it is important to remember that pattern shrinkage allowances such as those listed in Table 1 cannot be used blindly to predict actual casting shrinkage. Other factors, such as casting shape, section thickness, and mold rigidity, significantly influence the actual change in dimensions as the casting solidifies and cools to room temperature. The resistance of the mold to the normal contraction of the casting and the use of different molding materials and methods may require that different shrinkage allowances be used for different patterns (Ref 7, 8). The same pattern used to make castings in a hand-rammed green sand mold, by high-pressure green sand molding, and in a high-strength chemically

bonded sand mold will produce castings of varying dimensions because of the great differences in mold wall dilation during casting and solidification.

It is even possible that several different shrinkage allowances will be needed in one pattern, depending on constraint conditions. For example, in Fig. 5, two different contraction situations exist. Along dimension *X*, the casting has virtually no constraint to contraction, and the pattern should be made correspondingly larger along the *X* dimension surfaces. Dimension *Y*, however, is restrained from contraction by the core used to make the center hole and will require little or no shrinkage allowance on the pattern dimensions.

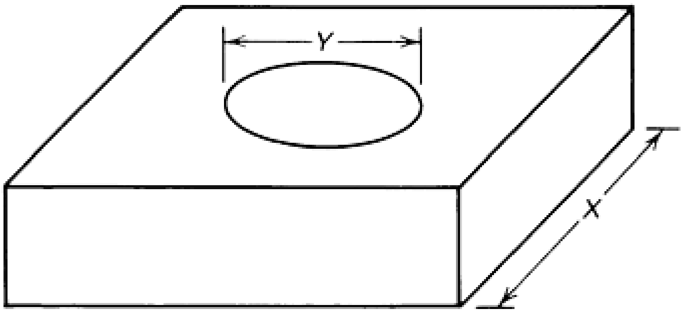

Fig. 5 Casting design that would require different shrinkage allowances than those normally used. Dimension *X* can contract freely, while dimension *Y* is restrained by the core used to make the hole.

Because casting design and foundry methods have a great influence on the required shrinkage allowance and on the shrinkage characteristics of the metal itself, the direct involvement of the foundry producing the castings in the determination of the required shrinkage allowances is essential. Where tight dimensional tolerances are required, an excessive shrinkage allowance can be used when making the initial pattern. The pattern dimensions are then corrected when the precise shrinkage that actually occurred in prototype castings can be measured.

Draft is taper allowed on the vertical faces of a pattern to permit its removal from the sand or other molding medium without tearing of the mold walls. (On vertically parted molds, draft is required on horizontal pattern surfaces.) The amount of draft required depends on the shape and size of the casting, the molding process used, the method of mold production, and the condition of the pattern. A draft angle of approximately 1.5° (16 mm/m, or 0.2 in./ft) is often added to design dimensions. The draft angle may be higher when manual molding techniques are used. Interior surfaces usually require somewhat more draft than exterior surfaces, and deep pockets or cavities may require considerably more draft.

In special cases, draft can even be eliminated. Vertical walls can sometimes be drawn if the pattern is smooth and clean and if the drawing equipment is properly aligned. Both liquid and dry proprietary parting compounds can assist in drawing the mold from the pattern. Patterns for V-process molding (vacuum molding; see the discussion in the article "Sand Molding" in this Volume) can be made without draft because the smooth plastic film that covers the sand mold face offers almost no resistance to drawing the pattern from the mold (Ref 9). Expendable patterns, such as EPS patterns, can also be designed with straight walls (no draft) or even with negative draft because they do not have to be withdrawn from the mold. This can offer the casting designer greater shape flexibility without the use of expensive cores.

The machine finish allowance provides for sufficient excess metal on all cast surfaces that require finish machining. The required machine finish allowance depends on many factors, including the metal cast, the size and shape of the casting, casting surface roughness and surface defects that can be expected, and the distortion and dimensional tolerances of the casting that are expected. Accurate patterns combined with automated molding can often produce close-tolerance castings with a minimum machine finish allowance that can reduce final machining costs considerably. Table 2 lists suggested machine finish allowances. However, the machining allowance for a given casting may vary greatly, depending on customer requirements and casting process capabilities. More demanding dimensional requirements should be discussed with the producing foundry prior to specification.

Distortion Allowances. Certain cast shapes, such as large flat plates and domeor U-shaped castings, sometimes distort when reproduced from straight or perfect patterns. This distortion is caused by the nonuniform contraction stresses during the solidification of irregularly shaped designs. Minor distortions are normally corrected by mechanically pressing or straightening the casting, but if distortions are consistent and prominent, the pattern shape can be intentionally changed to counteract the casting distortions. The "distorted" pattern will then produce a distortion-free casting. Prior consultation with the foundry is necessary to review their experience with the warpage distortion of similarly shaped castings.

Pattern Materials

A wide variety of both traditional materials and advanced composite materials are used in the manufacture of reusable patterns and core boxes (Ref 10, 11, 12, and 13). These pattern materials vary greatly in their physical characteristics, the techniques used for manufacturing and repairing the patterns, and the applications for which they are best suited. Pattern material selection is based on many factors, including the number of castings to be made, the dimensional accuracy required, the molding or coremaking process to be used, and the size and shape of the casting. General pattern standards concerning the use and specification of patterns and pattern materials have been published by the National Association of Pattern Manufacturers (Ref 14), but they are not very widely used. Table 3 lists some general characteristics and properties for four commonly used pattern materials: wood, aluminum, cast iron, and polyurethane. Improvements in pattern performance and durability often require that patterns be made of a combination of materials (such as wood with metal or plastic inserts on wear surfaces), coated materials, or composite materials.

Table 3 Characteristics of pattern materials

Characteristic	Pattern material			
	Wood	**Aluminum**	**Cast**	Polyurethane

			iron	
Machinability	E	G	F	**G**
Wear resistance	P	G	E	**E**
Strength	P	G	E	**F**
Repairability	E	F	G	**E**
Corrosion resistance	**E**	**E**	**P**	**E**

E, Excellent; G, Good; F, Fair; P, Poor

Wood is widely used for both master patterns and production patterns because it is inexpensive and easy to shape (Ref 1). However, wood patterns, especially those constructed of pine, are susceptible to shrinkage or swelling and warpage due to changes in atmospheric moisture. Figure 6 shows how atmospheric humidity can affect the dimensions of woods used in patternmaking. Mahogany is a popular pattern material because it has good strength and wear resistance compared to pine and slightly more dimensional stability. As Fig. 6 shows, the ideal moisture content of lumber as-received is 5%. When the initial moisture content of unprotected mahogany or northern pine is increased by an additional 5% (due to an atmospheric humidity of 50%), a volumetric expansion of 1.5% results. At an atmospheric humidity of 75%, the volumetric expansion may be 3% or more. From these data, it is apparent that appreciable changes in humidity can result in loss of dimensional accuracy, which translates to a corresponding loss in the dimensional accuracy of castings. Proper construction of wood patterns can inhibit warpage somewhat.

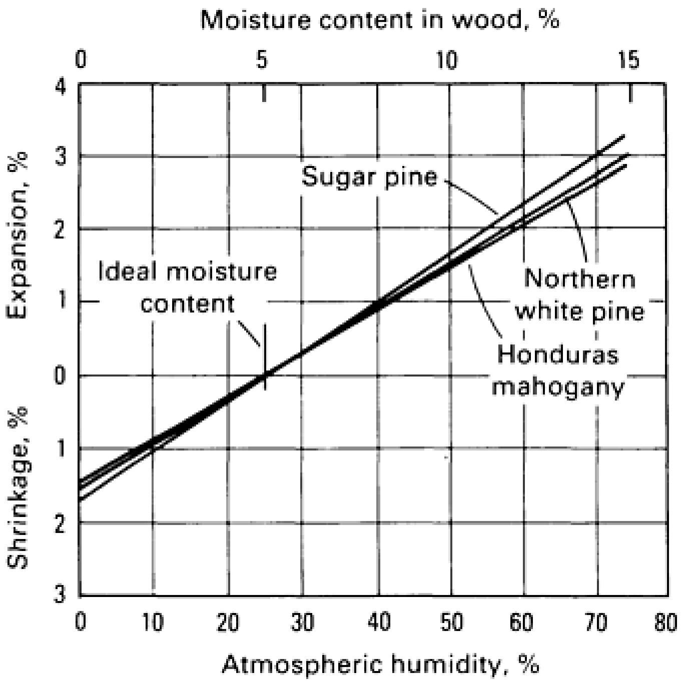

Fig. 6 Effects of moisture content of wood and atmospheric humidity on the expansion and shrinkage of three pattern woods

Pattern and core box sections made of white pine can be joined with glue and nails; pattern sections made of hardwoods, which are more durable than white pine, are usually joined by bolts, screws, and glue (Ref 1). This construction resists the cyclic stresses set up by the expansion and contraction of the wood. Pattern sections are sawed from suitable lumber, machined, and sanded to the required dimensions (considerations for draft and shrinkage allowances will be discussed later in this article). Good construction also calls for three or more coats of pattern lacquer, which minimizes moisture absorption and the resultant volumetric changes in the pattern. Automotive primer paints can also be used to finish wood patterns.

Patterns can also be made from compressed wood laminates (primarily plywood). These hardwood laminates weigh about twice as much as untreated wood, but have a high strength-to-weight ratio. In addition to their strength, they are tough and have much more resistance to abrasion and moisture than untreated wood. They are readily machined with conventional wood patternmaking machinery, with some adjustment in speeds, feeds, and cutting tools. The life of wood laminate patterns can be considerably longer than that of conventional wood patterns. Wood laminate pattern sections are joined by screws, bolts, or epoxy resins or can be fully machined from a block of material. When subjected to high humidity for long periods of time, these patterns swell so slowly that dimensional changes and warping are

negligible for most applications. Protective coatings such as lacquers make wood laminate patterns nearly impervious to the humidity conditions typical of foundry operations.

Metal or plastic inserts or pieces can also be a part of wood production patterns. These materials are often used in high-wear regions of the pattern to improve pattern life and durability. Repair of wood patterns is commonly done with wood inserts or plastic resins (epoxies or polyurethanes). Worn areas can be rebuilt and then finished to the desired final dimensions. Polyurethane pattern block materials (machinable plastic boards) are also available for producing master patterns with even higher dimensional accuracy, stability, and pattern life than wood. Patterns can be formed and constructed with standard woodworking equipment and techniques.

Metal pattern equipment is particularly well suited to long production runs. Compared to wood patterns, metal patterns and core boxes are more costly, stronger, more abrasion resistant, and are dimensionally stable under changing humidity. They can be fabricated for use with automated high-pressure molding equipment, can be made to high dimensional tolerances, and can be used for a large number of castings before pattern repair or rework is necessary.

Metal patterns and core boxes are normally made from aluminum alloys, gray iron, ductile iron, or steel. Metal patterns are required for shell molds and cores and molds from sands bonded with thermal-setting resins. Patterns used for this purpose are typically made of cast iron because aluminum tends to gall and wear quickly at elevated temperatures. The properties on which metal pattern material selection is based include wear resistance, dimensional stability, machinability, and the ability to provide a smooth surface finish after machining.

Metal patterns are either cast to shape in precision plaster or sand molds made from wood master patterns (cast to shape tooling) or machined directly from metal stock. Multiple-production pattern shapes can be made from one master pattern.

Metal patterns can be cast to shape in plaster (ceramic) or sand molds made from wood master patterns. The master pattern must be oversized to account for both the shrinkage of the metal pattern as it cools and the final shrinkage of the metal casting as it cools in the mold made from the metal pattern (double shrinkage allowance). After metal patterns are cast, gating and flash must be removed, and considerable machining, filling of surface imperfections, and polishing are required so that the final pattern surfaces are smooth and free of imperfections. These finishing operations may require 50% or more of the time needed for pattern construction (Ref 6).

Precision ceramic molding processes with dimensional accuracies of ±0.001 mm/mm (0.001 in./in.) can be effectively used to produce cast-to-size patterns with good as-cast surface finishes and minimum final machining (Ref 15). Even when precision molding methods are used to cast the original pattern plates or core boxes to close tolerances, some final machining and polishing may be needed. Aluminum pattern equipment is usually made by pressure casting processes to reduce the amount of finishing required.

Metal patterns and core boxes can also be machined directly from metal stock without the intermediate steps involved in producing a master pattern and the initial casting of semifinished pattern plates. The expanding use of computer numerical control (CNC) machining and computer-aided design data bases for parts dictates that direct machining of pattern equipment will continue to grow (see the section "Automation in Pattern Design and Manufacture" in this article).

The abrasion resistance of metal patterns can be improved even further by the use of abrasion-resistant coatings. Both electrolytically deposited hard chromium platings and electroless nickel platings can increase the life of metal pattern equipment. Polyurethane plastic inserts adhesively bonded to high-wear locations on metal patterns can also increase metal pattern life.

Plastic Pattern Equipment. The versatility, desirable properties, and cost effectiveness of plastic pattern equipment have resulted in the continued growth of plastics for patterns and core boxes. Plastics are primarily used for small- and intermediate-size patterns. Plastic patterns are more durable but are also usually more expensive than wood patterns. The use of plastic patterns and core boxes is increasing because plastic is replacing wood patterns in medium-volume applications and is replacing metal high-production pattern equipment. Multiple plastic patterns can be inexpensively made from one master pattern (usually wood). Plastic patterns have excellent dimensional stability and can be produced with less skill and expense than comparable metal patterns. They have been successfully used in high-pressure molding machines (Ref 11). In addition, the polyurethane and epoxy resins typically used for patterns have the following desirable characteristics:

- Better compressive strength, bending strength, abrasion resistance, and impact resistance than wood

- Resistance to environmental and chemical attack
- Good bonding to other pattern materials for repairs and inserts
- Easy release from molding sands

When properly made, plastic patterns shrink very little; therefore, the molds do not require double shrinkage allowance, as in the production of metal patterns from master patterns. This simplifies construction and results in a considerable cost savings for designs with intricate contours.

Epoxy patterns are suitable for small patterns and core boxes for limited production. Larger or higher-production patterns often require glass fiber reinforcement of the epoxy resin for increased strength and durability. Epoxy pattern life can also be extended with metal coatings. The polyurethane elastomers are used much more extensively than the epoxies and are becoming one of the most widely used pattern materials. The urethanes are more wear resistant and less brittle than the epoxies. They are used for complete patterns and core boxes, for loose pieces on wood or metal pattern plates, as a thin pattern face skin material, and as wear-resistant inserts on wood or metal patterns.

Techniques for producing plastic patterns depend on the type of pattern required, the type of resin system used, and the choice of reinforcement or backing, if any. Plastic patterns and gates and risers are usually mounted on metal pattern plates, but one-piece pattern and pattern plates can be manufactured. Because of the high cost of the resins and the distortion caused by the heat generated during the curing process, less expensive rigid backing materials are used whenever possible for medium and large patterns and core boxes. Metal reinforcing frames can also be used to stiffen and support large pattern plates for high-pressure molding equipment. Four common techniques for producing plastic pattern equipment are solid casting, casting with a core, various layup techniques, and direct machining of plastic board stock.

Solid patterns are manufactured using either a reverse master pattern or a reverse plaster mold made from a master pattern (usually wood). A sealer and a release agent are applied to the negative pattern or negative mold surface to prevent the resin from bonding to the mold. The resin system (usually two-part or three-part) is poured into the mold and allowed to harden. Curing times and temperatures vary greatly, depending on the resin and specific resin formulation used. Cured patterns can be readily stripped and mounted on pattern boards.

Fillers are often added to resins to reduce the amount of resin needed to make a pattern, to provide strengthening reinforcement, and/or to control shrinkage. A wide variety of mineral or metal powders are used as filter materials. Other low-density filler materials can be used when strength is not critical for large patterns. By reducing the amount of casting resin for a given volume with fillers, the temperature rise during the early stages of curing can be lessened to minimize overall pattern shrinkage and distortion.

A variation of the solid casting method (face casting) uses a 1 to 3 mm (0.04 to 0.12 in.) face or skin layer of resin that is allowed to cure partially. The remainder of the mold is then filled with a less expensive backing mix that is heavily reinforced with fillers such as silica sand. Thicker solid molds can also be built up in this way rather than with resins alone. Thin, brush-on surface (gel) coats can also be applied to wood patterns to produce inexpensive patterns with considerably longer pattern life than wood alone.

Patterns with a Core. In this method, an undersize core (plug) of wood, aluminum, plastic foam, or some other inert material is supported in the reverse pattern mold. The resin is poured or injected under pressure to fill the clearance space between the mold and the core and then cured to create the pattern surface. The use of the core minimizes the amount of resin needed for a given pattern volume, which minimizes shrinkage during curing. This method is most applicable for small- and medium-size castings of simple shape (Ref 16, 17).

Composite Patterns. A wide variety of techniques have been developed for building composite pattern equipment using plastic resins. Resin skins can be backed or supported by layers of glass fiber reinforcement. The rest of the mold is then filled with a suitable backing material using methods described previously.

Machined Patterns. Patterns, particularly master patterns, can also be fabricated from machinable polyurethane boards using the same patternmaking techniques and patternmaking tools used for wood patterns. The additional cost of using urethane stock rather than wood is justified when patterns must be made to close dimensional tolerances. Patterns of this type are usually machined using CNC machine tools. Large patterns of this type can be fabricated by using the machinable plastic board only as a facing material, along with a foam core or other backing material to support the urethane face to be machined.

Pattern Coatings. The performance and service lives of wood, metal, and plastic patterns can be improved with an appropriate wear-resistant coating. Standard electrolytic plating methods, electroless nickel plating, and metal spraying (metallizing) can all be used (Ref 18, 19). Table 4 illustrates the coating methods that are applicable for the various pattern substrates.

Table 4 Pattern coating materials and methods used to enhance wear resistance

Coating/method	Applicability to pattern substrate material			
	Wood	**Epoxy**	**Aluminum**	Cast iron
Metal spraying				
Tin-zinc alloys	X	X	. . .	**. . .**

Electrolytic plating				
Nickel	. . .	. . .	X	**X**
Chromium	. . .	X	X	**X**
Electroless plating				
Nickel	**. . .**	**X**	**X**	**X**

Figure 7 illustrates pattern wear rates for coated and uncoated pattern materials. In the investigation that yielded these data, laboratory sand erosion tests were conducted to evaluate the relative wear resistance of various coated and uncoated pattern materials. The test method was thought to simulate the impact abrasion that occurs on patterns from core blowers or other sand-blowing equipment. These results may not simulate other pattern abrasive wear conditions, because wear rates for different materials depend strongly on the angle of attack of the abrading particle. The relative wear resistance of the various pattern materials is indicated by the percentage of weight loss during abrasion testing. Materials with less weight loss are more abrasion resistant and would likely have longer pattern service lives. The formulations of the epoxy and urethane materials have also been improved since these data were obtained; this may affect the results indicated for these materials. The methods for applying metal coatings to the various pattern substrates will be briefly described. More detailed descriptions of these coating techniques are available in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

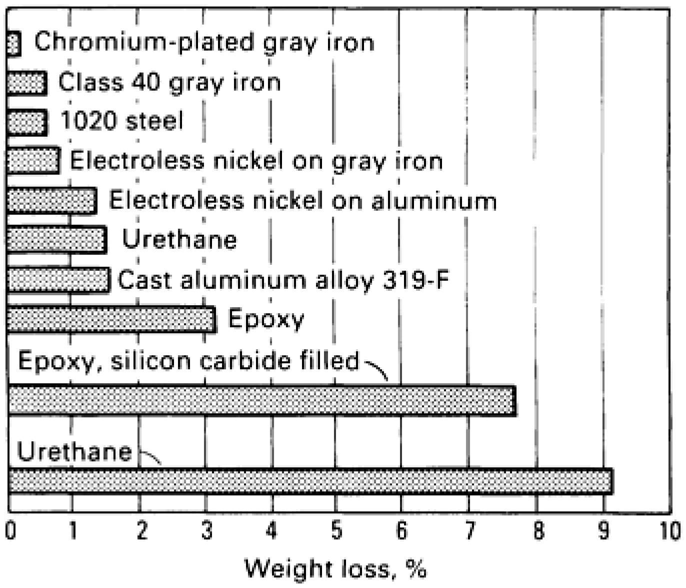

Fig. 7 Average weight losses (percent) of pattern materials tested for 12 h in silica erosion. Source: Ref 20

In electrolytic plating, the coating is electrolytically deposited on patterns negatively charged (anode) in aqueous solutions containing metal salts. Pattern coating thicknesses usually range from 0.05 to 0.13 mm (0.002 to 0.005 in.). Coating thickness may vary somewhat for a pattern, depending on the distance from the electrode.

In electroless nickel plating, a nickel alloy containing 8 to 10% P is chemically plated from a hot aqueous solution of nickel salts and activators. A typical plating cycle consists of 6 to 8 h in an 80 °C (180 °F) bath. The coatings produced have a high hardness and low coefficient of friction. Average coating thicknesses range from 0.08 to 0.13 mm (0.003 to 0.005 in.) or more. The as-deposited hardness of electroless nickel can be substantially increased by subsequent heat treatment at temperatures between 290 and 400 °C (550 and 750 °F). Epoxy pattern equipment can also be electroless nickel coated.

Metal Spraying (Metallizing). Metal spraying is the most rapid and least expensive method of applying a thin metal coating on a wood, epoxy, or metal substrate. Because a sprayed metal coating can be applied uniformly or nonuniformly by directing the spray pattern, metal spraying can also be used to rebuild areas of patterns where excessive wear has taken place. Arc spray or plasma spray guns are used to spray atomized liquid metal onto a pattern. Low-melting alloys can even be sprayed on wood patterns. Coating thicknesses of 1.5 to 2 mm (0.060 to 0.080 in.) are common except when pattern repair necessitates thicker coatings. Sprayed metal coatings are often more nonuniform than other plated coatings and therefore may require more finishing and polishing. Metal spraying can also be used to coat a negative mold (usually epoxy coated with a release agent), which is then backed up with cast epoxy. The metallized epoxy pattern is then removed from the negative mold.

Pattern Repair and Rebuilding. Pattern rebuilding must be carried out on a regular basis to repair patterns that have been damaged by use or abuse and to build up worn areas of the pattern that are no longer producing castings within tolerance. The rebuilding procedures used depend on the pattern material and the service life required for the rebuilt pattern. Epoxies and urethanes are widely used to rebuild all types of pattern materials. Metal spraying or weld overlaying can also be used to build up worn areas of production metal patterns.

Pattern Handling and Storage. Because significant investments are made in pattern equipment, pattern handling and storage must be carefully considered by the foundry. Improper storage and handling can cause pattern deterioration and damage, particularly for wood patterns because humidity and temperature changes can cause severe distortion. The foundry typically has many patterns in inventory. Obsolete or discontinued patterns should be routinely destroyed to make room for new patterns.

Expendable Pattern Materials. Wax patterns used for investment casting and EPS patterns used for the evaporative casting process are the two most common expendable pattern materials. Aspects of these pattern materials and pattern processing are discussed in the following sections of this article. Details on the investment casting and evaporative foam casting processes are available in the articles "Investment Casting" and "Sand Molding" in this Volume.

Wax Patterns. Various types of specially formulated waxes are used to make wax patterns. Patterns are made by injecting liquid or semisolid wax into a multiple-piece pattern die. The wax is allowed to solidify, the die is parted, and the wax pattern is removed. Injection waxes are usually blended from selected waxes, resins, and modifiers (Table 5). A typical pattern wax formulation might be:

Ingredient	Composition, %
Hard wax[a]	**40**
Microcrystalline wax	**25**
Soft resinous plasticizers[b]	**15**
Hard resins[b]	**20**
Antioxidant	**0.05**

(a) Microcrystalline, amorphous.

(b) Amorphous

Many important properties and characteristics of pattern waxes are measured and controlled, including the following:

- Solidification temperature range (freezing range)
- Ash content
- Viscosity
- Strength and hardness
- Softening temperature

Table 5 Materials used in formulating waxes for expendable patterns

Material	Melting point M or softening point S, °C (°F)
Hard waxes	
Vegetable wax (candelilla)	**M: 67 (152)**
Vegetable wax (carnauba)	**M: 89 (192)**
Mineral wax (montan)	**M: 86 (187)**
Synthetic wax (nonchlorinated)	**M: 85.5 (186)**
Synthetic wax (chlorinated)	**M: 93 (199)**
Microcrystalline waxes	

Petroleum derivative	**M: 79 (175)**
Petroleum derivative	**M: 63 (145)**
Beeswax, USP	**M: 64 (147)**
Soft resinous plasticizers	
Rosin derivatives	**S: 43-71 (110-160)**
Terpene resins	**S: 40 (104)**
Coal-tar resins	**S: 25-75 (77-167)**
Petroleum hydrocarbon resins	**S: 70 (158)**
Chlorinated resins	**S: 60-73 (140-163)**
Elastomers	**S: Wide range**
Hard resins	
Rosin derivatives	**S: 138-193 (280-380)**
Terpene resins	**S: 85 (185)**
Coal-tar resins	**S: 70-107 (158-224)**
Petroleum hydrocarbon resins	**S: 95-100 (203-212)**
Chlorinated resins	**S: 98-110 (208-230)**
Modifiers	
Synthetic wax (nonchlorinated)	**S: 70-105 (158-221)**
Elastomers	**S: 149 (300)**
Polyethylene resins	**S: 99-108 (210-226)**

Depending on the number of patterns to be cast at one time and the complexity of the wax pattern dies, some wax pattern assembly may be required in order to attach the gating system and sprue. Patterns are typically joined to the feeding system by dip sealing to create pattern clusters surrounding a central sprue or tree.

Expanded Polystyrene Patterns. Expanded polystyrene is polystyrene containing a hydrocarbon blowing agent (usually pentane). When heat is applied, the dense polystyrene beads soften, and the blowing agent vaporizes to form a low-density foam. Patterns for prototype or short-run castings are machined and assembled from EPS shapes and adhesively bonded together. Production quantities of EPS patterns are molded to shape in equipment similar to that used to make wax patterns. The use of the evaporative foam casting process is rapidly increasing (Ref 21, 22, 23, 24, and 25).

The production of EPS patterns for the foundry involves two major processing steps: preexpansion and molding. During preexpansion, the EPS beads are heated to soften them, and the blowing agent vaporizes, causing the bead to expand to a predetermined bulk density close to that of the final pattern bulk density. The preexpanded beads are blown loosely into a pattern cavity, where additional heat (steam) is again used to soften the beads and cause them to expand further to fill the void spaces between the beads and to bind them together. The molded pattern is then cooled to harden the pattern for removal from the die cavity. Patterns are often made from pattern pieces that are adhesively bonded together.

The final bulk density of the EPS pattern is a very important consideration. Increasing the bulk density increases the strength, durability, and dimensional stability of the pattern during storage. However, low pattern bulk densities are usually required to minimize the amount of carbon picked up by the molten metal when it is poured into the mold over the EPS pattern to make a casting (particularly for cast steel). Common EPS pattern bulk densities used for the various cast metals are:

Metal cast	Recommended EPS pattern density	
	kg/m^3	lb/ft^3
Aluminum	24.0-25.6	**1.5-1.6**
Brass, bronze	20.0-21.6	**1.25-1.35**
Gray iron	20.0	**1.25**
Steel	**17.6**	**1.10**

The pattern dimensions must take into account the fact that the EPS patterns themselves will shrink with age. Patterns will shrink a maximum of 8.3 mm/m (0.100 in./ft) over a period of 30 days. The dimensional variations that take place during the first 2 days after pattern manufacture are shown in Fig. 8. Metal shrinkage in evaporative foam casting is generally the same as for other conventionally bonded sand molds and must be considered along with the pattern shrinkage when designing the EPS mold. Shrinkage of EPS patterns depends on many factors, including the time period between pattern fabrication and pattern use, the size and bulk density of the foam, the section size, the pentane (expander) content, and the storage environment. Expanded polystyrene patterns are coated with a thin, ceramic slurry coating that is allowed to dry before molding.

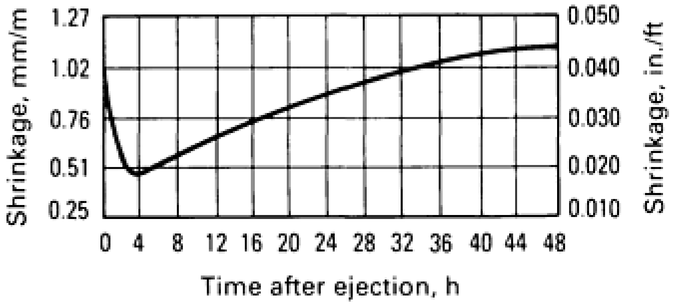

Fig. 8 Shrinkage of EPS patterns after ejection from the pattern mold. Patterns are approximately 1.27 mm (0.050 in.) undersize when ejected from the mold. Source: Ref 21

In a variation of the evaporative foam process known as the ceramic shell or Replicast process, a heavier ceramic shell is built up around a high-density EPS pattern (Ref 24). As with wax patterns, the EPS pattern is then removed by firing before the molten metal is poured into the ceramic shell. This prevents carbon pickup in the molten metal before solidification that cannot be avoided with conventional evaporative foam techniques. More information on the ceramic shell process is available in the article "Replicast Process" in this Volume.

Selection of Pattern Type

The type of pattern or core box used and the pattern or core box material used for a given set of castings depend on the following fundamental factors:

- The number of castings to be produced
- The molding or coremaking process to be employed
- The casting design
- The dimensional tolerances required

The life and cost of a pattern can both vary dramatically, depending on the pattern material and the type of pattern equipment.

In the developmental stage of a pattern design, only a few prototype castings need to be produced before modifications are made to the pattern dimensions or to the gating and risering. If such revisions are likely, an inexpensive wood pattern is often used first. This will enable engineering changes to be made quickly and inexpensively. After the design and the tolerances of the casting have been approved, a permanent pattern is selected based on production quantity and the molding or coremaking processes to be used.

Costs that are influenced by pattern equipment selection depend largely on the pattern material and pattern type and are dictated by production quantity. Expensive pattern equipment can often be justified if production quantities are high. The complexity of the pattern and the quality of the material used to make the pattern generally increase with the number of castings to be produced from one set of patterns. For example, an unmounted or loose softwood pattern could be used only for very limited production before it would require repair or replacement. A similar pattern made from a more durable material and mounted on a pattern board would increase the useful life of the pattern dramatically. Table 6 lists the basic types of patterns, indicating typical pattern materials and pattern lives for each during automatic green sand molding. Figure 9 indicates the general relationship between casting cost and production rate for various reusable pattern materials.

Table 6 Approximate life before repair of various pattern materials

Approximate number of castings produced before pattern repairs		Materials
Pattern	**Core box**	
Small castings (largest dimension: ≤610 mm, or 24 in.)		
200	300	**Hardwood patterns and core boxes**
2000	2000	**Hardwood patterns and core boxes, wearing surfaces faced with metal**
6000	6000	**Aluminum patterns and core boxes; plastic match plate patterns; urethane patterns or urethane-lined magnesium-framed core boxes**

100,000	100,000	**Cast iron patterns and core boxes**
Medium castings (largest dimension: ≤1.8 m, or 72 in.)		
100	100	**Hardwood patterns and core boxes**
1000	750	**Hardwood patterns and core boxes, wearing surfaces faced with metal**
3000	3000	**Aluminum patterns and core boxes; urethane inserts in wear areas**
Large castings (largest dimension: >1.8 m, or 72 in.)		
50	50	**Softwood patterns and core boxes**
200	150	**Softwood patterns with exposed projections metal faced; softwood core boxes, metal faced**
500	**500**	**Hardwood patterns reinforced with metal; hardwood, metal-faced core boxes**

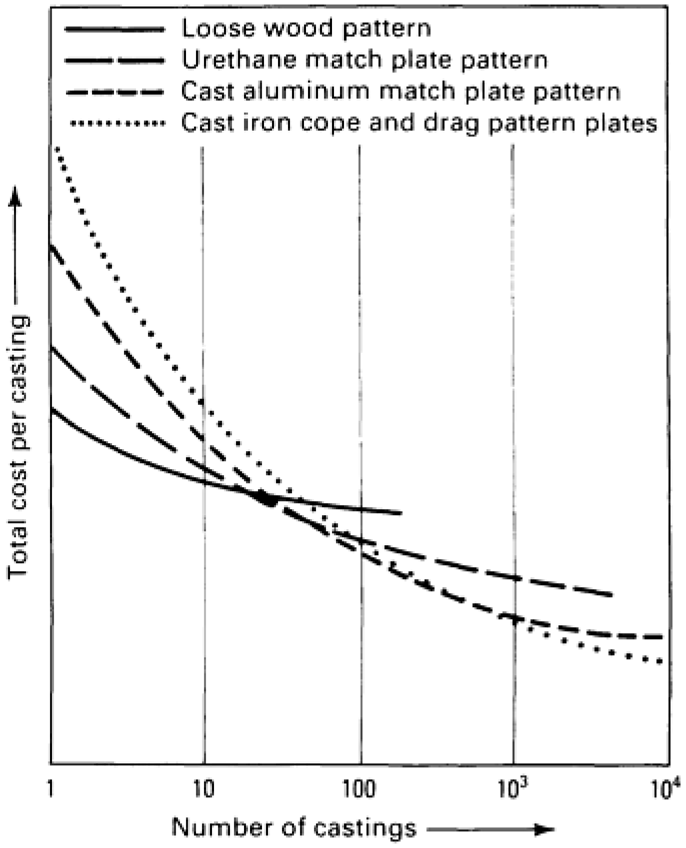

Fig. 9 Generalized casting costs versus production quantity for four pattern materials

Foundries also use various molding processes, casting processes, and coremaking processes. Therefore, during molding, patterns and core boxes can be subjected to differing degrees of abrasion, temperature, and stress that affect the pattern type and choice of pattern material.

For example, the stresses that the pattern encounters during automated high-pressure green sand molding necessitate the use of high-strength pattern materials and rigid pattern construction. When large green sand molds are made with sand slingers, the rapid abrasive wear of softer pattern materials is a major concern. Shell molds or cores can be made only from metal patterns because they are heated to temperatures of approximately 260 °C (500 °F). In V-process molding, a thin polyethylene sheet prevents the sand mold from contacting the pattern during molding, and this allows inexpensive wood patterns to have an almost indefinite pattern life.

Tolerances. The type of pattern used also has a significant effect on the casting tolerances that can be obtained and maintained. In general, final casting tolerances can be held within tighter limits as the rigidity and durability of the pattern equipment increase. When close tolerances are required, it may be desirable to construct the pattern equipment so that it can be dimensionally adjusted based on the results of prototype castings. These adjustments may involve refitting and remachining.

It is very difficult to compare the cost of castings made from EPS patterns to similar castings made from permanent patterns. The additional casting design flexibility and reduced molding costs associated with the evaporative foam casting process may off-set high pattern and pattern die costs, resulting in lower total casting cost.

Automation in Pattern Design and Manufacture

The continued development of computer-aided design and manufacturing technology has had a direct effect on both pattern design and patternmaking methods (Ref 26, 27, 28, and 29). The influence of CAD/CAM technology will continue to grow as it becomes more affordable for the small foundry and the pattern shop. Maximum benefit can be achieved with CAD/CAM technologies if pattern design, inspection, and manufacture are fully integrated.

This integrated patternmaking approach begins with a geometric data base of the part to be cast. The data base may already exist or may have to be constructed from drawings. The pattern designer adds a parting line and draft and machining allowances at his CAD workstation. The part dimensions can be automatically scaled up to the designed pattern dimensions that included the shrinkage allowance by inputting the appropriate scale factor. At the current stage of development of CAD software systems, necessary pattern features such as the parting line and draft must be added interactively by the pattern designer. To complete the pattern design, appropriate gates and risers can be added by using one of a number of software packages (see the articles "Riser Design" and "Gating Design" in this Volume). These procedures result in a software pattern geometry data base that can be easily used and modified.

Solidification modeling software can be used to model the solidification of the final resultant casting from geometry data alone before even prototype patterns are made (see the articles in the Section "Computer Applications in Metal Casting" in this Volume). Pattern dimensions, gating, and riser design can all be evaluated and readily modified by adjusting the pattern geometry data base. The use of solidification modeling programs can dramatically reduce or eliminate pattern prototyping stages. A prototype pattern and final pattern design changes and/or modifications may still be necessary, but these can also be easily performed by adjusting the pattern data base. For example, a different pattern shrinkage could be readily accommodated by rescaling the data base model.

Numerical control (NC) machining of patterns to very close tolerances can also be readily performed using the pattern geometry data base. Numerical control programs for automatic machining of the desired pattern shape can be automatically or interactively generated from the pattern data base. The NC part programmer can retrieve the pattern geometry model and use that model to construct the appropriate cutter paths for pattern machining. Graphical simulation of the NC machining operation on the CAD terminal can be used to verify the correctness of the NC part program before actual pattern machining takes place. Any future modifications to the pattern geometry can be readily incorporated. Changes are made to the pattern data base, and the modified NC output is used to modify the appropriate pattern dimensions. Multiple impression tooling can be made with the assurance that each impression is dimensionally accurate.

An example of the benefits that can be obtained using CAD/CAM patternmaking techniques compared to conventional patternmaking techniques is shown in Table 7. A 17% reduction in the time necessary to produce a final pattern is shown.

Table 7 Comparison of traditional and CAD/CAM patternmaking times for an aluminum investment die

Technique	Time
Traditional methods (Accuracy of pattern: ±0.01 in.)	
1) Design	**50 h**
2) Wooden model	**50 h**
3) Duplicating	**40 h**
4) Other machining	**85 h**
5) Polishing and finishing	**40 h**
Total	265 h
CAD/CAM methods (Accuracy of pattern: ±0.002 in.)	
1) CAD/CAM design	**40 h**
2) NC cutter path development	**40 h**
3) CNC machining	**25 h**
4) Other machining	**85 h**
5) Polishing and finishing	**30 h**
Total	220 h

Complete NC machining of patterns will continue to expand as the benefits of CAD/CAM technology continue to be exploited. The close dimensional tolerances and complex geometries required on many patterns are more suited to NC pattern machining than to manual construction by patternmakers and machinists. Numerical control machining can be used to machine master pattern equipment from which production patterns and core boxes are made. However, it is more common for production patterns and core boxes to be machined directly from NC data, with the NC pattern data base itself serving as the master pattern. Although CAD/CAM has made inroads in the tooling and die industries, the technology is just beginning to be used for the design and manufacture of metal casting patterns.

Verification of pattern and casting dimensions is also a tedious process when traditional manual layout techniques are used. An automated coordinate-measuring machine is an extremely accurate inspection tool that can dramatically improve the speed and reliability of pattern inspection (Ref 27). Such machines provide absolute

measurement capabilities in three dimensions simultaneously; this eliminates the need to make tedious comparisons between the pattern and gage blocks or other length standards. With data processing capabilities, the pattern need not even be aligned with the axes of the coordinate measuring machine, but is digitally aligned. Data storage and printout capabilities allow easy measurement of many important pattern features. For example, cope and drag pattern plate alignment can be readily determined from comparisons of the locating pin and bushing positions for each pattern plate. Pattern dimensions or pattern inserts can also be inspected at specific intervals during pattern use with little downtime for monitoring pattern wear.

Classification of Processes and Flow Chart of Foundry Operations

Thomas S. Piwonka, University of Alabama

Introduction

CASTING PROCESSES have existed since prehistoric times (see the article "History of Casting" in this Volume). Over the years a wide variety of molding and casting methods have been developed, because the only limitation is human ingenuity. These methods will be introduced and classified in this article. More detailed information on each process can be found in the subsequent articles in this Section.

Casting Processes (Ref 1)

Figure 1 shows a simplified flow diagram of the basic operations for producing a sand casting. There are variations from this flow sheet depending on the type of material cast, the complexity of the component shape, and the quality requirements established by the customer. There are also many alternative methods of accomplishing each of these tasks.

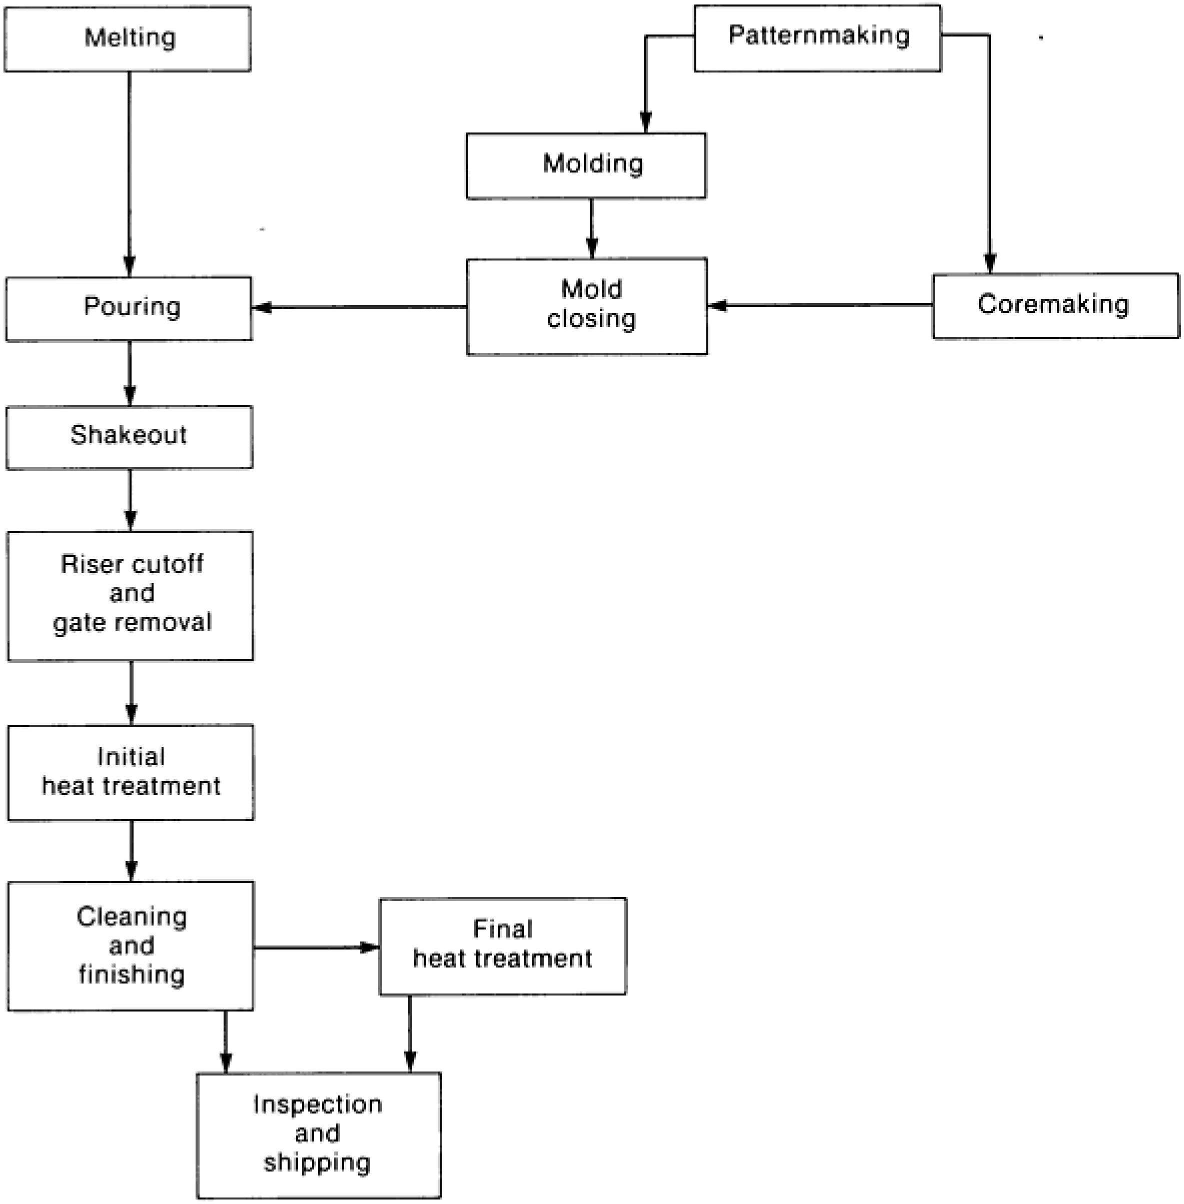

Fig. 1 Simplified flow diagram of the basic operations for producing a steel casting. Similar diagrams can be

applied to other ferrous and nonferrous alloys produced by sand molding. Source: Ref 1

The right side of Fig. 1 begins with the task of patternmaking. The article "Patterns and Patternmaking" in this Volume describes in detail the various pattern materials and considerations necessary in producing a quality pattern. A pattern is a specially made model of the component to be produced, used for producing molds.

Generally, sand is placed around the pattern and, in the case of clay-bonded sand, rammed to the desired hardness. In the case of chemical binders, the mold is chemically hardened after light manual or machine compaction. Molds are usually produced in two halves so that the pattern can be easily removed. When these two halves are reassembled, a cavity remains inside the mold in the shape of the pattern. Mold-making equipment and processing are described in the article "Sand Processing" in this Volume.

Internal passageways within a casting are formed by the use of cores. Cores are parts made of sand and binder that are sufficiently hard and strong to be inserted in a mold. Thus, the cores shape the interior of a casting, which cannot be shaped by the pattern itself. The patternmaker supplies core boxes for the production of precisely dimensioned cores. These core boxes are filled with specially bonded core sand and compacted much like the mold itself. Cores are placed in the drag, or bottom section, of the mold, and the mold is then closed by placing the cope, or top section, over the drag. Mold closing completes the production of the mold, into which the molten metal is then poured. Procedures for making cores are described in detail in the articles "Resin Binder Processes" and "Coremaking" in this Section.

Casting production begins with melting of the metal (left side, Fig. 1). Molten metal is then tapped from the melting furnace into a ladle for pouring into the mold cavity, where it is allowed to solidify within the space defined by the sand mold and cores. Melting, refining, and pouring of castings are described in the following articles in the Section "Foundry Equipment and Processing" in this Volume:

- "Melting Furnaces: Electric Arc Furnaces"
- "Melting Furnaces: Induction Furnaces"
- "Melting Furnaces: Reverberatory Furnaces and Crucible Furnaces"
- "Melting Furnaces: Cupolas"

After it has solidified, the casting is shaken out of the mold, and the risers and gates are removed. Risers (also called "feeders") are shapes that are attached to the casting to provide a liquid-metal reservoir and control solidification. Metal in the risers is needed to compensate for the shrinkage that occurs during cooling and solidification. Gates are the channels through which liquid metal flows into the mold cavity proper. Heat treatment, cleaning and finishing, and inspection follow. These steps are outlined in the articles "Shakeout and Core Knockout", "Blast Cleaning of Castings", "Welding of Cast Irons and Steels", "Hot Isostatic Pressing of Castings", "Testing and Inspection of Casting Defects", "Coating of Castings", and in the articles on specific metals and alloys in the Sections "Ferrous Casting Alloys" and "Nonferrous Casting Alloys" in this Volume.

Classification of Molding and Casting Processes

Foundry processes can be classified based on whether the molds are permanent or expendable. Similarly, subclassifications can be developed from patterns, that is, whether or not the patterns are expendable. A second subclassification can be based on the type of bond used to make the mold. For permanent molding, processes can be classified by the type of mechanism used to fill the mold. Table 1 provides one possible classification system for the molding and casting processes described in this Section. Permanent pattern, expendable pattern, and permanent mold processes, as categorized in Table 1, are summarized below.

Table 1 Classification system for foundry processes based on mold type

The processes listed are all shape casting methods. Continuous casting, which is also covered in this Volume, is not listed.

Expendable Mold Processes

- Permanent patterns
  - Clay/water bonds (green sand molding)
    - Silica sand
    - Olivine sand
    - Chromite sand
    - Zircon sand
  - Heat-cured resin binder processes
    - Shell process (Croning process)
    - Furan hot box
    - Phenolic hot box
    - Warm box (furfuryl/catalyst)
    - Oven bake (core oil)
  - Cold box resin binder processes
    - Phenolic urethane
    - Furan/SO_2
    - Free radical cure (acrylic/epoxy)
    - Phenolic ester
  - No-bake resin binder processes
    - Furan (acid catalyzed)
    - Phenolic (acid catalyzed)
    - Oil urethane
    - Phenolic urethane
    - Polyol urethane
  - Silicate and phosphate bonds
    - Sodium silicate/CO_2
    - Shaw process (ceramic molding)
    - Unicast process (ceramic molding)
    - Alumina phosphate
  - Plaster bonds
    - Gypsum bond

- No bond
  - Magnetic molding
  - Vacuum molding
- Expendable patterns
  - Foamed patterns
    - Lost foam casting
    - Replicast process
  - Wax patterns (investment casting)
    - Ethyl silicate bonded block molds
    - Ethyl silicate bonded ceramic shell molds
    - Colloidal silica bond
    - Plaster bond
    - Counter-gravity low-pressure casting

Permanent Mold Processes

- Die casting
  - High-pressure die casting
  - Low-pressure die casting
  - Gravity die casting (permanent mold)[a]
- Centrifugal casting
  - Vertical centrifugal casting
  - Horizontal centrifugal casting
- Hybrid processes
  - Squeeze casting
  - Semisolid metal casting (rheocasting)
  - Osprey process[b]

(a) When sand or plastic complex cores are used instead of metal cores, the term semipermanent mold casting should be used.

(b) The Osprey process, which involves the production of preforms by a buildup of sprayed (atomized) metal powder, is discussed in the article "Ultrafine and Nanophase Powders" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Permanent Pattern Processes. As indicated in Table 1, a number of processes use permanent patterns. Of these processes, however, green sand molding is the most prevalent. The typical steps involved in making a casting from a green sand mold are shown in Fig. 2 and described below (Ref 1).

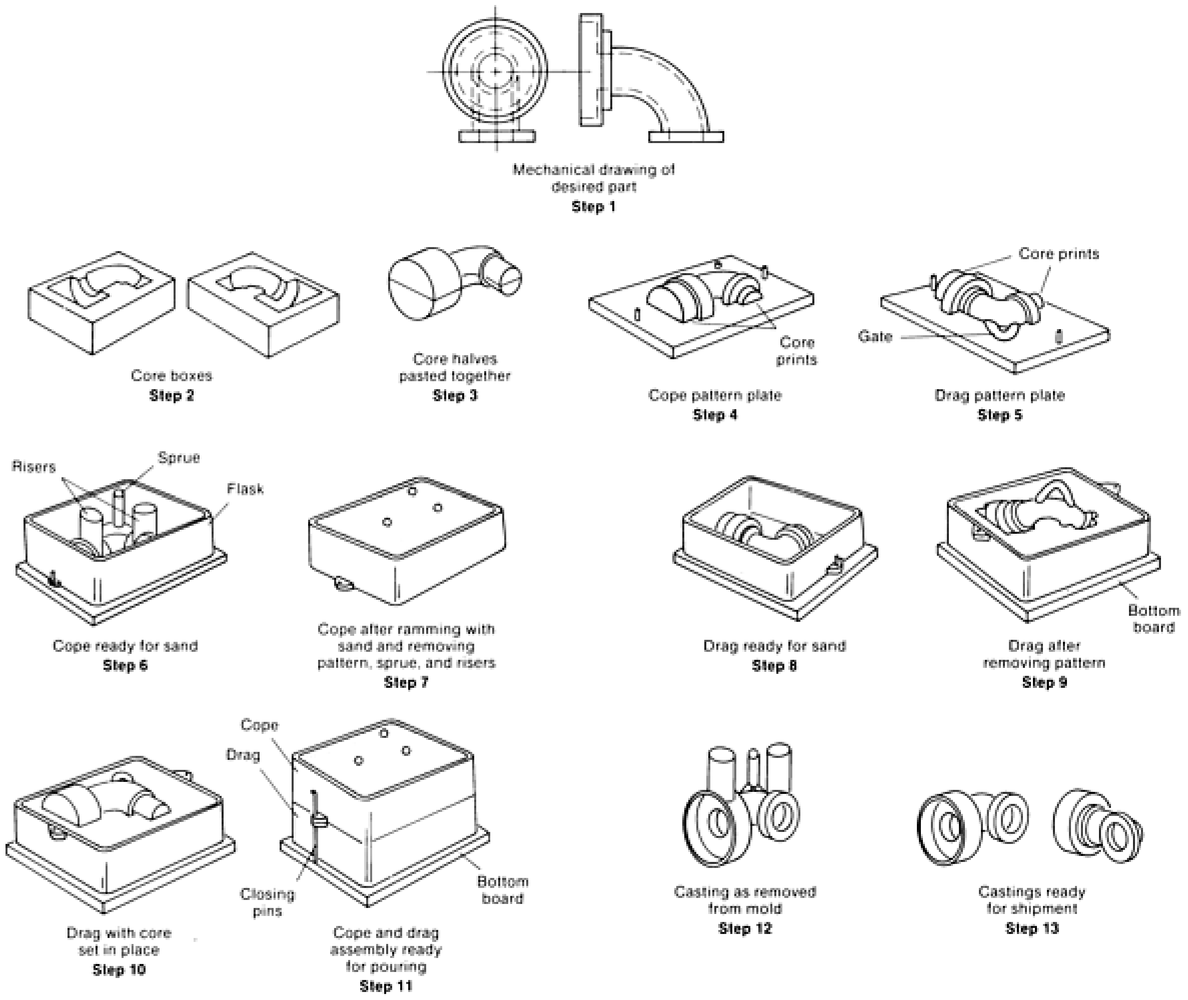

Fig. 2 Basic steps involved in making a casting from a green sand mold

The sequence begins with a mechanical drawing of the desired part. Patterns are then produced and mounted on pattern plates. Both the cope and drag patterns include core prints, which will produce cavities in the mold to accommodate extensions on either end of the core. These extensions fit solidly into the core prints to hold the core in place during pouring. The gate or passageway in the sand mold through which the molten metal will enter the mold cavity is usually mounted on the drag pattern plate. Locating pins on either end of the pattern plates allow for accurately setting the flask over the plate.

Cores are produced separately by a variety of methods. Figure 2 shows the core boxes, which are rammed with a mixture of sand and core binder (see the article "Coremaking" in this Section). If the cores must be assembled from separately made components, they are pasted together after curing. They are then ready to be inserted into the sand mold.

The mold is made by placing a flask (an open metal box) over the cope pattern plate. Before molding can begin, risers are added to the pattern at predetermined points to control solidification and supply liquid metal to the casting to compensate for the shrinkage that takes place during cooling and solidification. Thus, any shrinkage voids form in the risers, and the casting will be sound. A hole or holes (called sprues) must also be formed in the cope section of the mold to provide a channel through which the molten metal can enter the gating system and the mold cavity.

The cope half of the mold is produced by ramming sand into the flask, which is located on the pattern plate with pins. The flask full of sand is then drawn away from the pattern board, and the riser and sprue pieces removed.

A flask is subsequently placed over the drag pattern plate using the locating pins on the plate. Sand is rammed around the pattern, and a bottom board is placed on top of the flask full of sand. The pattern, flask, and bottom board are then rolled over 180°, and the pattern is withdrawn.

The completed core is set into the core prints in the drag half of the mold and the cope half of the mold is set on top of the drag. Proper alignment of the mold cavity in the cope and drag portions of the mold is ensured by the use of closing pins, which align the two flasks. The flasks can be clamped together, or weights can be placed on top of the cope, to counteract the buoyant force of the liquid metal, which would otherwise tend to float the cope off the drag during pouting.

Metal is then poured into the mold cavity through the sprue and allowed to solidify. The casting is shaken from the sand and appears as shown in Fig. 2, with the sprue, gating system, and risers attached. Following shakeout, the flasks, bottom boards, and clamps are cycled back to the molding station while the casting is moved through the production process. When the gates and risers are removed from the casting, they are returned to the furnace to be remelted. After cleaning, finishing, and heat treating, the castings are ready for shipment.

Expendable pattern processes use polystyrene patterns (lost foam casting and Replicast process) or wax patterns (see discussion below on investment casting). Both of these foundry processes are increasing in use.

The investment casting process has been known for at least 6000 years, but its use for the production of commercial castings has grown considerably during the second half of the 20th century. The process is also referred to as the lost wax process and as precision casting. The term precision implies high accuracy of dimensions and tight tolerances. Investment casting also yields smoother, high-integrity surfaces that require little or no machining, depending on the application.

The basic steps of the investment casting process are as follows:

- Production of heat-disposable patterns, usually made of wax or wax/resin mixtures
- Assembly of these patterns onto a gating system
- Investing, or covering, the pattern assembly with ceramic to produce a monolithic mold
- Melting out the pattern assembly to leave a precise mold cavity
- Firing the ceramic mold to remove the last traces of the pattern material, to fire the ceramic and develop the high-temperature bond, and to preheat the mold ready for casting
- Casting (pouring)
- Shakeout, cutoff, and finishing

These basic process steps are outlined schematically in Fig. 3. Detailed information on each of these processing steps can be found in the article "Investment Casting" in this Section.

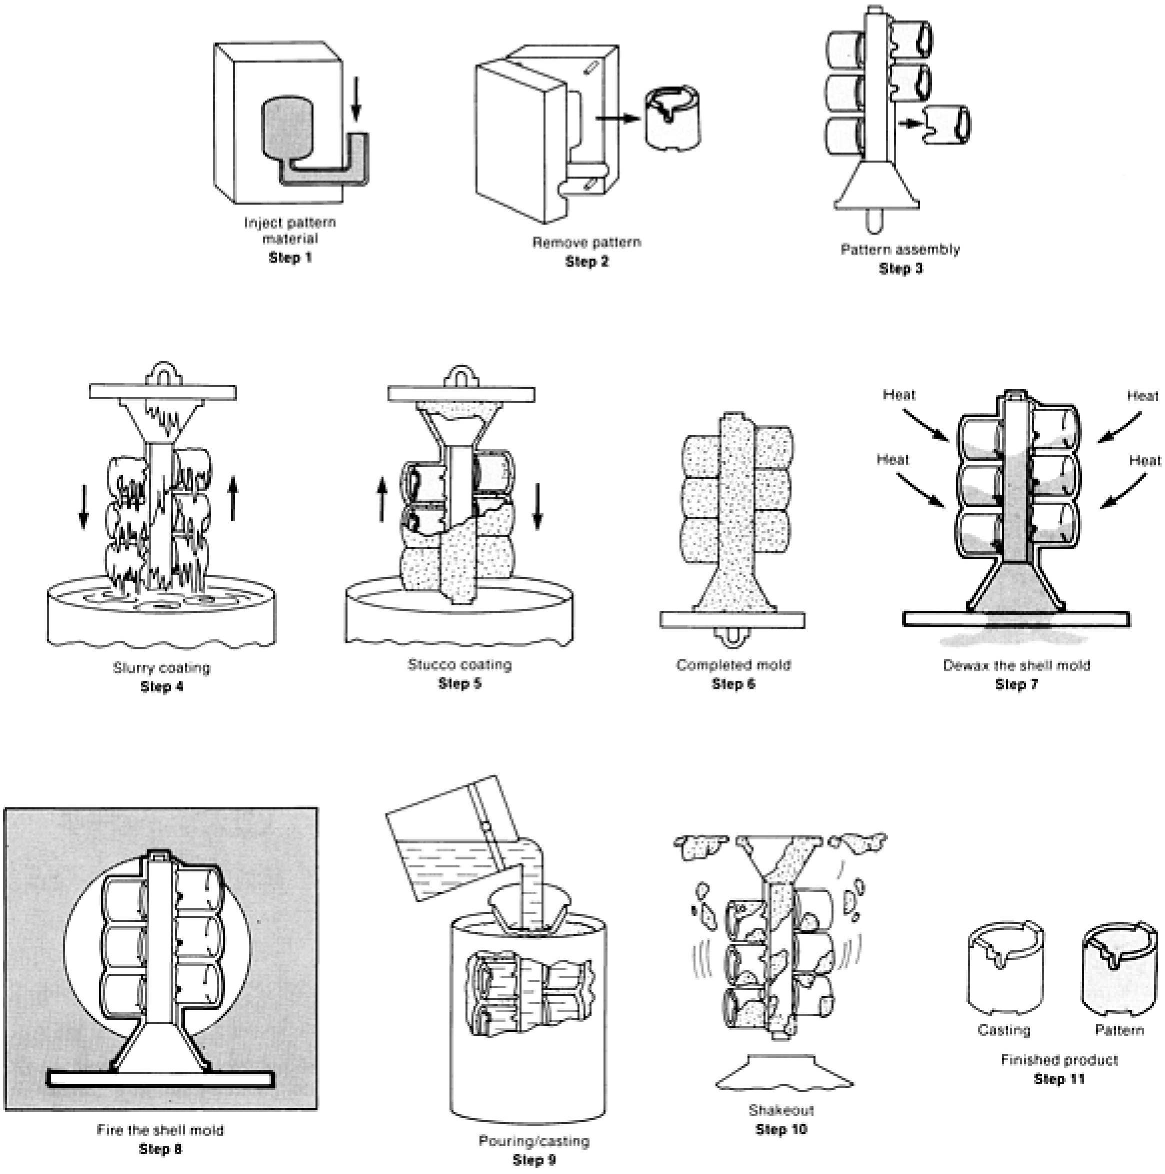

Fig. 3 Basic steps involved in investment casting

Although it has a wide variety of applications, investment casting is particularly favored for the production of parts for gas turbine blades and vanes (nickel and cobalt alloys) and aircraft structural components (titanium, superalloys, and 17-4 PH stainless steel). The application of directional solidification (DS) and single-crystal (SC) technology to investment casting has also increased interest and use. Detailed information on developments in DS/SC technology can be found in the following articles in this Volume:

- "Solidification of Single-Phase Alloys"
- "Directional and Monocrystal Solidification"
- "Vacuum Melting and Remelting Processes"
- "Nickel and Nickel Alloys"

Examples of investment castings for critical applications are shown in Fig. 4(a), 4(b), and 4(c).

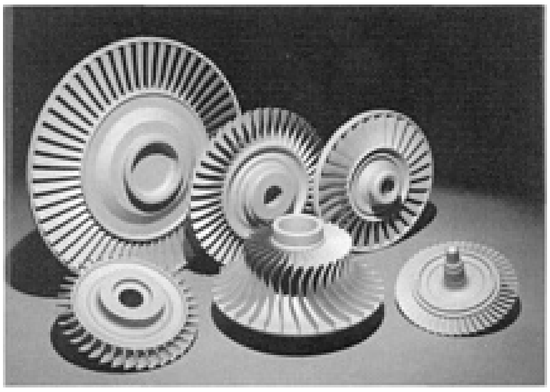

Fig. 4(b) Radial and axial turbine wheels made from investment cast Mar-M-247 nickel-base superalloy. Courtesy of Howmet Corporation, Whitehall Casting Division

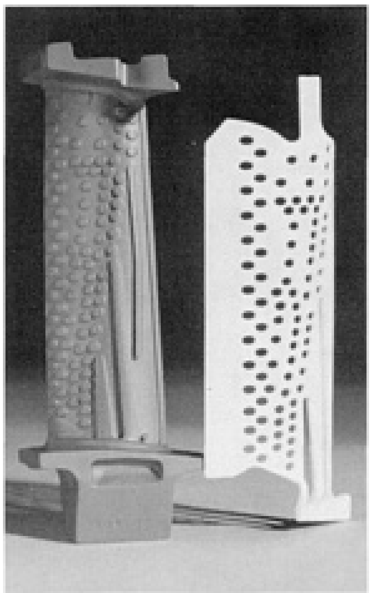

Fig. 4(c) Investment cast turbine blade with convex wall removed showing complex core

Permanent mold processes involve the use of metallic (ferrous) or solid graphite molds. On a volume basis, die casting, centrifugal casting, and permanent mold (gravity die) casting are the most important. Each of these is covered in detail in this Section. As indicated in Table 1, however, a number of hybrid processes, such as squeeze casting and semisolid metal processing have been developed that use permanent molds. Figure 5 shows a flowchart of operations for the rheocast method of semisolid casting. This process involves vigorous agitation of the melt during the early stages of solidification to break up the solid dendrites into small spherulites. The benefits provided by semisolid forming processes, as well as the microstructures produced by these methods, are discussed in the articles "Semisolid Metal Casting and Forging" and "Zinc and Zinc Alloys" in this Volume.

Aggregate Molding Materials

Thomas S. Piwonka, University of Alabama

Introduction

THE CASTING PROCESS involves the pouring of molten metal into a mold; therefore, the mold material and molding method must be selected with care. Most castings are made in sand molds because metallic molds wear out too quickly to be economical for ferrous metals production. For low and medium production runs, the lower tooling costs of sand molding give it an overwhelming cost advantage over permanent molds or die casting.

Selection of the molding material and its bonding system depends on the type of metal being poured, the type of casting being made, the availability of molding aggregates, the mold and core making equipment owned by the foundry, and the quality requirements of the customer. A thorough understanding of all of these factors is necessary to optimize the molding system used in the foundry.

This article will discuss the various materials used to produce molds and cores for sand casting. These materials include sands, clays, additions to sand mixes, and plastics. The principles that explain how these materials are bonded together are discussed in the articles "Bonds Formed in Molding Aggregates" and "Resin Binder Processes" in this Section. Additional information on the preparation, mulling, handling, and reclamation of sands is available in the article "Sand Processing" in this Volume.

Sands

The refractory molds used in casting consist of a particulate refractory material (sand) that is bonded together to hold its shape during pouring. Although various sands can be used, the following basic requirements apply to each (Ref 1):

- Dimensional and thermal stability at elevated temperatures
- Suitable particle size and shape
- Chemically unreactive with molten metals
- Not readily wetted by molten metals
- Freedom from volatiles that produce gas upon heating
- Economical availability
- Consistent cleanliness, composition, and pH
- Compatibility with binder systems

Many minerals possess some of these features, but few have them all.

Silica Sands

Most green sand molds consist of silica sands bonded with a bentonite-water mixture. (The term green means that the mold, which is tempered with water, is not dried or baked.) The composition, size, size distribution, purity, and shape of the sand are important to the success of the moldmaking operation.

Sands are sometimes referred to as natural or synthetic. Natural sands contain enough naturally occurring clays that they can be mixed with water and used for sand molding. Synthetic sands have been washed to remove clay and other impurities, carefully screened and classified to give a desired size distribution, and then reblended with clays and other materials to produce an optimized sand for the casting being produced. Because of the demands of modern high-pressure

molding machines and the necessity to exercise close control over every aspect of casting production, most foundries use only synthetic sands.

Composition. Foundry sands are composed almost entirely of silica (SiO_2) in the form of quartz. Some impurities may be present, such as ilmenite ($FeO-TiO_2$), magnetite (Fe_3O_4), or olivine, which is composed of magnesium and ferrous orthosilicate [(Mg,Fe) SiO_4]. Silica sand is used primarily because it is readily available and inexpensive. However, its various shortcomings as a foundry sand necessitate the addition of other materials to the sand mix to produce satisfactory castings, as described later in this article.

Quartz undergoes a series of crystallographic transitions as it is heated. The first, at 573 °C (1064 °F), is accompanied by expansion, which can cause mold spalling. Above 870 °C (1598 °F), quartz transforms to tridymite, and the sand may actually contract upon heating. At still higher temperatures (> 1470 °C, or 2678 °F), tridymite transforms to cristobalite.

In addition, silica reacts with molten iron to form a slag-type compound, which can cause burn-in, or the formation of a rough layer of sand and metal that adheres to the casting surface. However, because these problems with silica can be alleviated by proper additions to the sand mix, silica remains the most widely used molding aggregate.

Shape and Distribution of Sand Grains. The size, size distribution, and shape of the sand grains are important in controlling the quality of the mold. Most mold aggregates are mixtures of new sand and reclaimed sand, which contain not only reclaimed molding sand but also core sands. In determining the size, shape, and distribution of the sand grains, it is important to realize that the grain shape contributes to the amount of sand surface area and that the grain size distribution controls the permeability of the mold.

As the sand surface area increases, the amount of bonding material (normally clay and water) must increase if the sand is to be properly bonded. Thus, a change in surface area, perhaps due to a change in sand shape or the percentage of core sand being reclaimed, will result in a corresponding change in the amount of bond required.

Rounded grains have a low surface-area-to-volume ratio and are therefore preferred for making cores because they require the least amount of binder. However, when they are recycled into the molding sand system, their shape can be a disadvantage if the molding system normally uses a high percentage of clay and water to facilitate rapid, automatic molding. This is because rounded grains require less binder than the rest of the system sand.

Angular sands have the greatest surface area (except for sands that fracture easily and produce a large percentage of small grains and fines) and therefore require more mulling, bond, and moisture. The angularity of a sand increases with use because the sand is broken down by thermal and mechanical shock.

The subangular-to-round classification is most commonly used, and it affords a compromise if shape becomes a factor in the sand system. However, control of grain size distribution is more important than control of grain shape. The grain size distribution, which includes the base sand size distribution plus the distribution of broken grains and fines from both molding sand and core sands, controls both the surface area and the packing density or porosity of the mold.

The porosity of the mold controls its permeability, which is the ability of the mold to allow gases generated during pouring to escape through the mold. The highest porosity will result from grains that are all approximately the same size. As the size distribution broadens, there are more grains that are small enough to fill the spaces between large grains. As grains break down through repeated recycling, there are more and more of the smaller grains, and the porosity of the mold decreases.

However, if the porosity of the mold is too great, metal may penetrate the sand grains and cause a burn-in defect. Therefore, it is necessary to balance the base sand distribution and continue to screen the sand and use dust collectors during recycling to remove fines and to determine the proper bond addition. Most foundries in the United States use the American Foundrymens' Society (AFS) grain fineness number as a general indication of sand fineness. The AFS grain fineness number of sand is approximately the number of openings per inch of a given sieve that would just pass the sample if its grains were of uniform size, that is, the weighted average of the sizes of grains in the sample. It is approximately proportional to the surface area per unit weight of sand exclusive of clay.

The AFS grain fineness number is determined by taking the percentage of sand retained on each of a series of standard screens, multiplying each by a multiplier, adding the total, and then dividing by the total percentage of sand retained on

the sieves (Ref 2). Table 1 lists the series of sieves used to run the standard AFS standard sieve analysis. A typical calculation of the AFS fineness number, which includes the multiplier factor, is given in Table 2.

Table 1 Screen scale sieves equivalent

USA series No.	Tyler screen scale sieves, openings per lineal inch	Sieve opening, mm	Sieve opening, µm	Sieve opening, in., ratio $\sqrt{2}$, or 1.414	Permissible variation in average opening, ±mm	Wire diameter, mm
6	6	3.35	3350	. . .	0.11	1.23
8[a]	8[a]	2.36	2360	0.0937	0.08	1.00
12	10	1.70	1700	0.0661	0.06	0.810
16[a]	14[a]	1.18	1180	0.0469	0.045	0.650
20	20	0.850	850	0.0331	0.035	0.510
30	28	0.600	600	0.0234	0.025	0.390
40	35	0.425	425	0.0165	0.019	0.290
50	48	0.300	300	0.0117	0.014	0.215
70	65	0.212	212	0.0083	0.010	0.152
100	100	0.150	150	0.0059	0.008	0.110
140	150	0.106	106	0.0041	0.006	0.076
200	200	0.075	75	0.0029	0.005	0.053
270	270	0.053	53	0.0021	0.004	0.037

Note: A fixed ratio exists between the different sizes of the screen scale. This fixed ratio between the different sizes of the screen scale has been taken as 1.414, or the square root of 2 ($\sqrt{2}$). For example, using the USA series equivalent No. 200 as the starting sieve, the width of each successive opening is exactly 1.414 times the opening in the previous sieve. The area or surface of each successive opening in the scale is double that of the next finer sieve or one-half that of the next coarser sieve. That is, the widths of the successive openings have a constant ratio of 1.414, and the areas of the successive openings have a constant ratio of $\sqrt{2}$. This fixed ratio is very convenient; by skipping every other screen, a fixed ratio of width of 2 to 1 exists. Source: Ref 2

(a) These sieves are not normally used for testing foundry sands.

Table 2 Typical calculation of AFS grain fineness number

Size of sample: 50 g; AFS clay content: 5.9 g, or 11.8%; sand grains: 44.1 g, or 88.2%

USA sieve series No.	**Amount of 50 g sample retained on sieve**		**Multiplier**	Product
	g	**%**		
6	none	0.0	3	**0**
12	none	0.0	5	**0**
20	none	0.0	10	**0**
30	none	0.0	20	**0**
40	0.20	0.4	30	**12**
50	0.65	1.3	40	**52**
70	1.20	2.4	50	**120**
100	2.25	4.5	70	**315**
140	8.55	17.1	100	**1710**
200	11.05	22.1	140	**3094**
270	10.90	21.8	200	**4360**
Pan	9.30	18.6	300	**5580**
Total	44.10	88.2		15,243

It is important to understand that various grain distributions and grain shape classifications can result in similar grain fineness numbers. Table 3 provides a sample sieve analysis demonstrating that two sands assigned the same AFS grain fineness number can have very different grain size distributions.

Table 3 Similarity in AFS grain fineness number of two sand samples with different grain size distributions

USA sieve No.	Percentage retained

	Sand A	Sand B
6	0.0	**0.0**
12	0.0	**0.0**
20	0.0	**0.0**
30	1.0	**0.0**
40	24.0	**1.0**
50	22.0	**24.0**
70	16.0	**41.0**
100	17.0	**24.0**
140	14.0	**7.0**
200	4.0	**2.0**
270	1.7	**0.0**
Pan	0.3	**1.0**
Total	**100.0**	100.0
AFS grain fineness No	**60.0**	**60.0**

Source: Ref 2

Preparation of Sands. The production of sand for the foundry industry requires a series of mining and refining steps to yield pure, consistent sands (Ref 3). The actual production flow sheets vary with the source of the sand, but in general they include mining, one or more scalping operations to remove roots and pebbles, and then repeated washing and desliming operations to remove naturally occurring clays. The sand is screened and/or classified and then prepared for shipment to the foundry.

Zircon

Zircon is zirconium silicate ($ZrSiO_4$). It is highly refractory and possesses excellent foundry characteristics (Ref 2). Its primary advantages are a very low thermal expansion, high thermal conductivity and bulk density (which gives it a chilling rate about four times that of quartz), and very low reactivity with molten metal. Zircon requires less binder than other sands because its grains are rounded. The very high dimensional and thermal stabilities exhibited by zircon are the reasons it is widely used in steel foundries and investment foundries making high-temperature alloy components.

Olivine

Olivine minerals (so called because of their characteristic green color) are a solid solution of forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4). Their physical properties vary with their chemical compositions; therefore, the composition of the olivine used must be specified to control the reproducibility of the sand mixture. Care must be taken to calcine the olivine sand before use to decompose the serpentine content, which contains water (Ref 4).

The specific heat of olivine is similar to that of silica (Ref 5), but its thermal expansion is far less. Therefore, olivine is used for steel casting to control mold dimensions. Olivine is somewhat less durable than silica (Ref 1), and it is an angular sand.

Chromite

Chromite ($FeCr_2O_4$), a black, angular sand, is highly refractory and chemically unreactive, and it has good thermal stability and excellent chilling properties (Ref 1). However, it has twice the thermal expansion of zircon sand, and it often contains hydrous impurities that cause pinholing and gas defects in castings. It is necessary to specify the calcium oxide (CaO) and silicon dioxide (SiO_2) limits in chromite sand to avoid sintering reactions and reactions with molten metal that cause burn-in (Ref 4).

Aluminum Silicates

Aluminum silicate (Al_2SiO_5) occurs in three common forms: kyanite, sillimanite, and andalusite. All break down at high temperatures to form mullite and silica (Ref 1). Therefore, aluminum silicates for foundry use are produced by calcining these minerals. Depending on the sintering cycle, the silica may be present as cristobalite or as amorphous silica. The grains are highly angular. These materials have high refractoriness, low thermal expansion, and high resistance to thermal shock. They are widely used in precision investment foundries, often in combination with zircon.

Clays

Bonds in green sand molds are produced by the interaction of clay and water. Each of the various clays has different properties, as described below.

Bentonites

The most common clays used in bonding green sand molds are bentonites, which are forms of montmorillonite or hydrated aluminum silicate. Montmorillonite is built up of alternating tetrahedra of silicon atoms surrounded by oxygen atoms, and aluminum atoms surrounded by oxygen atoms, as shown in Fig. 1. This is a layered structure, and it produces clay particles that are flat plates. Water is adsorbed on the surfaces of these plates, and this causes bentonite to expand in the presence of water and to contract when dried.

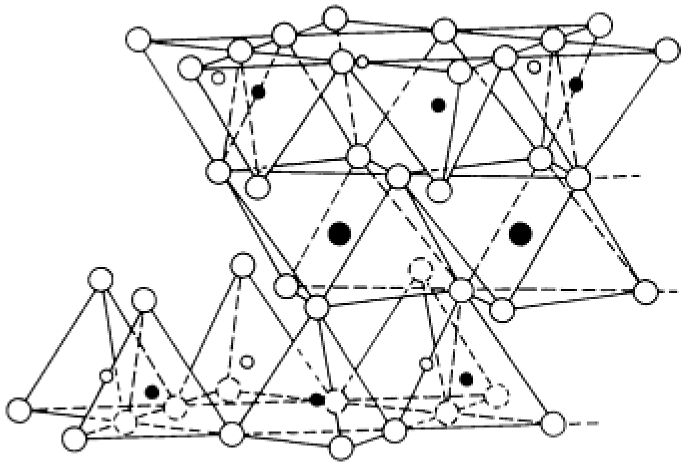

Fig. 1 Structure of montmorillonite. Large closed circles are aluminum, magnesium, sodium, or calcium. Small closed circles are silicon. Large open circles are hydroxyls. Small open circles are oxygen.

There are two forms of bentonite: Western (sodium) and Southern (calcium). Both are used in foundry sands, but they have somewhat different properties.

Western Bentonite. In Western bentonite, some of the aluminum atoms are replaced by sodium atoms. This gives the clay a net negative charge, which increases its activity and its ability to adsorb water. Western bentonite imparts high green and dry strengths to molding sand, and it has advantages for use with ferrous alloys, as follows.

First, Western bentonite develops a high degree of plasticity, toughness, and deformation, along with providing good lubricity when mulled thoroughly with water. Molding sand bonded with plasticized Western bentonite squeezed uniformly around a pattern produces excellent mold strengths.

Second, because of its ability to swell with water additions to as much as 13 times its original volume, Western bentonite is an excellent agent between the sand grains after compaction in the mold. It therefore plays an important role in reducing sand expansion defects.

Finally, Western bentonite has a high degree of durability. This characteristic allows it to be reused many times in a system sand with the least amount of rebonding additions.

In using Western bentonite, it is important to control the clay/water ratio. Failure to do so can result in stiff, tough, difficult-to-mold sand with poor shakeout characteristics. Although these conditions can be alleviated by adding other materials to the molding sand, control of the mixture is preferable.

Southern Bentonite. In Southern bentonites, some of the aluminum atoms are replaced by calcium atoms. Again, this increases the ion exchange capability of the clay. Southern bentonite is a lower-swelling clay, and it differs from Western bentonite in the following ways:

- It develops a higher green compressive strength with less mulling time
- Its dry compressive strength is about 30 to 40% lower
- Its hot compressive strength is lower, which improves shakeout characteristics
- A Southern bentonite bonded sand flows more easily than Western bentonite and can be squeezed to higher densities with less pressure; it is therefore better for use with complex patterns containing crevices and pockets

Use of Southern bentonite also requires good control of the clay-water mixture. Southern bentonite requires less water than Western bentonite and is less durable.

In practice, it is common to blend Western and Southern bentonites together to optimize the sand properties for the type of casting, the molding equipment, and the metal being poured. Examples of the effect of mixing bentonites on various sand properties are shown in Fig. 2. At high temperatures, bentonites lose their adsorbed water and therefore their capacity for bonding. The superior high-temperature properties of Western bentonite are due to the fact that it retains water to higher temperatures than Southern bentonite (Ref 6). However, if the sand mix is heated to more than 600 °C (1110 °F), water is driven out of the clay crystal structure. This loss is irreversible, and the clay must be discarded.

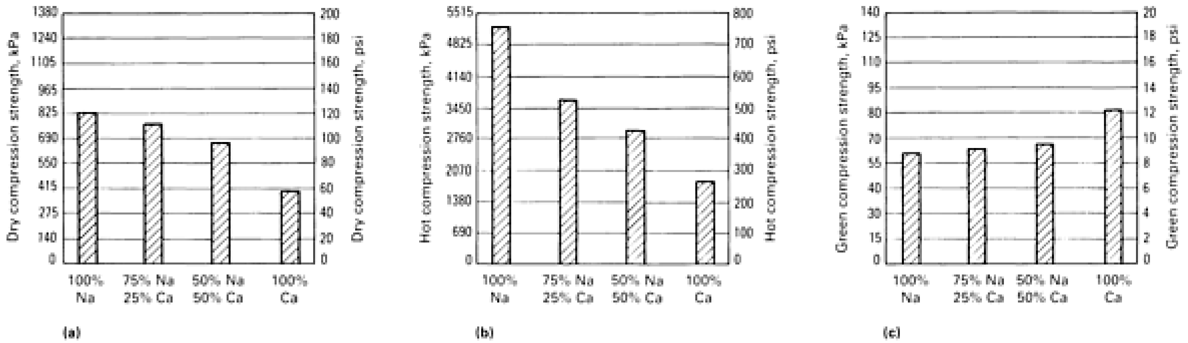

Fig. 2 Effect of blending sodium and calcium bentonites on molding sand properties. (a) Dry compression strength. (b) Hot compression strength at 900 °C (1650 °F). (c) Green compression strength

Fireclay

Fireclay consists essentially of kaolinite, a hydrous aluminum silicate that is usually combined with bentonites in molding sand. It is highly refractory, but has low plasticity. It improves the hot strength of the mold and allows the water content to be varied over greater ranges. Because of its high hot strength potential, it is used for large castings. It is also used to improve sieve analysis by creating fines whenever the system does not have an optimum wide sieve distribution of the base sand. However, because of its low durability, its use is generally limited. In addition, the need for fireclay can usually be eliminated through close control of sand mixes and materials.

Other Additions to Sand Mixes

As noted above, silica sand, although inexpensive, has some shortcomings as a molding sand. If done properly, the addition of other materials can alleviate these deficiencies.

Carbonaceous Additions. Carbon is added to the mold to provide a reducing atmosphere and a gas film during pouring that protects against oxidation of the metal and reduces burn-in. Carbon can be added in the form of seacoal (finely ground bituminous coal), asphalt, gilsonite (a naturally occurring asphaltite), or proprietary petroleum products. Seacoal changes to coke at high temperatures expanding three times as it does so; this action fills voids at the mold/metal interface. Too much carbon in the mold gives smoke, fumes, and gas defects, and the use of asphalt products must be controlled closely because their overuse waterproofs the sand.

The addition of carbonaceous materials will give improved surface finish to castings. Best results are achieved with such materials as seacoal and pitch, which volatilize and deposit a pyrolytic (lustrous) carbon layer on sand at the casting surface (Ref 7).

Cellulose is added to control sand expansion and to broaden the allowable water content range. It is usually added in the form of wood flour, or ground cereal husks or nut shells. Cellulose reduces hot compressive strength and provides good collapsibility, thus improving shakeout. At high temperatures, it forms soot (an amorphous form of carbon), which deposits at the mold/metal interface and resists wetting by metal or slags. It also improves the flowability of the sand during molding. Excessive amounts generate smoke and fumes and can cause gas defects. In addition, if present when the clay content drops too low, defects such as cuts, washes, and mold inclusions will occur in the castings.

Cereals, which include corn flour, dextrine, and other starches, are adhesive when wetted and therefore act as a binder. They stiffen the sand and improve its ability to draw deep pockets. However, use of cereals makes shakeout more difficult, and excessive quantities make the sand tough and can cause the sand to form balls in the muller. Because cereals are volatile, they can cause gas defects in castings if used improperly.

Plastics

Plastic materials, or resins, are widely used in metal casting as binders for sand, particularly for cores of all sizes and production volumes, and for low-volume high-accuracy molding. Generally, these materials fall into three categories:

- Those composed of liquid polymeric binders that cross link and set up in the presence of a catalyst (thus transforming from a liquid to a solid)
- Those composed of two reactants that form a solid polymeric structure in the presence of a catalyst
- Those that are heat activated

Fluid-to-solid transition plastics are primarily furfuryl alcohol-base binders that are cured with acid catalysts. The polymers coat the sand when in the liquid form and are mixed with the liquid catalyst just before being placed in the core box. Alternatively, the catalyst can be delivered to the mix as a gas once the sand mix is in the core box.

Reaction-based plastics include phenolics (phenol/aldehyde), oil/urethanes, phenolic/polymeric isocyanates, and polyol/isocyanate systems. Curing catalysts include esters, amines, and acids, which can be delivered to the core mix either as liquids or gases.

Heat-activated plastics are primarily thermoplastics or thermosetting resins such as novolacs, furans (furfuryl alcohols), phenols, and linseed oils. They are applied as dry powders to the sand, and the mix is heated, at which time the powders melt, flow over the sand, and then undergo a thermosetting reaction. Alternatively, they may consist of two liquids that react to form a solid in the presence of heat.

Most binder systems are proprietary. The major ingredients are often mixed with non-reactive materials to control the reaction rate. The reactants are often dissolved in solvents to facilitate handling. Although various materials and schemes are used to form organic bonds in mold and core making, the technology rests on only a few compounds.

The presence of so many different systems allows casting producers to tailor the bonding system to the particular application. However, selection of the bonding system requires care. Care must also be taken in controlling process parameters because the systems are sensitive to variations in temperature and humidity. Consideration must also be given to environmental issues in the selection of the system because some organic systems emit noxious odors and fumes. More detailed information on organic binders can be found in the article "Resin Binder Processes" in this Volume.

Bonds Formed in Molding Aggregates

Thomas S. Piwonka, University of Alabama

Introduction

MOLDING AGGREGATES must be held together, or bonded, to form a mold. By far the most common types of bonds are those formed from sand, clay, and additives. These materials are described in the previous article "Aggregate Molding Materials" in this Section. Organic bonds, described briefly here and in detail in the following article "Resin Binder Processes," also have a substantial part of the market for core making.

Silica-Base Bonds

Because of the abundance and low cost of clays, green sand molds are normally clay bonded, but various forms of silica can also be used in bonding molding aggregates.

Clay-Water Bonds. As noted in the article "Aggregate Molding Materials," bentonites are not electrically neutral and can therefore attract water molecules between the clay plates. Water is also adsorbed on the quartz surfaces. Thus, there is a network of water adsorbed on sand and clay particles that is set up throughout the molding sand. If the clay covers each sand grain entirely, then clay-water bridges form between grains (Ref 1). In the case in which the clay coverage is nonuniform, similar bridges are formed.

The clay-water bond can also be explained in terms of the specific surface area of the clay, the type and strength of the water bond at the clay surface, and the hydration envelopes of the adsorbed cations (Ref 2, 3). Clay particles hold adsorbed cations on their surfaces. The bonding of cations on clay particles is weak, and ion exchange is possible in the presence of appropriate electrolytes. Therefore, clay particles and ions are surrounded by electric force fields that direct the water dipoles (the water is polarized at the clay surface) and bind the water network. The field strength decreases with increased distance from the surface of the clay, so that the dipoles closest to the clay surface are bonded most strongly. Beyond the distance at which the force field is effective, the water behaves as a liquid and has no bonding action.

There is an ideal water content at which all of the water is polarized and active in the bonding process (because the water added to activate the clay bond is called temper water, this is known as the temper point). Above this water content, some of the water will exist as liquid water, which is not involved in bonding. Below this value, there is insufficient water to develop the bond fully. At the temper point, the green strength of the sand is at its maximum, and additions of water beyond this point decrease the strength of the sand/clay/water mixture. The effect of this can be seen quite clearly in Fig. 1.

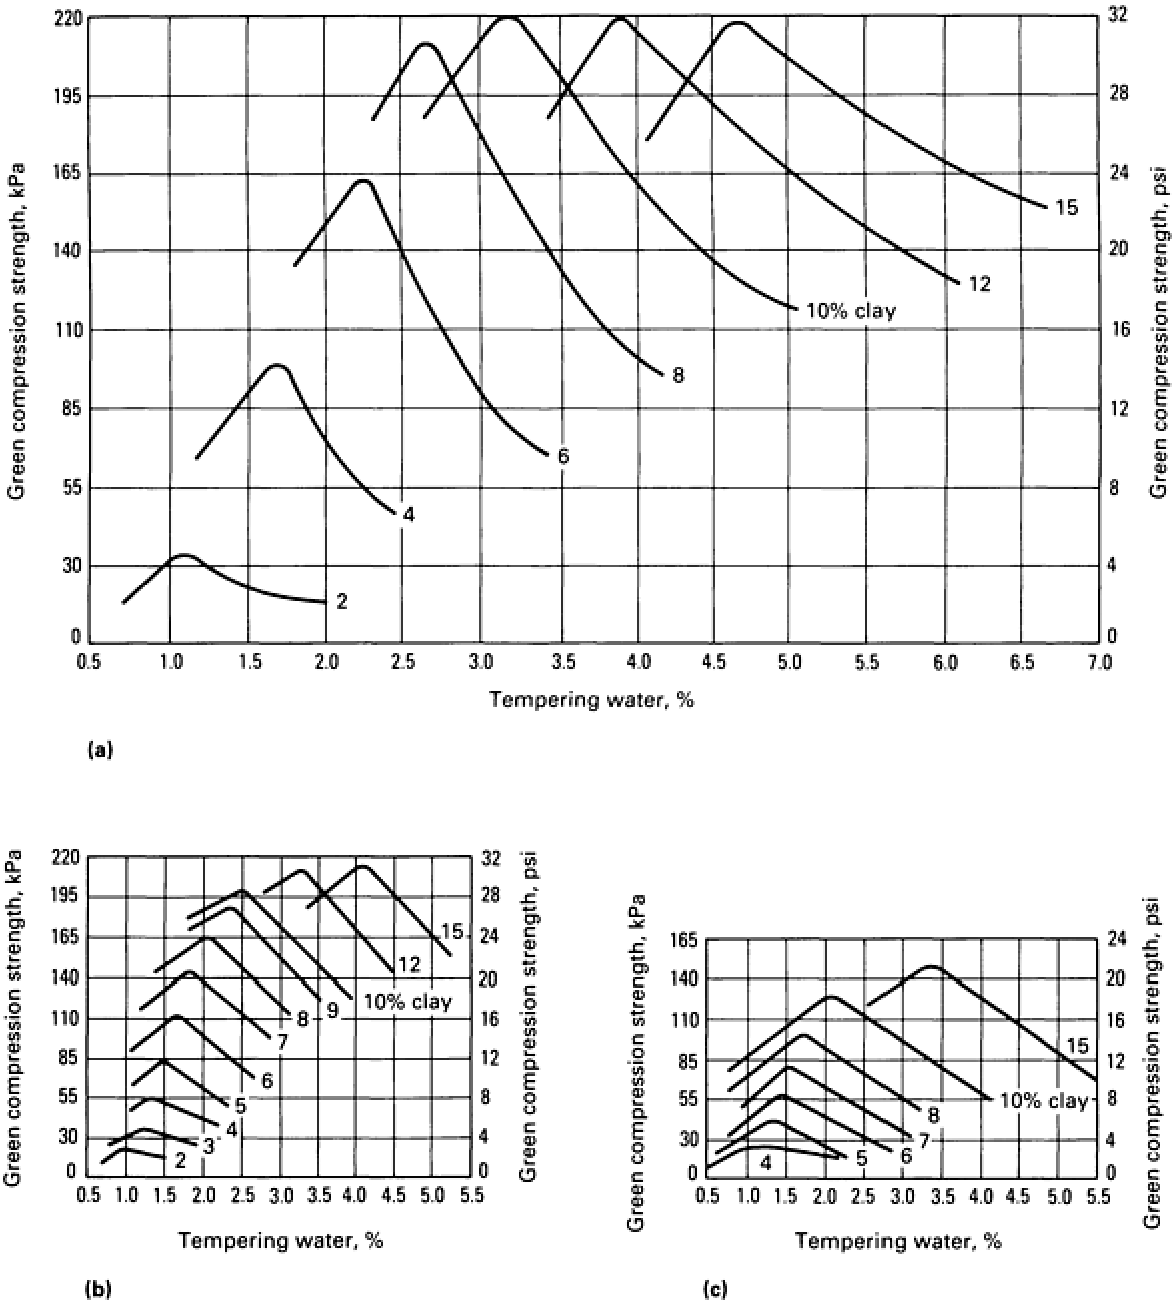

Fig. 1 Variation of mold properties with water content. (a) Southern bentonite. (b) Western bentonite. (c) Kaolinite. Source: Ref 1

Colloidal silica bonds are used in investment casting. Colloidal silica particles are about 4 to 40 nm in diameter and form a sol in water. Their stability is determined by surface charge, pH, particle size, concentration, and electrolyte content (Ref 4). The silica is spherical and amorphous, and it contains a small amount of a radical, such as a hydroxide, to impart a negative charge to each particle so that they repel each other and do not settle out. When water evaporates from these sols (as happens when the mold layers are dried), the silica particles are forced close enough together for hydroxyl groups to condense, splitting out the water and forming siloxane bonds between the aggregates (Ref 5).

The molds made from colloidal silica are dried in air and have enough strength to retain their shapes. However, they must be fired at an elevated temperature (>815 °C, or 1500 °F) to develop a strong silica ceramic bond. Each mold system has an optimum silica content for maximum mold strength. More detailed information on colloidal silica bonds can be found in the article "Investment Casting" in this Volume.

Ethyl Silicate. An alternate silica bond can be produced from hydrolyzed ethyl silicates. These are precipitation bonds, such as (Ref 4):

$$[n\ Si(OH)_4] \rightarrow [SiO(OH)_{2n} + nH_2O]$$

The precipitated silicate bond is a gel that comes out of suspension by a change in binder ion concentration.

Hydrolyzed ethyl silicate is manufactured by the reaction of silicon tetrachloride with ethyl alcohol. Two types of ethyl silicate are commonly available. Ethyl silicate 30, the first type, is a mixture of tetraethyl orthosilicate and polysilicates containing about 28% silica. Ethyl silicate 40, the second type, is a mixture of branched silicate polymers containing about 40% silica.

Slurries formed from these ethyl silicates and mold aggregates, such as fused silica or zircon, are very sensitive to changes in pH. The slurries are normally kept at a pH of around 3. To gel them around a pattern, they are exposed to ammonia vapor, and their pH increases to 5, where they gel. The shells are then fired, and the ethyl alcohol evaporates or burns off, causing the silica binders to condense and form the silica bond. Ethyl silicate molds have an advantage over colloidal silica in that they do not require long drying times between dips and can be used for monolithic block molds. However, the mold strength of these molds is much less than that of colloidal silicate bonded molds because of the fine craze cracking that occurs during firing. On the other hand, this fine network of cracks is also responsible for the high dimensional reproducibility of castings made in block molds. Additional information on ethyl silicate molds can be found in the article "Investment Casting" in this Volume.

Sodium Silicate Bonds. The sodium silicate process is another method of forming a bond made up of a silicate polymer. In this case, carbon dioxide is used to precipitate sodium from what is essentially silicic acid containing large quantities of colloidal sodium. The reaction is:

$$Na_2O\ 2SiO_2 + CO_2 \rightarrow Na_2CO_3 + 2SiO_2$$

Continued gassing gives:

$$Na_2O\ 2SiO_2 + 2CO_2 + H_2O \rightarrow 2Na_2HCO_3 + 2SiO_2$$

This shows that continued gassing dehydrates the amorphous silica gel and increases the strength of the mold (Ref 6).

Sodium silicate molds are widely used for large cores and castings where there is a premium on mold hardness and dimensional control. The bond breaks down easily at high temperatures and therefore facilitates shakeout. The silicate-bonded sand, after pouring and shakeout, can be reclaimed by mechanical means, and up to 60% of the reclaimed sand can be reused. Wet reclamation of silicate sand systems is also possible. Additional information on sodium silicate molds can be found in the article "Sand Molding" (see the section "Bonded Sand Molds") in this Volume.

Phosphoric Acid Bonds

Phosphoric acid bonds are used in both ferrous and nonferrous precision casting to produce monolithic molds. They are a reaction-type bond with the general form:

$$[MO + H_3PO_4 \rightarrow M(HPO_4) + H_2O]$$

where *M* is an oxide frit or mixture of frits. The pH must be controlled carefully and kept acidic (Ref 4). The powdered metal oxide hardener is dry blended with the sand, and the liquified phosphoric acid is then incorporated. The coated sand is compacted into core or pattern boxes and allowed to harden chemically before removal. A similar procedure for producing phosphate bonds is described in the article "Sand Molding" (see the section "Bonded Sand Molds") in this Volume.

Organic Bonds

Organic bonds are used in resin-bonded sand systems. These systems vary widely. The sand is coated with two reactants that form a resin upon the application of heat or a chemical catalyst. The resin is a solid plastic that coats the sand so that it holds its shape during pouring. A thorough review of organically bonded systems can be found in the following article, "Resin Binder Processes," in this Section.

Resin Binder Processes

James J. Archibald and Richard L. Smith, Ashland Chemical Company

---

Introduction

THE FOUNDRY INDUSTRY uses a variety of procedures for casting metal parts. These include such processes as permanent mold casting, centrifugal casting, evaporative pattern casting, and sand casting, all of which are described in the Section "Molding and Casting Processes" in this Volume. In sand casting, molds and cores are used. Cores are required for hollow castings and must be removed after the metal has solidified.

Binders were developed to strengthen the cores, which are the most fragile part of a mold assembly. Although the use of binders in mold production is increasing, most sand casting employs green sand molds, which are made of sand, clay, and additives (green sand molding is described in the section "Bonded Sand Molds" in the article "Sand Molding" in this Volume).

Inorganic binders, such as clay or cement, are materials that have long been used in the production of foundry molds and cores. This article is limited to organic resin-base binders for sand molding. In practice, these binders are mixed with sand, the mixes are compressed into the desired shape of the mold or core, and the binders are hardened, that is, cured, by

chemical or thermal reactions to fixate the shapes. Typically, 0.7 to 4.0 parts (usually 1 to 2 parts) of binder are added to 100 parts of sand.

Classification of Resin Binder Processes

Although a wide variety of resin binder processes are currently used, they can be classified into the following categories:

- No-bake binder systems
- Heat-cured binder systems
- Cold box binder systems

In the no-bake and cold box processes, the binder is cured at room temperature; in the shell molding, hot box, and oven-bake processes, heat cures are applied. Selection of the process and type of binder depends on the size and number of cores or molds required, production rates, and equipment. Properties of the various binder systems are described below and compared in Tables 1, 2, and 3. Figure 1 summarizes the trends in resin binder usage in the foundry industry.

No-Bake Processes

A no-bake process is based on the ambient-temperature cure of two or more binder components after they are combined on sand. Curing of the binder system begins immediately after all colponents are combined. For a period of time after initial mixing, the sand mix is workable and flowable to allow the filling of the core/mold pattern. After an additional time period, the sand mix cures to the point where it can be removed from the box. The time difference between filling

and stripping of the box can range from a few minutes to several hours, depending on the binder system used, curing agent and amount, sand type, and sand temperature.

Furan Acid Catalyzed No-Bake. Furfuryl alcohol is the basic raw material used in furan no-bake binders. Furan binders can be modified with urea, formaldehyde, phenol, and a variety of other reactive or non-reactive additives.

The great variety of furan binders available provides widely differing performance characteristics for use in various foundry applications. Water content may be as high as 15% and nitrogen content as high as 10% in resins modified with urea. In addition, zero-nitrogen and zero-water binders are available. The choice of a specific binder depends on the type of metal to be cast and the sand performance properties required. The amount of furan no-bake binders used ranges between 0.9 and 2.0% based on sand weight. Acid catalyst levels vary between 20 and 50% based on the weight of the binder. The speed of the curing reaction can be adjusted by changing the catalyst type or percentage, given that the sand type and temperature are constant. The furan no-bake curing mechanism is shown in Fig. 2.

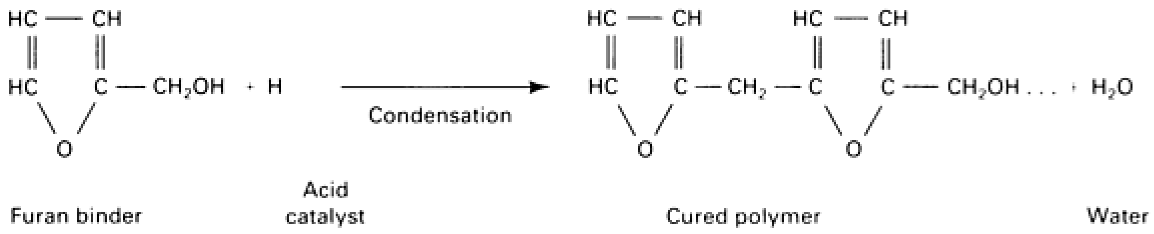

Fig. 2 The furan acid-catalyzed no-bake curing mechanism

Furan no-bake binders provide high dimensional accuracy and a high degree of resistance to sand/metal interface casting defects, yet they decompose readily after the metal has solidified, providing excellent shakeout. Furan no-bake binders also exhibit high tensile strength, along with the excellent hot strength needed for flaskless no-bake molding. They often run sand-to-metal ratios of as low as 2:1.

Phenolic Acid Catalyzed No-Bake. Phenolic resins are condensation reaction products of phenol(s) and aldehyde(s). Phenolic no-bake resins are those formed from phenol/formaldehyde where the phenol/formaldehyde molar ratio is less than 1. Again, as with furan no-bakes, these resins can be modified with reactive or nonreactive additives.

These resins are clear to dark brown in appearance, and their viscosities range from medium to high. Sand mixes made with these resins have adequate flowability for the filling of mold patterns or core boxes. Resins of this type contain free phenol and free formaldehyde. Phenol and formaldehyde odors can be expected during sand-mixing operations.

One disadvantage of acid-cured phenolic no-bake resins is their relatively poor storage stability. Phenolic binders are usually not stored for more than 6 months. Phenolic resole resins contain numerous reactive methylol groups, and these are generally involved in auto-polymerization reactions at ambient or slightly elevated temperatures. The storage period can be considerably longer during the winter months if the temperature of storage remains at 20 °C (70 °F) or lower. The viscosity advances as the binder ages.

The catalyst needed for the phenolic no-bake resin is a strong sulfonic acid type. Phosphoric acids will not cure phenolic resins at the rate required for most no-bake foundry applications.

The phenolic no-bake reaction mechanism is:

$$\text{Phenolic resin} + \text{Acid catalyst} \rightarrow \text{Cured polymer} + \text{Water}$$

The catalyst initiates further condensation of the resin and advances the cross-linking reaction. The condensation reactions produce water which results in a dilution effect on the acid catalyst that tends to slow the rate of cure. Because of this effect, it is necessary to use strong acid catalysts to ensure an acceptable rate of cure and good deep set properties.

Ester-Cured Alkaline Phenolic No-Bake. The ester-cured phenolic binder system is a two-part binder system consisting of a water-soluble alkaline phenolic resin and liquid ester co-reactants. The reaction mechanism is:

Alkaline phenolic resin + Ester co-reactant
$\rightarrow$ Suspected unstable intermediate
$\rightarrow$ Splits to form:
Polymerized phenolic resin
Alkaline salts and alcohol

A secondary reaction is thought to occur when the partially polymerized resin contacts heat during the pouring operation, yielding an extremely rigid structure.

The viscosity of the ester-cured phenolic is similar to that of the acid-catalyzed phenolic no-bakes. It has a shelf life of 4 to 6 months at 20 °C (70 °F). Typically, 1.5 to 2.0% binder based on sand and 20 to 25% co-reactant based on the resin are used to coat washed and dried silica sand in most core and molding operations.

Both the resin and co-reactant are water soluble, permitting easy cleanup. Physical strength of the cured sand is not as high as that of the acid-catalyzed and urethane no-bakes at comparable resin contents. However, with care in handling and transporting, good casting results can be obtained. The distinct advantages of the ester-cured phenolic no-bake systems are the reduction of veining in iron castings and excellent erosion resistance.

Silicate/Ester-Catalyzed No-Bake. This no-bake system consists of the sodium silicate binder and a liquid organic ester that functions as the hardening agent. High-ratio binders with SiO_2:Na_2O contents of 2.5 to 3.2:1 are employed for this process, and mixtures usually contain 3 to 4% binder. The ester hardeners are materials such as glycerol diacetate and triacetate, or ethylene glycol diacetate; they are low-viscosity liquids with either a sweet or acetic acid-like smell. The normal addition rate for the ester hardener is 10 to 15% based on the weight of sodium silicate and should be added to the sand prior to the addition of the silicate binder.

The curing rate depends on the SiO_2:Na_2O ratio of the silicate binder and the composition of the ester hardener. Suppliers produce blends of ester hardeners giving work times that are controllable from several minutes to 1 h or longer. The hardening reaction, involving the formation of silica gel from the sodium silicate, is a cold process, and no heat or gas is produced. When added to a sand mixture containing the alkaline sodium silicate, the organic esters hydrolyze at a controlled rate, reacting with sodium silicate to form a silica gel that bonds the aggregate. A simplified version of this curing mechanism is:

$$\text{Sodium silicate } (Na_2SiO_3) + \text{Liquid ester hardener} \rightarrow \text{Cured polymer}$$

Mixed sand must be used before hardening begins. Material that has exceeded the useful work time and feels dry or powdery should be discarded. The use of sand past the useful bench life will result in the production of weak, friable molds and cores that can result in penetration defects.

Curing takes several hours to complete after stripping. Large molds may need 16 to 24 h. Strengths can be higher than those of CO_2-cured molds, and shelf life is better. Although shakeout is easier than with CO_2-silicate systems, it is not as good as the other no-bake processes outlined in this article.

Odor and gaseous emission levels are low during mixing, pouring, cooling, and shakeout, but depend on the extent of organic additives in the mix. Casting defects such as veining and expansion are minimal. Burn-on and penetration are generally more severe than for the other no-bake systems and can be controlled by sand additives and a wash practice.

Oil urethane no-bake resins (also known as oil-urethane, alkyd-urethane, alkyd-oil-urethane, or polyester-urethane) are three-component systems that consist of Part A, an alkyd oil type resin; Part B, a liquid amine/metallic catalyst; and Part C, a polymeric methyl di-isocyanate (MDI) (the urethane component).

The three-part system uses the Part B catalyst to achieve a predictable work/strip time. It can be made into a two-part system by preblending Parts A and B when the amount of the Part B catalyst added to the resin controls the work/strip

time. Part A can also be modified for better coating action, improved performance in temperature extremes, or better strippability.

Part A is normally used at 1 to 2% of sand weight. The Part B catalyst, whether added as a separate component or preblended with Part A, is 2 to 10% by weight of Part A. The Part C isocyanate is always 18 to 20% by weight of Part A.

Although the oil urethane no-bake system is easy to use, the curing mechanisms are difficult to understand because there are two separate curing stages and two curing mechanisms. When the three components are mixed together on the sand, the polyisocyanate (Part C) quickly begins to cross-link with the alkyd oil resin (Part A) at a rate controlled by the urethane catalyst component of Part B, as shown in Fig. 3. This action produces a urethane coating on the sand with enough bonded sand strength to strip the pattern and handle the core or mold.

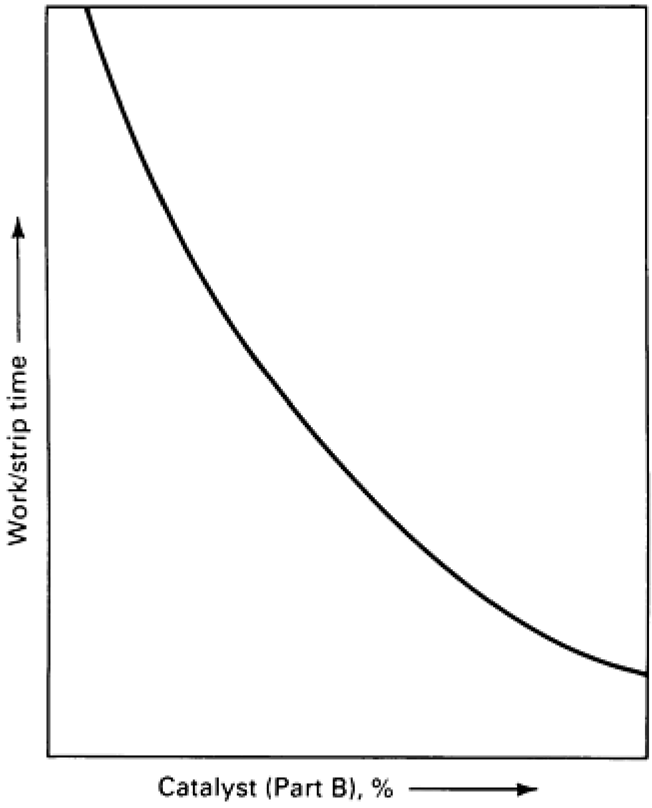

Fig. 3 Effect of increasing oil urethane system (Part B) (catalyst) on work time and strip time

The other stage of the curing reaction is similar to a paint-drying mechanism in which oxygen combines with the alkyd-oil resin component and nearly polymerizes it fully at room temperature to form a tough urethane bond. The metallic driers present in the Part B catalyst accelerate the oxygenation or drying (slowly at room temperature or quickly at 150 to 205 °C, or 300 to 400 °F), but because the full cure is oxygen dependent, section size and shape, along with temperature, determine how long it takes to attain a complete cure.

The alkyd-oil urethane mechanism is a two-stage process involving:

$$\text{Alkyd + NCO (polymeric isocyanate) (partial cross-link) + Urethane catalyst} \rightarrow \text{Alkyd urethane}$$

$$\text{Alkyd} + O_2 + \text{Metallic driers} \rightarrow \text{Rigid cross-linked urethane}$$

For maximum cure and ultimate casting properties, the mold or core should be heated to about 150 °C (300 °F) in a forced air oven for 1 h.

The oil urethane no-bake system, with its unique two-stage cure, results in unmatched stripping characteristics and provides foundrymen with a good method of producing large cores and molds that require long work and strip times.

The phenolic urethane no-bake (PUN) binder system has three parts. Part I is a phenol formaldehyde resin dissolved in a special blend of solvents. Part II is a polymeric MDI-type isocyanate, again dissolved in solvents. Part III is an amine catalyst that, depending on strength and amount, regulates the speed of the reaction between Parts I and II. The chemical reaction between Part I and Part II forms a urethane bond and no other by-products. For this reason and because air is not required for setting, the PUN system does not present the problems with through-cure or deep-set found in other no-bake systems. A simplified version of the curing mechanism for phenolic urethane no-bake systems is:

Liquid phenolic resin (Part I) + Liquid polyisocyanate (Part II)
+ Liquid amine catalyst (Part III) = Solid resin + heat

Phenolic urethane no-bake binders are widely used for the production of both ferrous and nonferrous castings and can be successfully used for high-production operations or jobbing shops because of their chemical reaction time and ease of operation.

Although many types of mixers can be used with PUN binders, zero-retention high-speed continuous mixers are the most widely used. Because the mixing takes place rapidly, the fast strip times (as fast as 30 s) of the PUN system can be utilized in practice. No mixed sand is retained in the mixer to harden after it is shut off. Further, the mixers can be coordinated with pattern movement, sand compaction, stripping operations, and mold or core finishing and storage to create a simple manual or fully automated no-bake loop.

Total binder level for the PUN system is 0.7 to 2% based on the weight of sand. It is common to offset the ratio of Part I to Part II at 55:45 or 60:40. The third-part catalyst level is based on the weight of Part I. Depending on the catalyst type and strip time required 0.4 to 8% catalyst (based on Part I) is normally added.

Compaction of the mixed sand can be accomplished by vibration, ramming, and tucking. The good flowability of PUN sand mixes allows good density with minimum effort. Because the PUN system cures very rapidly, the time required for the compacted pattern to reach rollover and strip must coincide with the setup or cure time of the sand mix.

For certain ferrous applications (most commonly steels), the addition of 2 to 3% iron oxide to the sand mix can improve casting surface finish. This addition is also beneficial in reducing lustrous carbon defects by promoting a less reducing mold atmosphere. The PUN resin system contains about 3.0 to 3.8% N (which is about 0.04% based on sand). To reduce the chance of nitrogen-related casting defects, the Part I to Part II ratio can be offset 60:40 in favor of the Part I because substantially all the nitrogen is in Part II. It has also been shown that as little as 0.25% red iron oxide is effective in suppressing the ferrous casting subsurface porosity associated with nitrogen in the melt and/or evolved from the PUN binder.

The polyol-isocyanate system was developed in the late 1970s for aluminum, magnesium, and other light-alloy foundries. Previously, the binder systems used in light-alloy foundries were the same as those used for the ferrous casting industry. The lower pouring temperatures associated with light alloys are not sufficient to decompose most no-bake binders, and removal of cores from castings is difficult. The polyol-isocyanate system was developed to provide improved shakeout.

The nonferrous binders are similar to the PUN system described previously. Part I is a special polyol designed for good thermal breakdown dissolved in solvents. Part II is a polymeric MDI-type isocyanate, again dissolved in solvents. Part II is an amine catalyst that can be used to regulate cure speed.

The chemical curing reaction of the polyolisocyanate system is as follows:

Liquid polyol resin + Liquid polyisocyanate = Solid resin + heat

In practice, polyol-isocyanate binders are used in much the same way as the PUN binders they evolved from. One difference is that the system does not require a catalyst. Several phenol formaldehyde (Part I) resins are available that

provide strip times from 8 min to over 1 h. For maximum control, however, an amine (Part III) catalyst can be used to regulate strip times to as fast as 3 min.

For light-alloy applications, binder levels range from 0.7 to 1.5% based on sand. Part I and Part II should be used at a 50:50 ratio for best results. Reactivity, strengths, and work-time-to-strip-time ratio are affected by the same variables as the PUN binders. Because of the fast thermal breakdown of the binder (Fig. 4), the polyol-urethane system is not recommended for ferrous castings.

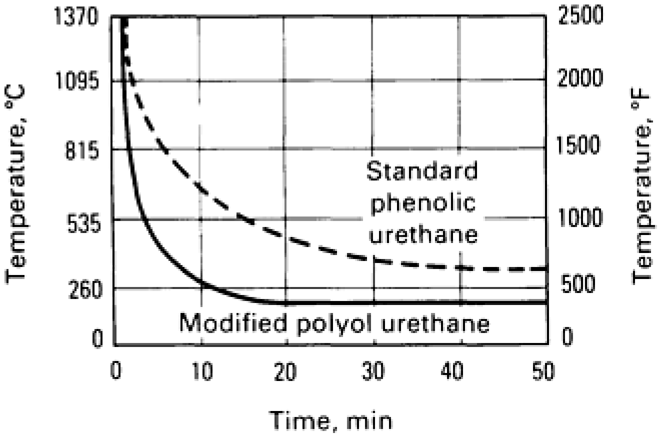

Fig. 4 Collapsibility of polyol urethane compared to that of phenolic urethane

Alumina-Phosphate No-Bake. Alumina-phosphate binders consist of an acidic, water-soluble alumina-phosphate liquid binder and a free-flowing powdered metal oxide hardener. Although this system is classified as a no-bake process (Table 1), both of its parts are inorganic; all other no-bake systems are organic or, in the case of silicate/ester systems, inorganic and organic. More detailed information on phosphate-bonded systems can be found in the article "Sand Molding" in this Volume (see the section "Bonded Sand Molds").

No-Bake Processes

A no-bake process is based on the ambient-temperature cure of two or more binder components after they are combined on sand. Curing of the binder system begins immediately after all colponents are combined. For a period of time after initial mixing, the sand mix is workable and flowable to allow the filling of the core/mold pattern. After an additional time period, the sand mix cures to the point where it can be removed from the box. The time difference between filling and stripping of the box can range from a few minutes to several hours, depending on the binder system used, curing agent and amount, sand type, and sand temperature.

Furan Acid Catalyzed No-Bake. Furfuryl alcohol is the basic raw material used in furan no-bake binders. Furan binders can be modified with urea, formaldehyde, phenol, and a variety of other reactive or non-reactive additives.

The great variety of furan binders available provides widely differing performance characteristics for use in various foundry applications. Water content may be as high as 15% and nitrogen content as high as 10% in resins modified with urea. In addition, zero-nitrogen and zero-water binders are available. The choice of a specific binder depends on the type of metal to be cast and the sand performance properties required. The amount of furan no-bake binders used ranges between 0.9 and 2.0% based on sand weight. Acid catalyst levels vary between 20 and 50% based on the weight of the binder. The speed of the curing reaction can be adjusted by changing the catalyst type or percentage, given that the sand type and temperature are constant. The furan no-bake curing mechanism is shown in Fig. 2.

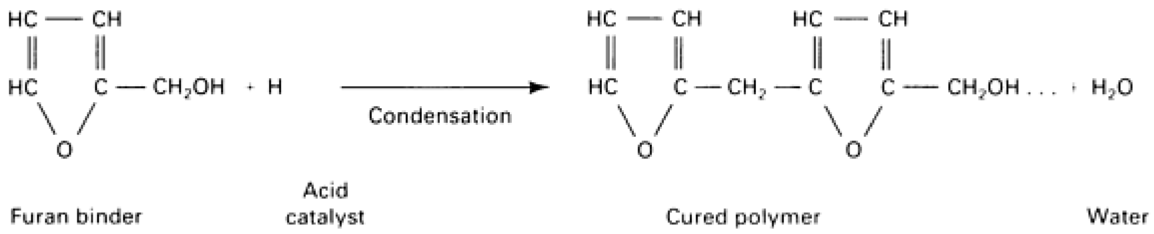

Fig. 2 The furan acid-catalyzed no-bake curing mechanism

Furan no-bake binders provide high dimensional accuracy and a high degree of resistance to sand/metal interface casting defects, yet they decompose readily after the metal has solidified, providing excellent shakeout. Furan no-bake binders also exhibit high tensile strength, along with the excellent hot strength needed for flaskless no-bake molding. They often run sand-to-metal ratios of as low as 2:1.

Phenolic Acid Catalyzed No-Bake. Phenolic resins are condensation reaction products of phenol(s) and aldehyde(s). Phenolic no-bake resins are those formed from phenol/formaldehyde where the phenol/formaldehyde molar ratio is less than 1. Again, as with furan no-bakes, these resins can be modified with reactive or nonreactive additives.

These resins are clear to dark brown in appearance, and their viscosities range from medium to high. Sand mixes made with these resins have adequate flowability for the filling of mold patterns or core boxes. Resins of this type contain free phenol and free formaldehyde. Phenol and formaldehyde odors can be expected during sand-mixing operations.

One disadvantage of acid-cured phenolic no-bake resins is their relatively poor storage stability. Phenolic binders are usually not stored for more than 6 months. Phenolic resole resins contain numerous reactive methylol groups, and these are generally involved in auto-polymerization reactions at ambient or slightly elevated temperatures. The storage period can be considerably longer during the winter months if the temperature of storage remains at 20 °C (70 °F) or lower. The viscosity advances as the binder ages.

The catalyst needed for the phenolic no-bake resin is a strong sulfonic acid type. Phosphoric acids will not cure phenolic resins at the rate required for most no-bake foundry applications.

The phenolic no-bake reaction mechanism is:

$$\text{Phenolic resin} + \text{Acid catalyst} \rightarrow \text{Cured polymer} + \text{Water}$$

The catalyst initiates further condensation of the resin and advances the cross-linking reaction. The condensation reactions produce water which results in a dilution effect on the acid catalyst that tends to slow the rate of cure. Because of this effect, it is necessary to use strong acid catalysts to ensure an acceptable rate of cure and good deep set properties.

Ester-Cured Alkaline Phenolic No-Bake. The ester-cured phenolic binder system is a two-part binder system consisting of a water-soluble alkaline phenolic resin and liquid ester co-reactants. The reaction mechanism is:

Alkaline phenolic resin + Ester co-reactant
$\rightarrow$ Suspected unstable intermediate
$\rightarrow$ Splits to form:
Polymerized phenolic resin
Alkaline salts and alcohol

A secondary reaction is thought to occur when the partially polymerized resin contacts heat during the pouring operation, yielding an extremely rigid structure.

The viscosity of the ester-cured phenolic is similar to that of the acid-catalyzed phenolic no-bakes. It has a shelf life of 4 to 6 months at 20 °C (70 °F). Typically, 1.5 to 2.0% binder based on sand and 20 to 25% co-reactant based on the resin are used to coat washed and dried silica sand in most core and molding operations.

Both the resin and co-reactant are water soluble, permitting easy cleanup. Physical strength of the cured sand is not as high as that of the acid-catalyzed and urethane no-bakes at comparable resin contents. However, with care in handling and transporting, good casting results can be obtained. The distinct advantages of the ester-cured phenolic no-bake systems are the reduction of veining in iron castings and excellent erosion resistance.

Silicate/Ester-Catalyzed No-Bake. This no-bake system consists of the sodium silicate binder and a liquid organic ester that functions as the hardening agent. High-ratio binders with SiO_2:Na_2O contents of 2.5 to 3.2:1 are employed for this process, and mixtures usually contain 3 to 4% binder. The ester hardeners are materials such as glycerol diacetate and triacetate, or ethylene glycol diacetate; they are low-viscosity liquids with either a sweet or acetic acid-like smell. The normal addition rate for the ester hardener is 10 to 15% based on the weight of sodium silicate and should be added to the sand prior to the addition of the silicate binder.

The curing rate depends on the SiO_2:Na_2O ratio of the silicate binder and the composition of the ester hardener. Suppliers produce blends of ester hardeners giving work times that are controllable from several minutes to 1 h or longer. The hardening reaction, involving the formation of silica gel from the sodium silicate, is a cold process, and no heat or gas is produced. When added to a sand mixture containing the alkaline sodium silicate, the organic esters hydrolyze at a controlled rate, reacting with sodium silicate to form a silica gel that bonds the aggregate. A simplified version of this curing mechanism is:

$$\text{Sodium silicate } (Na_2SiO_3) + \text{Liquid ester hardener} \rightarrow \text{Cured polymer}$$

Mixed sand must be used before hardening begins. Material that has exceeded the useful work time and feels dry or powdery should be discarded. The use of sand past the useful bench life will result in the production of weak, friable molds and cores that can result in penetration defects.

Curing takes several hours to complete after stripping. Large molds may need 16 to 24 h. Strengths can be higher than those of CO_2-cured molds, and shelf life is better. Although shakeout is easier than with CO_2-silicate systems, it is not as good as the other no-bake processes outlined in this article.

Odor and gaseous emission levels are low during mixing, pouring, cooling, and shakeout, but depend on the extent of organic additives in the mix. Casting defects such as veining and expansion are minimal. Burn-on and penetration are generally more severe than for the other no-bake systems and can be controlled by sand additives and a wash practice.

Oil urethane no-bake resins (also known as oil-urethane, alkyd-urethane, alkyd-oil-urethane, or polyester-urethane) are three-component systems that consist of Part A, an alkyd oil type resin; Part B, a liquid amine/metallic catalyst; and Part C, a polymeric methyl di-isocyanate (MDI) (the urethane component).

The three-part system uses the Part B catalyst to achieve a predictable work/strip time. It can be made into a two-part system by preblending Parts A and B when the amount of the Part B catalyst added to the resin controls the work/strip time. Part A can also be modified for better coating action, improved performance in temperature extremes, or better strippability.

Part A is normally used at 1 to 2% of sand weight. The Part B catalyst, whether added as a separate component or preblended with Part A, is 2 to 10% by weight of Part A. The Part C isocyanate is always 18 to 20% by weight of Part A.

Although the oil urethane no-bake system is easy to use, the curing mechanisms are difficult to understand because there are two separate curing stages and two curing mechanisms. When the three components are mixed together on the sand, the polyisocyanate (Part C) quickly begins to cross-link with the alkyd oil resin (Part A) at a rate controlled by the urethane catalyst component of Part B, as shown in Fig. 3. This action produces a urethane coating on the sand with enough bonded sand strength to strip the pattern and handle the core or mold.

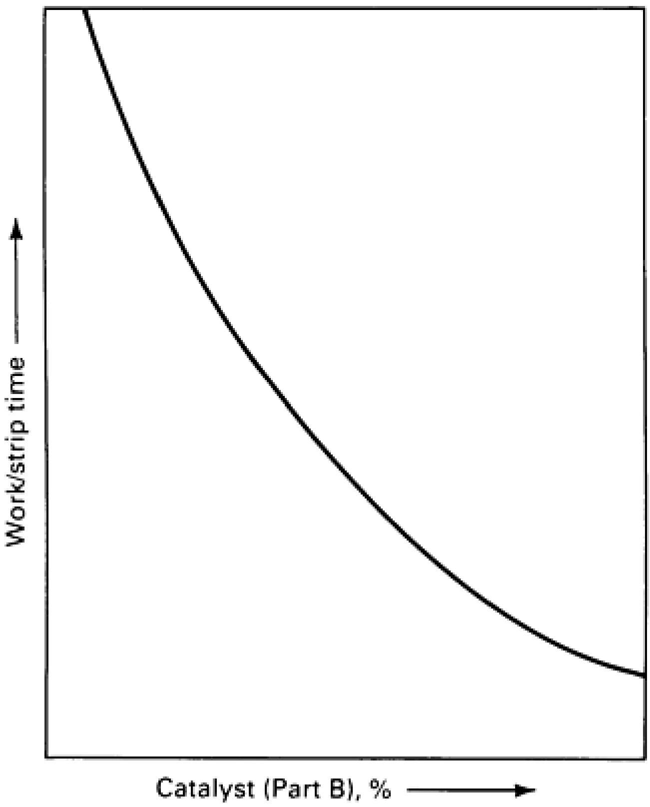

Fig. 3 Effect of increasing oil urethane system (Part B) (catalyst) on work time and strip time

The other stage of the curing reaction is similar to a paint-drying mechanism in which oxygen combines with the alkyd-oil resin component and nearly polymerizes it fully at room temperature to form a tough urethane bond. The metallic driers present in the Part B catalyst accelerate the oxygenation or drying (slowly at room temperature or quickly at 150 to 205 °C, or 300 to 400 °F), but because the full cure is oxygen dependent, section size and shape, along with temperature, determine how long it takes to attain a complete cure.

The alkyd-oil urethane mechanism is a two-stage process involving:

$$\text{Alkyd} + \text{NCO (polymeric isocyanate) (partial cross-link)} + \text{Urethane catalyst} \rightarrow \text{Alkyd urethane}$$

$$\text{Alkyd} + O_2 + \text{Metallic driers} \rightarrow \text{Rigid cross-linked urethane}$$

For maximum cure and ultimate casting properties, the mold or core should be heated to about 150 °C (300 °F) in a forced air oven for 1 h.

The oil urethane no-bake system, with its unique two-stage cure, results in unmatched stripping characteristics and provides foundrymen with a good method of producing large cores and molds that require long work and strip times.

The phenolic urethane no-bake (PUN) binder system has three parts. Part I is a phenol formaldehyde resin dissolved in a special blend of solvents. Part II is a polymeric MDI-type isocyanate, again dissolved in solvents. Part III is an amine catalyst that, depending on strength and amount, regulates the speed of the reaction between Parts I and II. The chemical reaction between Part I and Part II forms a urethane bond and no other by-products. For this reason and because air is not required for setting, the PUN system does not present the problems with through-cure or deep-set found in other no-bake systems. A simplified version of the curing mechanism for phenolic urethane no-bake systems is:

Liquid phenolic resin (Part I) + Liquid polyisocyanate (Part II)
+ Liquid amine catalyst (Part III) = Solid resin + heat

Phenolic urethane no-bake binders are widely used for the production of both ferrous and nonferrous castings and can be successfully used for high-production operations or jobbing shops because of their chemical reaction time and ease of operation.

Although many types of mixers can be used with PUN binders, zero-retention high-speed continuous mixers are the most widely used. Because the mixing takes place rapidly, the fast strip times (as fast as 30 s) of the PUN system can be utilized in practice. No mixed sand is retained in the mixer to harden after it is shut off. Further, the mixers can be coordinated with pattern movement, sand compaction, stripping operations, and mold or core finishing and storage to create a simple manual or fully automated no-bake loop.

Total binder level for the PUN system is 0.7 to 2% based on the weight of sand. It is common to offset the ratio of Part I to Part II at 55:45 or 60:40. The third-part catalyst level is based on the weight of Part I. Depending on the catalyst type and strip time required 0.4 to 8% catalyst (based on Part I) is normally added.

Compaction of the mixed sand can be accomplished by vibration, ramming, and tucking. The good flowability of PUN sand mixes allows good density with minimum effort. Because the PUN system cures very rapidly, the time required for the compacted pattern to reach rollover and strip must coincide with the setup or cure time of the sand mix.

For certain ferrous applications (most commonly steels), the addition of 2 to 3% iron oxide to the sand mix can improve casting surface finish. This addition is also beneficial in reducing lustrous carbon defects by promoting a less reducing mold atmosphere. The PUN resin system contains about 3.0 to 3.8% N (which is about 0.04% based on sand). To reduce the chance of nitrogen-related casting defects, the Part I to Part II ratio can be offset 60:40 in favor of the Part I because substantially all the nitrogen is in Part II. It has also been shown that as little as 0.25% red iron oxide is effective in suppressing the ferrous casting subsurface porosity associated with nitrogen in the melt and/or evolved from the PUN binder.

The polyol-isocyanate system was developed in the late 1970s for aluminum, magnesium, and other light-alloy foundries. Previously, the binder systems used in light-alloy foundries were the same as those used for the ferrous casting industry. The lower pouring temperatures associated with light alloys are not sufficient to decompose most no-bake binders, and removal of cores from castings is difficult. The polyol-isocyanate system was developed to provide improved shakeout.

The nonferrous binders are similar to the PUN system described previously. Part I is a special polyol designed for good thermal breakdown dissolved in solvents. Part II is a polymeric MDI-type isocyanate, again dissolved in solvents. Part II is an amine catalyst that can be used to regulate cure speed.

The chemical curing reaction of the polyolisocyanate system is as follows:

$$\text{Liquid polyol resin} + \text{Liquid polyisocyanate} = \text{Solid resin} + \text{heat}$$

In practice, polyol-isocyanate binders are used in much the same way as the PUN binders they evolved from. One difference is that the system does not require a catalyst. Several phenol formaldehyde (Part I) resins are available that provide strip times from 8 min to over 1 h. For maximum control, however, an amine (Part III) catalyst can be used to regulate strip times to as fast as 3 min.

For light-alloy applications, binder levels range from 0.7 to 1.5% based on sand. Part I and Part II should be used at a 50:50 ratio for best results. Reactivity, strengths, and work-time-to-strip-time ratio are affected by the same variables as the PUN binders. Because of the fast thermal breakdown of the binder (Fig. 4), the polyol-urethane system is not recommended for ferrous castings.

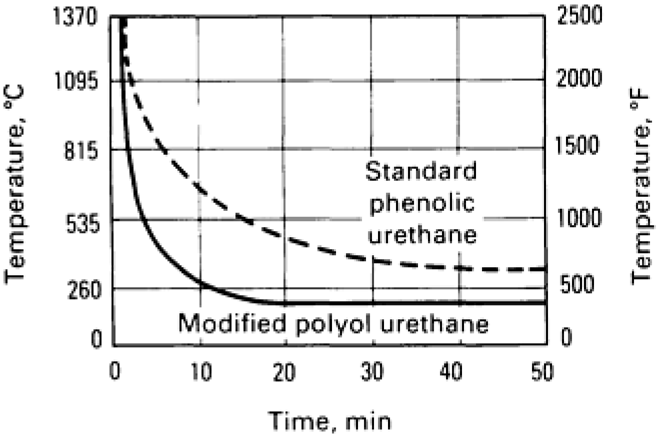

Fig. 4 Collapsibility of polyol urethane compared to that of phenolic urethane

Alumina-Phosphate No-Bake. Alumina-phosphate binders consist of an acidic, water-soluble alumina-phosphate liquid binder and a free-flowing powdered metal oxide hardener. Although this system is classified as a no-bake process (Table 1), both of its parts are inorganic; all other no-bake systems are organic or, in the case of silicate/ester systems, inorganic and organic. More detailed information on phosphate-bonded systems can be found in the article "Sand Molding" in this Volume (see the section "Bonded Sand Molds").

Shell Process

In the shell process, also referred to as the Croning process, the sand grains are coated with phenolic novolac resins and hexamethylenetetramine. In warm coating, dissolved or liquid resins are used, but in hot coating, solid novolac resins are used. The coated, dry, free-flowing sand is compressed and cured in a heated mold at 150 to 280 °C (300 to 535 °F) for 10 to 30 s. Sands prepared by warm coating cure fast and exhibit excellent properties. Hot-coated sands are generally more free flowing with less tendency toward caking or blocking in storage.

Novolac Shell-Molding Binders. Novolacs are thermoplastic, brittle, solid phenolic resins that do not cross-link without the help of a cross-linking agent. Novolac compositions can, however, be cured to insoluble cross-linked products by using hexamethylenetetramine or a resole phenolic resin as a hardener. A simplified version of the Novolac curing mechanism is:

$$\text{Novolac + Hexamethylenetetramine} \xrightarrow{HEAT} \text{Cured polymer + ammonia}$$

Phenol-formaldehyde novolac resins are the primary resins used for precoating shell process sand. These resins are available as powder, flakes, or granules or as solvent- or waterborne solutions. A lubricant, usually calcium stearate (4 to 6% of resin weight) is added during the resin production or the coating process to improve flowability and release properties. Hexamethylenetetramine, 10 to 17% based on resin weight, is used as a cross-linking agent.

Producing Cores and Molds. The shell-resin curing mechanism involves the transition from one type of solid plastic to another--thermoplastic to thermosetting. This physical conversion must be completed during a brief period of the shell cycle before the heat (necessary to cure the resin) begins to decompose the binder. Pattern temperatures are typically 205 to 315 °C (400 to 600 °F). Operating within the ideal temperature range provides a good shell thickness, optimum resin flow, and minimal surface decomposition. Higher pattern temperatures of 275 to 315 °C (525 to 600 °F) are often successfully used to make small cores, because the shell cycle is short enough that little surface definition is lost by decomposition of the resin at the pattern interface during the relatively brief cure cycle generally needed.

Various additives are used during the coating operation for specific purposes. They include iron oxide to prevent thermal cracking, to provide chill, and to minimize gas-related defects.

The shell process has some advantages over other processes. The better blowability and superior flowability of the lubricant-containing shell sand permits intricate cores to be blown and offers excellent surface reproduction in shell molding. Because the bench life of the coated shell sand is indefinite, machines do not require the removal of process sand at the end of a production period.

Storage life of cured cores or molds is excellent. A variety of sands are usable with the process, and nearly all metals and alloys have been successfully cast using shell sand for cores and molds.

Hot Box and Warm Box Processes

In the hot box and warm box processes, the binder-sand mixture is wet. A liquid thermosetting binder and a latent acid catalyst are mixed with dry sand and blown into a heated core box. The curing temperature depends on the process. Upon heating, the catalyst releases acid, which induces rapid cure; therefore, the core can be removed within 10 to 30 s. After the cores are removed from the pattern, the cure is complete as a result of the exothermic chemical reaction and the heat absorbed by the core. Although many hot box cores require postcuring in an oven to complete the cure, warm box cures require no postbake oven curing.

Hot Box Binders. Conventional hot box resins are classified simply as furan or phenolic types. The furan types contain furfuryl alcohol, the phenolic types are based on phenol, and the furan-modified phenolic has both. All conventional hot box binders contain urea and formaldehyde. The furan hot box resin has a fast cure compared to that of the phenolic-type system and can therefore be ejected faster from the core box. Furan resin also provides superior shakeout and presents fewer disposal problems because of the lack of phenol. Typical resin content is 1.5 to 2.0%.

A simplified hot box reaction mechanism is:

$$\text{Liquid resin} + \text{Catalyst} + \text{Heat} = \text{Solid resin} + \text{water} + \text{heat}$$

Catalyst selection is based on the acid demand value and other chemical properties of the sand. Sand temperature changes of 1 °C (20 °F) and/or variations of ±5 units in the acid demand value of the sand require a catalyst adjustment to maintain optimum performance. When a liquid catalyst is used, many operations have winter and summer grades that can be mixed together during seasonal transitions. Both chloride and nitrate catalysts are used. The chloride catalyst is the more reactive. Therefore, the chloride is the winter grade, and the nitrate the summer grade.

Hot box resins have a limited shelf life and increase in viscosity with storage. If possible, containers should be stored out of the sun in a cool place and used on a first-in-first-out basis. Hot box catalysts have indefinite storage lives.

Pattern temperature should not vary more than 28 °C (50 °F). Measurements should be made at the highest and lowest points across the pattern. Most production shops run hot box pattern temperatures of 230 to 290 °C (450 to 550 °F), but the ideal temperature is between 220 and 245 °C (425 and 475 °F). The most common mistake made with the hot box process is to run too high a pattern temperature, which causes poor core surfaces. This condition results in a friable core finish that is especially detrimental to thin-section cores.

The color of the core surface shows how thoroughly the core is cured and is a good curing guideline. The surface should be slightly yellow or very light-brown--not dark brown or black. Overall, the phenolic and furan hot box resins are extensively used in the automotive industry for producing intricate cores and molds that require good tensile strengths for low cost gray iron castings.

Warm Box Binders. The warm box resin is a minimum-water (<5%) furfuryl alcohol-type resin (furfuryl alcohol content: ~70%) that is formulated for a nitrogen content of less than 2.5%. Because the resin/sand mix exhibits a high degree of rigid thermoset properties when fully cured, little or no post strip distortion or sagging occurs. High hot and cold tensile properties are characteristic of warm box sands and generally permit a binder level between 0.8 to 1.8%, or 20% less than the conventional hot box resin content.

Warm box catalysts are copper salts based primarily on aromatic sulfonic acids in an aqueous methanol solution. The catalyst amount used is 20 to 35%, based on resin weight. These catalysts are unusual in that they impart an excellent latent property (unreactive at room temperature) to the binder system, but still form strong acids when heated. They promote a thorough curing action at temperatures at approximately 65 °C (150 °F) or higher.

A simplified warm box curing reaction mechanism is:

$$\text{Furan resin + Latent acid } (H^+) \xrightarrow{HEAT} \text{Cured furan binder}$$

The binder components remain stable when mixed together in the proper ratios in sand until activated by heat, which decomposes the catalyst and releases the acid that causes the resin to polymerize.

The pattern temperatures used range from 150 to 230 °C (300 to 450 °F). The optimum temperature of 190 °C (375 °F) is about 55 °C (100 °F) below the operating temperature for hot box binders. Low resin and catalyst viscosity combine to produce a flowable sand mix. Castings produced with warm box binders exhibit casting features that are very similar to those of a furan no-bake system. Good dimensional accuracy and excellent erosion resistance are observed with warm box binders.

Oven-Bake Processes/Core-Oil Binders

Core-oil binder is used in combination with a water-activated cereal to produce a coated sand mix that has green strength. Green strength permits the wet sand mix to be blown or hand rammed into a simple vented, relatively low-cost core box at room temperature and to retain its shape when removed from the pattern.

The uncured plasticlike cores are generally placed on a flat board or a dryer plate (a supporting structure to maintain the shape of the core) for oven drying. This process translates into a fast method of producing cores or molds. Except for the subsequent drying operations, the cores are in effect made almost as fast as they are blown.

Types of Core Oil. A binder system that uses water and cereal to develop green strength and then cures or dries in a hot, forced air oven is normally referred to as a core-oil process. Several types of binders fall into this category. Linseed or vegetable oil binders account for most of the volume, but urea formaldehyde and resole phenolic resins are also used. The sand-coating procedure, sand formulation, coremaking techniques, and general foundry procedures are chemically different, but are similar for all types of core-oil processes.

Urea formaldehyde is noted for its excellent shakeout and is used in aluminum foundries and shops that operate dielectric curing ovens instead of the hot, forced air ovens. Because of its high nitrogen content and low hot strength, urea formaldehyde has found rather limited application outside of nonferrous shops.

Additives. Core mixes generally contain 1% or less cereal, based on sand weight. The cereal is kept to a minimum because it generates gas. Normally, when more green strength is required for core stripping and/or handling, the cereal is mulled along with the water for a longer time.

Small additions of Southern and/or Western bentonite (up to $\frac{1}{2}$% based on sand weight) to cereal have also proved useful for developing green strength. An additional benefit is that bentonite evolves far less gas than cereal does.

Water is added to the mix to activate the cereal and to create green strength. The amount must be controlled to develop optimum properties, as indicated in Table 4. Baked strength, green strength, and baking rate are influenced by moisture content. A 2% water addition gives optimum results.

Table 4 Effects of moisture on core-oil sand mixes

1% cereal, 1% oil, 90 min bake at 200 °C (400 °F), AFS 62 GPN silica sand

Property	Percentage of moisture							
	0	**0.5**	**1.0**	**1.5**	**2.0**	**3.0**	**4.0**	5.0
Green strength, kPa (psi)	1.4	3.4	6.2	8.9	9.6	7.6	6.9	**6.2**

	(0.2)	(0.5)	(0.9)	(1.3)	(1.4)	(1.1)	(1.0)	**(0.9)**
Tensile strength, kPa (psi)	1205	1450	1825	2275	2480	2345	2135	**1725**
	(175)	(210)	(265)	(330)	(360)	(340)	(310)	**(250)**
Percentage baked	100	100	100	100	100	97	88	**78**
Scratch hardness index	**60**	**71**	**82**	**92**	**96**	**95**	**90**	**88**

Operational Considerations. A number of points are essential for effective use of core-oil systems:

- *Basic Mix.* A standard core-oil mix contains about 1% cereal, 1 to 3.5% water, 1% binder, and 0.1% of a flowability/release agent
- *Mixing Order.* As indicated in Table 5, the sequence of additions to the muller has a significant effect on core properties. The best order of addition to the sand clearly is (1) cereal and dry additives, (2) water, (3) oil, and (4) flowability/release agent
- *Oven Drying.* Forced hot air is the principal means of curing core-oil binders. Heat causes the binder in the core-oil sand mix to cross-link and provide strength. The proper combination of oven temperature, drying humidity, and time determines the final strength, dimensional stability, and surface finish of the core

Table 5 Sequence of muller additions to core-oil sands

1% cereal, 1% oil, 1.5% water, 90 min bake at 200 °C (400 °F), silica sand

Property	Percentage of moisture						
	All at once	**1. Cereal 2. Oil 3. Water**	**1. Cereal 2. Water 3. Oil**	**1. Oil 2. Cereal 3. Water**	**1. Oil 2. Water 3. Cereal**	**1. Water 2. Oil 3. Cereal**	1. Water 2. Cereal 3. Water
Green strength, kPa (psi)	6.9	2.0	10.3	3.4	4.1	3.4	**7.6**
	(1.0)	(0.3)	(1.5)	(0.5)	(0.6)	(0.5)	**(1.1)**
Tensile strength, kPa (psi)	1930	1345	2495	1725	1450	1380	**2275**
	(280)	(195)	(362)	(250)	(210)	(200)	**(330)**

It is important to note that mixing cores produced by other binder processes in the same drying oven with uncured core-oil cores usually weakens the non-core-oil cores because of the steam evolved from the water used in the core-oil process

Cold Box Processes

The term cold box process implies the room-temperature cure of a binder-sand mixture accelerated by a vapor or gas catalyst that is passed through the sand. Several different cold box systems are currently used, employing different binders and gas or vapor catalysts--for example, triethylamine or dimethylethylamine for phenolic urethane binders, sulfur dioxide for furan and acrylic epoxy binders, methyl formate for ester-cured alkaline phenolic binders, and carbon dioxide for silicate binders.

Phenolic Urethane Cold Box (PUCB). The process uses a three-part binder system consisting of a phenolic resin (Part I), a polymeric isocyanate (Part II), and a tertiary amine vapor catalyst (Part III). Sand is coated with the Part I and Part II components and compacted into a pattern at room temperature. The tertiary amine catalyst is introduced through vents in the pattern to harden the contained sand mix. The catalyst gas cycle is followed by an air purge cycle that forces the amine gas through the sand mass and removes residual amine from the hardened core. It is recommended that the exhaust from the core box be scrubbed chemically to remove the amine.

The reactive component of the PUCB Part I is phenolic resin. It is dissolved in solvents to yield a low-viscosity resin solution to facilitate coating the sand and blending it with the second component. Part II is a polymeric MDI-type isocyanate that again is blended with solvents to form a low-viscosity resin solution. The hydroxyl groups provided by the phenolic resin in Part I react with the isocyanate groups in Part II in the presence of the amine catalyst to form the solid urethane resin. It is this urethane polymer that bonds the sand grains together and gives the PUCB process its unique properties.

A simplified curing reaction mechanism for the PUCB process is:

$$\text{Phenolic resin} + \text{Polyisocyanate} \xrightarrow{\text{Vapor amine catalyst}} \text{Urethane}$$

The urethane reaction does not produce water or any other by-product. The system contains 3 to 4% N, which is introduced from the Part II polymeric isocyanate component. The organic resins and solvents in the PUCB system make it high in carbon content, which contributes to the formation of lustrous carbon and a reducing mold atmosphere during casting.

The PUCB process can be used with all of the sands commonly used for coremaking in the foundry industry. Some consideration must be given, however, to the effects of sand temperature, chemistry, and moisture content on the resin performance of PUCB. The ideal sand temperature is 20 to 25 °C (70 to 80 °F). Lower temperature can reduce mixing efficiency and increase cure times. Higher sand temperatures reduce gassing cycles and the amount of catalyst required, but shorten the usable life of the coated sand mix.

A maximum sand moisture content of 0.2% is acceptable for the PUCB process at room temperature (~20 °C, or 70 °F), but when the sand temperature rises to 30 °C (90 °F), the moisture content of the sand must be kept at less than 0.1% for the process to function properly.

All types of popular sand-mixing equipment can be used with the PUCB process. A sand delivery system that causes the least amount of aeration is best. Typically, 1.5% total binder, consisting of equal parts of Part I and Part II components, is used on a washed and dried sand for ferrous castings. Many foundries prefer to offset the ratio and use slightly more Part I for various technical reasons. For the casting of aluminum, magnesium, and other low pouring temperature alloys, binder levels of 1% and less are used to facilitate shakeout.

The volatile liquid tertiary amines commonly used to cure the PUCB binders are triethylamine or dimethylethylamine. Various designs of generators vaporize and blend these amines with carrier gas and deliver them to the core machine. The best generators provide a consistently high concentration of amine to facilitate fast, predictable cure cycles.

The exhaust from the core box is delivered to a chemical scrubber, and the amine is removed by reacting it with dilute sulfuric acid to form an amine sulfate salt. In larger foundry operations, concentrated liquor from the scrubber has been recycled through chemical processing to convert it back into usable amine, thus providing economic and ecological advantages.

Certain sand additives can be used with the PUCB system to eliminate specific casting defects. Veining in ferrous and brass castings can be substantially reduced by the addition of 1 to 2% proprietary clay-sugar blends or 1 to 3% iron oxide.

Black and red iron oxide additions of 2 to 3% are recommended for steel castings. Red iron oxide at levels as low as 0.25% can be effective in eliminating binder-induced subsurface pinhole porosity in alloys prone to those defects.

SO_2 Process (Furan/SO_2). The sulfur dioxide (SO_2) process can be described as a rapid-curing, gas-activated, furan no-bake. Various furfuryl alcohol-base resins, blended with an adhesion promoter, are used to coat the sand in the range of 0.9 to 1.5%. Organic hydroperoxides at 30 to 50% by weight of the resin are added to the sand mixture and/or blended with the resin. Methanol-diluted silane (5 to 10%, based on resin weight) is used to increase strength, to improve shelf life, and to increase humidity resistance.

Once the sand is in place, SO_2 gas is introduced. It reacts with the peroxide and water in the furan resin, causing an *in situ* formation of a complex group of acids that cures the furan binder.

The simplified curing reaction mechanism for the SO_2 process is:

$$\text{Furan binder} + H^+ \xrightarrow{HEAT} \text{Cross-linking (polycondensation)} + \text{dehydration}$$

The curing reaction begins when the SO_2 first contacts the peroxide and continues even after removal from the pattern. As the catalyzed furan/SO_2 resin bonded sand ages, the water of condensation resulting from the furan polymerization continues to dissipate from the still-curing sand until the reaction is complete. Upon curing, the sand changes from a light color to dark green or black.

The recommended sand temperature for the SO_2 process is 25 to 40 °C (80 to 100 °F). Lower temperatures reduce cure speed and may produce partially cured cores. Higher temperatures promote evaporation of solvents and reduce mixed-sand bench life. Hot purging with air at 95 °C (200 °F) is required to achieve optimum cure.

The SO_2 process develops approximately 20 to 50% of its overall tensile strength upon ejection from the core box. It then builds strength rapidly to 85 to 95% of overall tensile strength after about 1 h. Bench life of the mixed sand is 12 to 24 h. In typical core blowing operations, relatively low blow pressures of 275 to 415 kPa (40 to 60 psi) are possible because excellent flowability is characteristic of the system.

The free radical cure (FRC) process includes all acrylic and acrylic-epoxy functional binders. The binders are cured using an organic hydroperoxide and SO_2. A variety of acrylic-epoxy binders have been developed for both ferrous and nonferrous applications, ranging from 100% acrylic binders to approximately 30:70 ratios of acrylic-epoxy blends. Sand performance and casting properties are influenced by the ratio of acrylic to epoxy functional components present in the binder system.

Acrylic binders are based on acrylic functional components. When combined with small amounts of organic hydroperoxides, acrylic binders can be cured through the application of a wide range of concentrations of sulfur dioxide with inert gas carriers such as nitrogen (1 to 100% SO_2).

Acrylic binders are primarily used in light-metal applications because of their good shakeout properties; however, they have specific applications in ferrous metals where veining defects are troublesome with other binder systems. When acrylic binders are used in ferrous applications, a refractory coating and nonturbulent gating design are recommended to reduce the threat of erosion.

Acrylic-epoxy binders are blends of acrylic and epoxy functional components. The acrylic-epoxy binder systems offer alternatives to existing cold box systems. The process utilizes a two-part liquid binder system consisting of (1) an unsaturated resin and/or monomer and (2) an organic hydroperoxide with an epoxy resin. The mixed sand, once exposed to SO_2 gas, yields a cured polymer. A simplified version of this reaction mechanism is:

Epoxy resin + Unsaturated polymer and monomer **MATH OMITTED** Cured polymer

Varying the acrylic-epoxy composition influences such core- and moldmaking properties as rigidity, cure speed, SO_2 consumption, humidity resistance, tensile and transverse strengths, and core release. In addition, casting properties such as veining resistance, shakeout, erosion resistance, and surface finish can be influenced by changing the acrylic-epoxy composition.

The FRC process employs a variety of binder systems, including specific systems for ferrous and nonferrous casting applications. Binder levels range from 0.6 to 1.8%, depending on the type of sand used and the type of metal poured.

Because the FRC process components do not react until SO_2 is introduced to the pattern, the prepared sand mix has an extremely long bench life when compared to other cold box and hot box binder systems. This feature minimizes waste sand, provides for consistent flowability, and, most important, decreases the machine downtime because sand magazines, hoppers, and mixers do not have to be cleaned on a daily basis.

Tooling and equipment requirements are similar to those of the other cold box processes. Gassing units used for the phenolic-urethane or the SO_2 process are replaced or simply converted for use with the FRC system. Substitutions of caustic solutions for acid solutions are made in the wet scrubbers when the FRC process replaces the phenolic urethane system.

Disposal of SO_2 Gas. Scrubbing of the gas is accomplished with a wet scrubbing unit that utilizes a shower of water and a sodium hydroxide. A 5 to 10% solution of sodium hydroxide at a pH of 8 to 14 provides efficient neutralization of the SO_2 and prevents the by-product (sodium sulfite) from precipitating out of solution. Higher sodium hydroxide concentrations will cause precipitation of the neutralized product. Stoichrometrically, 0.58 kg (1.27 lb) of sodium hydroxide is required to neutralize 0.45 kg (1.0 lb) of SO_2.

Casting dimensional accuracy and resistance to veining of ferrous and nonferrous metals are influenced by the thermal expansion of sand and by the hot distortion characteristics of the binder system. The antiveining feature of specific FRC binders has eliminated the need for specialty sands, sand additives, and special slurry applications in iron and steel castings. Further, the lack of nitrogen and the absence of water minimize the nitrogen and/or hydrogen pinholing porosity formation often associated with cold box systems containing water or nitrogen.

The phenolic ester cold box (PECB) process was introduced to the foundry industry in 1984. A two-part system, it consists of a water-soluble alkaline phenolic resole resin and a volatile ester vapor co-reactant. Sand is coated with the phenolic resin and blown into the core box. The liquid ester coreactant is vaporized and injected as gas through the sand mix. The theoretical reaction is as follows:

$$\text{Alkaline phenolic resin} + \text{Ester co-reactant} \xrightarrow[\text{Reactive intermediate}]{} \text{Polymerized phenolic resin}$$

Because the ester is consumed in the curing reaction, purging of excess ester vapor can be accomplished with the minimum volume of purge air. However, purge air helps to distribute the ester vapor throughout the sand mix.

Methyl formate is the preferred ester for curing the phenolic resin because it is volatile and vaporized more easily than other esters. Methyl formate is readily available and relatively inexpensive.

The alkaline-phenolic binder is a low-viscosity (0.1 to 0.2 Pa · s) liquid at typically 50 to 60% solids in aqueous solution. The system contains less than 0.1% N and produces a less reducing mold atmosphere than the cold box binder systems.

The PECB system is affected by the physical characteristics of the sand, such as grain fineness, grain shape, and screen distribution. The best strengths are achieved with high-purity, washed and dried, round-grain silica sands. Because of the alkaline nature of the resin, however, it is not very sensitive to sand acid demand value. The fact that it is a water-soluble aqueous resin makes the system less sensitive to moisture, and it can tolerate up to 0.3% water in the sand.

The PECB system can be mixed using conventional mullers and continuous mixers. Binder levels vary, depending on sand type, but 1.75 to 2.5% resin is typically used with washed and dried silica sands. For sufficient handling strength, somewhat higher binder levels are required than for other gas-cured organic binder systems.

Methyl formate is volatilized in generating equipment designed especially for the PECB process. Because the methyl formate is not a catalyst, but a co-reactant of the system, the generating equipment must be capable of delivering a large volume of highly concentrated vapor to promote cure.

Stoichiometrically, about 15% methyl formate based on phenolic resin is required to harden the binder/sand mixture. In practice, the methyl formate requirement ranges from 30 to 80% and is largely dependent on venting and negative exhaust on the tooling. Lower gassing pressures and longer curing times promote the most efficient use of the ester co-reactant.

Despite the low handling strengths characteristic of the PECB system, castings made from all alloys show good surface finish. The erosion resistance and veining resistance of the PECB system are better than those of the phenolic urethane and phenolic hot box systems. A coating is recommended to control penetration defects. The PECB system does not usually require sand mix additives such as iron oxides or sugars to reduce veining and to control nitrogen defects. Because of the alkaline nature of the PECB sand, care must be taken so that it does not contaminate sand systems that are sensitive to pH change, especially if the reclaimed sand is used for other binder processes.

Sodium Silicate/CO_2 System. This system consists of liquid sodium silicate and CO_2 gas, and it is an inorganic system. Silicate binders are odorless, nonflammable, suitable for all types of work (high production to large molds), applicable to all types of aggregates, produce no noxious gases upon mixing/molding/coring, and produce a minimum of volatile emissions at pouring/cooling/shakeout. More detailed information on sodium silicate/CO_2 systems can be found in the article "Sand Molding" in this Volume (see the section "Bonded Sand Molds").

Sand Molding

Introduction

SAND MOLDING (CASTING) is one of the most versatile of metal-forming processes, providing tremendous freedom of design in terms of size, shape, and product quality. Sand molding processes are classified according to the way in which the sand is held (bonded). For the purposes of this Handbook, sand molding processes have been categorized as:

- *Resin Binder Processes.* These organically bonded systems include no-bake binders, heat-cured binders (the Shell process and warm box, hot box, and oven-bake processes), and cold box binders. Each of these systems is described in the articles "Resin Binder Processes" and "Coremaking" in this Volume
- *Bonded sand molds* are based on inorganic bonds and include such processes as green sand molding, dry sand molding, skin dried molds, and loam molding, sodium silicate-carbon dioxide systems, and phosphate bonded molds
- *Unbonded Sand Molds.* With unbonded sand molding processes, dry, unbonded, free-flowing sand surrounds the pattern. Lost foam processing, which uses expandable polystyrene patterns, and vacuum molding, are examples of unbonded sand molds. Lost foam molds for large castings are sometimes backed up with a no-bake binder system

This article will describe the latter two categories. More information on sand molding equipment and processing can be found in the article "Sand Processing" in this Volume.

Bonded Sand Molds

Patrick O'Meara, Intermet Foundries Inc.; Larson E. Wile, Consultant; James J. Archibald and Richard L. Smith, Ashland Chemical Company; Thomas S. Piwonka, University of Alabama

---

According to the American Foundrymen's Society (AFS), approximately 90% of all castings produced annually in the United States are processed by sand molding (Ref 1). This section will review a number of sand molding methods that use bonded sand (see classification system described above) with emphasis on green sand molds, the most widely used molding method for small-to-medium castings in all metals.

Green Sand Molds

The phrase green sand refers to the fact that the medium has been tempered with water for use in the production of molds (temper water, which is the water added to activate clay/water bonds in green sand molds, is described in the article "Bonds Formed in Molding Aggregates" in this Volume). As will be described below, the control of a green sand process requires an understanding of the interaction of the various parameters normally measured in a system sand.

Process Control Requirements

A realistic approach to sand control is to target those system variables with which actual control can be implemented and realized. Put in more simple terms, one must control those system parameters that are directly affected by actions taken on the foundry floor. Clay and water are the primary additives of a system sand. The functions they perform are measured by determining the clay content and the percent of compactability of the prepared sand. Seacoal, cellulose, and starches may also be added to the sand. These organic components of the system sand are normally measured by the percent volatile and/or the total combustible test.

The percent volatile test measures the volatile content of the system sand at a specified temperature, usually 650 °C (1200 °F). The total combustible test is conducted by burning the samples of system sand at an elevated temperature, normally 1010 °C (1850 °F). Detailed procedures for these tests can be found in the AFS *Mold and Core Test Handbook.*

The remaining parameters measured on a system sand, such as green strength and permeability are secondary controls. They should be tracked using trend line analysis techniques. This type of analysis allows the monitoring of the variable in question over an extended time so that subtle changes in the magnitude of the variable can be detected. Significant changes in these secondary parameters indicate equipment problems, changes in raw material quality or consistency, and/or changes in product mix being made in the system sand.

Sand Systems

Types of Sand. Sand for green sand molding is composed of various ingredients, each with a specific purpose. The most basic of these ingredients is the base sand itself. The most predominant type of base sand is silica sand. It is classified in two categories: naturally bonded and synthetic sand.

The naturally bonded sand (or bank sand, as it is sometimes called) contains clay-base contaminants. These naturally occurring clays are the result of sedimentation deposits produced during the formation of the sand deposit. The use of this type of sand as a green sand molding medium is determined by the type of metal being cast, economics, casting quality, and the degree of consistency demanded by the final product.

Synthetic sand is composed of base sand grains of various grain distributions. Bonding agents are added to these base sands to produce the desired molding characteristics. The major base sand in this category is silica, although zircon, olivine, and chromite are used for special applications.

Controlling Sand Properties. Sand grain structure is a very important characteristic in the selection of a base sand. The selection dictates the ultimate mold permeability and density, and both of these parameters are critical to the production of quality castings.

When molten metal is introduced into a green sand mold, gases and steam are generated as a result of the thermal decomposition of the binder and other additives or contaminants that are present. If the permeability of the mold is not sufficient to allow the escape of the generated gases, mold pressures will increase, impeding the flow of molten metal, or even causing the metal to be blown from the mold. Thus, the selection of a base sand that provides adequate mold porosity is very important.

Because resistance to gas flow increases as the size of the pores (voids) between the sand grains decreases, the minimum porosity required is determined by the volume of the gas generated within the mold cavity. In like turn, the selection of the base sand is determined by the total amount of gas produced within the mold cavity, as well as by surface finish requirements.

The fact that gas is generated within the mold cavity is not always a disadvantage. Pressures within the mold from the generation of gases help prevent metal penetration into the sand. This minimizes burned-on sand grains and resulting problems associated with cleaning and machining the casting. Thus, a balance between mold permeability and gas generation must be maintained. For example, if mold permeability is low because of the fineness of the base sand, the

sand additives should be those conducive to the production of a low volume gas. On the other hand, if permeability is high, it is advantageous to select materials that yield higher levels of gas.

Permeability is controlled by the amount and size of the voids between densely packed sand grains. The size of the voids is determined by the size, size distribution, shape, and packing pattern of the grains. Figure 1 illustrates two sizes of rounded sand grains. Figure 2 shows that the voids in a mold face are large for a coarse sand and small for a fine sand, although the total void area per cubic unit of volume is almost the same for both sands. However, these distribution criteria also govern the dimensional stability of the base sand.

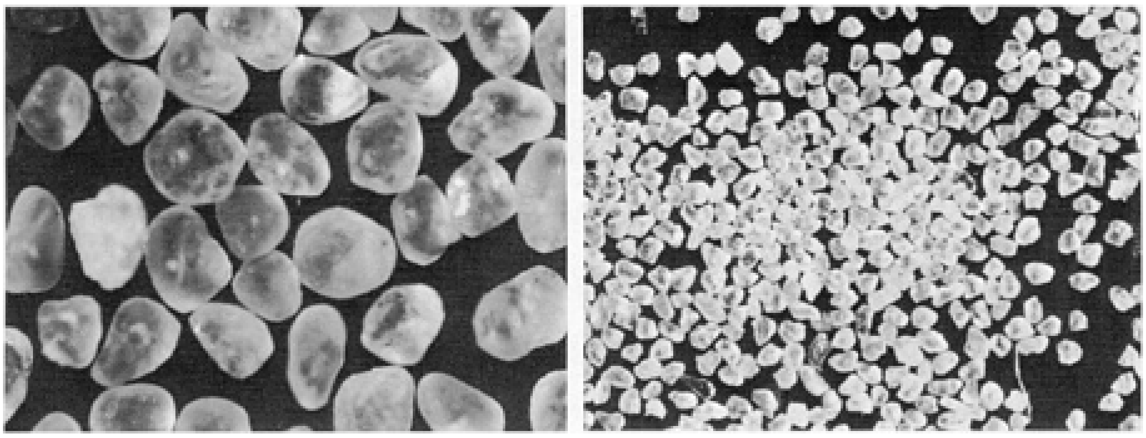

Fig. 1 Two sizes of rounded sand grains. 35×.

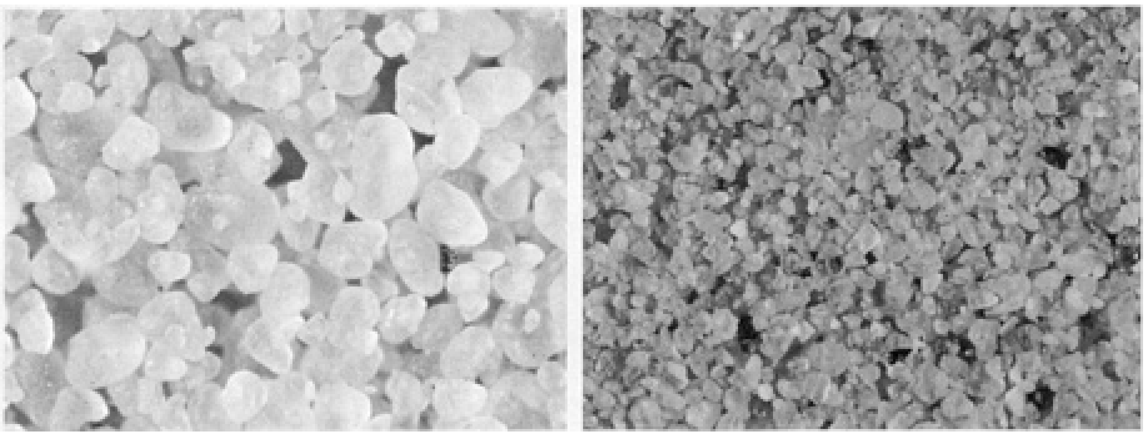

Fig. 2 Sizes of pores in faces of molds made from coarse sand and from fine sand. 35×.

A green sand mold must withstand the erosion caused by the metal impinging on and flowing over the sand surface. If the individual sand grains are not held firmly in place during metal flow, the result will be loose sand grains that will wash into the casting cavity and cause a defective casting. Sand grains are held in place by a combination of two mechanisms: a wedging action in which the sand grains are mechanically locked to adjacent grains, and the clay-water bond established between the grains. The combined action of these two mechanisms forms the basis of the sand strength developed in the mold cavity. The best sand condition for optimum mold strength and density development is produced by sand grains that show a normal distribution over four or more adjacent screen sizes.

As molten metal is introduced into the mold cavity, heat is transferred from the molten metal to the adjacent sand grains, causing the sand grains to expand. Between 425 and 600 °C (800 and 1110 °F), silica undergoes a phase change from alpha to beta, which is accompanied by a rapid increase in volumetric size (Fig. 3). Each sand grain must be allowed to expand, or the mold surface will be altered or destroyed, with resultant loss in casting quality. Therefore, the silica sand

grains must not be compacted so densely or rammed so tightly that they are unable to expand without disrupting the mold surface.

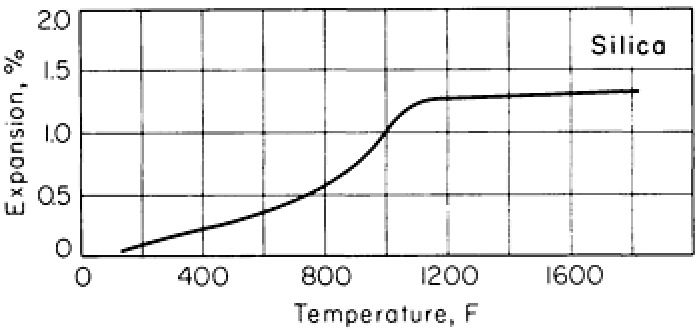

Fig. 3 The effect of temperature on the expansion of silica.

Four methods for optimizing the dimensional stability of the base sand are:

- Selection of a base sand aggregate suitable for a dimensionally stable mold surface. Generally, this will be a four-screen sand, although three-screen sands may be used for certain castings
- Addition of carbonaceous additives such as seacoals and cellulose to the green sand system. The thermal decomposition of these additives creates voids, which allow for the expansion of the silica sand grains
- Increasing clay content to develop higher green strengths, which tend to produce more stable molds
- Controlling the mold density produced by the molding equipment

If it is necessary to use a mold material with less thermal expansion than silica, alternate materials such as zircon, olivine, chromite, or calcined clay may be chosen. Zircon and chromite have the additional advantage of possessing higher heat transfer capabilities. Calcined clay is sometimes used in the production of very large castings in dry sand molds because of its extremely low thermal expansion.

The sand-to-metal ratio for a given mold influences the required pore or void size. The amount of heat transferred to the sand is a function of pouring temperature, volume of metal poured, and amount of time the sand is exposed to the elevated temperatures. These same conditions dictate the volume of gas generated for a given sand formulation. Therefore, for large, heavy castings with high pouring temperatures, a sand with large pores is preferred. For small castings, a sand with smaller pores is the sand of choice.

Finer sands with smaller pores may have reduced ability to allow the decomposition gases to escape. However, they do improve the surface finish and enhance the reproduction of pattern detail. Sand of a single mesh size distribution provides the best venting action, but affords the least protection against erosion or expansion defects. It should be noted that fine sand may require higher amounts of bonding agents (clay, water) because of the higher surface area that must be coated. This further aggravates the gas generation problems because the increased level of bonding agents generates increased amounts of gas that have to permeate the less permeable mold.

The selection of a suitable base sand is a compromise at best. The optimum selection is a multiscreen sand with adequate permeability for the metal and geometry being poured. Factored into the decision also are the economics of the raw materials and the surface finish and casting quality required.

Clays for Green Sand Molding

Green sand additives can be divided into two categories, clays and carbonaceous materials. The major purpose of the clays is to function as a bonding agent to hold together the sand grains during the casting process. The carbonaceous materials aid dimensional stability of the mold, surface finish, and cleanability of the finished casting.

Types of Clay. Clays normally used in green sand molding are of three general types:

- *Montmorillonite,* or bentonite clays. These are subdivided into two general types: Western, or sodium, bentonite; and Southern, or calcium, bentonite. The two clays differ in their chemical composition as well as in their physical behavior within a system sand
- *Kaolinite,* or fireclay as it is normally called
- *Illite,* a clay not widely used. The material is derived from the decomposition of certain shale deposits

The most significant clays used in green sand operations are the bentonites. Western and Southern bentonites differ in chemical makeup and, thus, their physical characteristics also. In general, Western bentonite develops lower green strength and higher hot strength than the same amount of Southern bentonite. Southern bentonite, at the same concentration, produces higher green strength and lower hot strength. This phenomenon is sometimes confused with what is referred to as durability.

Controlling Clay Properties. All clays can be made plastic and will develop adhesive qualities when mixed with the proper amounts of water. All clays can be dried and then made plastic again by the addition of water, provided the drying temperature is not too high. However, if the temperature does become too high, they cannot be replasticized with water. It is this third condition that dictates the durability of the clay in a system sand.

All clays, regardless of type, develop both adhesive and cohesive properties when mixed with water. The amount of adhesive or cohesive property depends on the amount of water added. When the water content is low, the cohesive properties are enhanced and the clays tend to cohere, or stick to themselves, rather than adhere, or stick to the sand grains to be bonded. With high water additions, the converse is true.

In addition to having different bonding and durability characteristics, the various clays have very distinctive behavior patterns as a result of their differing physical characteristics. System sands formulated with high levels of Western bentonite have high levels of hot strength. A system sand formulated with an equivalent level of Southern bentonite will have a significantly lower hot strength. In addition, the flowability of the two sands is different because of the greater swelling tendency of the Western bentonite clays compared to that of the Southern bentonite materials. Therefore, the proper formulation of clay materials for a green sand system must take into consideration the flowability requirements as well as the shakeout requirements of the sand.

The ratio of clay to water is of critical importance in optimizing the properties of clays. The shear strength of a clay-water mixture is representative of the green strength of the compacted sand, because it is the shear strength of the films of clay coating the sand grains that bonds the sand together. This parameter is controlled by the amounts of water and clay added to the mixture and is measured by monitoring the pressure required to extrude various clay-water mixtures through a fixed orifice (Fig. 4).

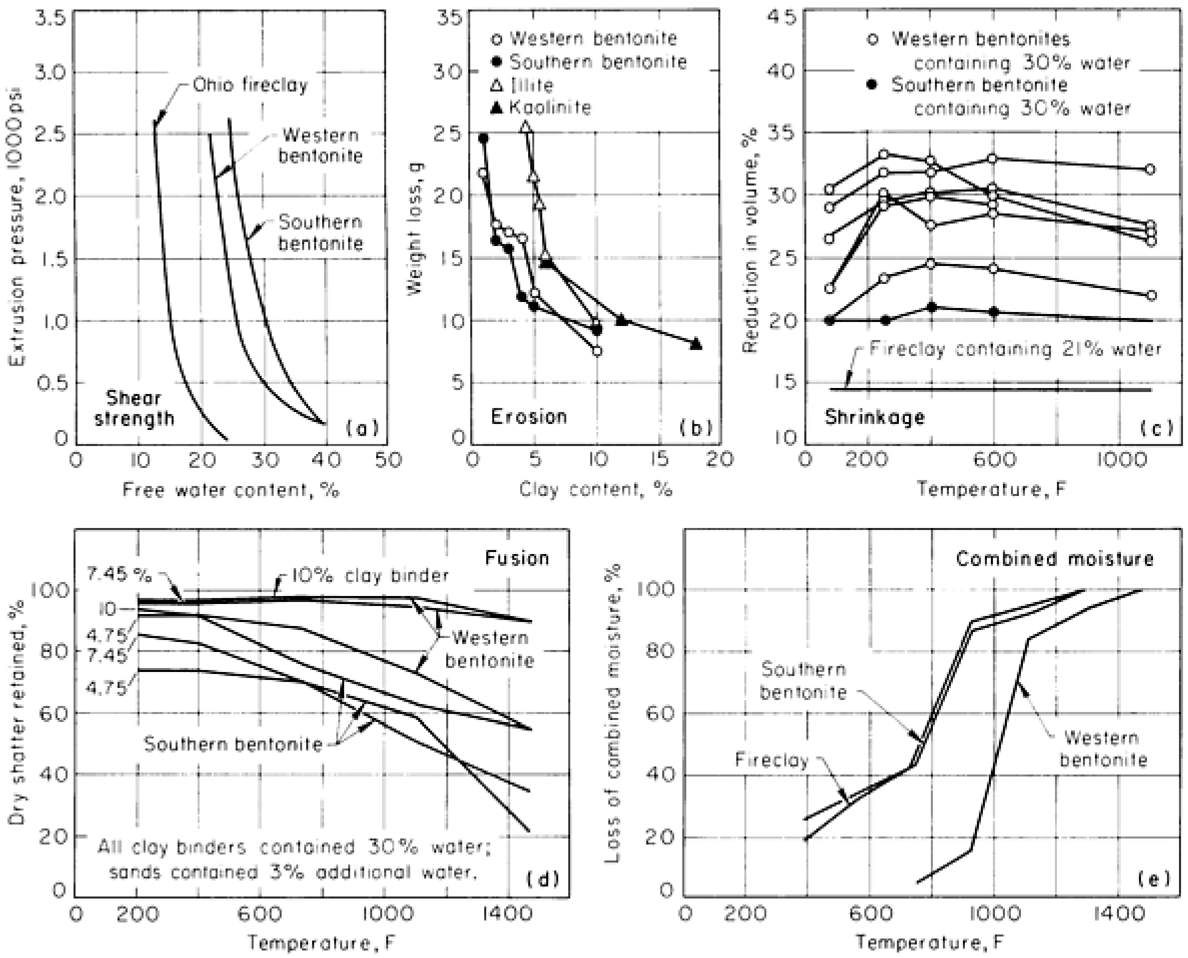

Fig. 4 The effect of several variables on the efficiency of clay used as a bonding agent in sand molds. (a) Relationship of shear strength, as measured by pressure required for extruding a continuous worm of clay through an orifice, to water content, for three clays. (b) Effect of type and quantity of clay on erosion of sand-clay mixtures. (c) Effect of temperature on shrinkage of various types of clays. (d) Effect of mold temperature during casting on fusion of clay binder. (e) Effect of temperature on loss of combined moisture in clays.

In a sand and clay mixture, water is absorbed by the clay up to its maximum capacity. Any additional water is carried as free water in the system sand and does not contribute to bonding. Therefore, high water content clay yields low shear strength. As water content is decreased, a sharp rise in shear strength occurs. The free water content in bentonite clays is normally in the range of 28 to 40%, and for fireclays it is from 15 to 20%.

While the ratio of clay to water in a sand mixture controls the ultimate strength of the sand mixture, the origin of the clay has a significant contribution on the strength potential. Clays from different geographic regions, even though they may be classified as being the same, have different strength curves. However, many of these differences are minimized by modern techniques used in the mining of the clays.

Clay quality is generally measured against the amount required to develop a specified green strength in a sand mixture. Care must be taken when evaluating a clay in this fashion because of the effects of water on strength. The term "the sticky point" defines the point of transition from predominantly cohering properties to those of adhesion. Clays selected for foundry use should have compositions near their "sticky point," or the state at which their cohesive and adhesive properties are balanced.

Once the type of clay is determined for the system sand, economic considerations must be evaluated, because the geographic location of the foundry will, in part, dictate the type, or the combination, of clays used in the operation.

Western bentonite requires a higher energy output to develop its properties than do the Southern bentonites. The fireclays contribute little to green property development, but contribute dramatically to dry and hot property development. The proper combinations of clays allow the formulation of a system sand conducive to the production of quality castings.

System Formulation

Of utmost importance in controlling a green sand system is the selection and consistency of the raw materials introduced into the system sand. Acquisition of the basic raw materials should be from reputable sources only, that is, those that have ongoing quality improvement programs, including the understanding and application of statistical process control techniques. This is critical for a successful control program: Inconsistency in the raw materials used in the system results in sand variations that no amount of attention or corrective action can overcome.

Next in importance is the condition of the sand processing equipment. This includes the sand muller or mixer, sand cooling equipment, and dust collection equipment. It is important to coat the individual sand grains with a uniform thickness of the bonding agent; this governs the physical property development of the sand. The coating action, in turn, is controlled by the condition of the mixing and/or the muller equipment. Failure to monitor the equipment and to maintain it adds appreciably to variations in the sand and a loss of casting quality. More detailed information on equipment for green sand processing can be found in the article "Sand Processing" in this Volume.

Third is the identification of the critical primary and secondary control parameters. The primary control parameters for a system sand are:

- Determination of the organic components measured by the total combustible and/or percent volatile tests
- Determination of clay content measured by the methylene blue titration method
- Percent compactability of the sand controlled by the molding machine

For the majority of foundries, primary controls are limited to the system clay and the content of water and carbonaceous material (secondary control parameters are discussed below).

Actual sampling of a system sand should be accomplished as close to the point in time of use as is practical without compromising worker safety. By so doing, corrective actions can be carried out prior to the molding operation. Tests should be conducted when applicable according to standard procedures outlined in the AFS *Mold and Core Test Handbook.*

The clay content of the system sand is normally measured by the methylene blue titration method. This method of determining clay content is based on the ability of a test sample of the system sand to absorb the methylene blue dye. In this test, the dye is added to the test sample by a buret. The end point of the titration is read by the technician as a "bursting halo" when a drop of the test material is placed onto a hardened piece of filter paper with a stirring rod. The "halo" is an indication that the dye-absorbing ability of the clay has been reached. The amount of dye required to reach the end point (measured in milliliters) is compared against a known standard mixture.

Care should be exercised in the use of the methylene blue titration test because of its vulnerability to operator error. Provision should be made to obtain a test analysis of each revolution of the system sand. However, it is more important to react properly to the available test results than to be concerned with the quantity of the available test data. Clay control can be enhanced by close monitoring of clay additions. Simply knowing what goes into the sand can result in a significant reduction in system sand variations.

Raw Material Additions

The sand in a green sand molding system is primarily made up of recycled, reclaimed, and reused sand. The rejuvenation of this sand is the principal function of the sand preparation system. Sand for the green sand molding system is recovered from the shakeout, cooled, cleaned, and screened. New sand is added to compensate for that which has been lost from spillage or carried away in deep pockets of the casting. Clay, water, and other additives are introduced to bring the sand mix to specification.

Maintaining Sand System Quality. Because the system sand is basically made up of recycled sand, it consists not only of mold sand, but also of core sand. The size and shape of core sand, and the binders used for core sands, are frequently quite different from those used for molding sands, and this must be considered for maintaining the sand system. Also, over time, the sand in the system breaks down as a result of mechanical attrition and thermal cycling, and therefore changes in size, size distribution, and shape. Daily variations in the product mix affect the ratio of core sand to molding sand being recycled. Raw or virgin sand additions to the system should be made to dilute the contaminating effects of residual core binders.

The introduction of additives to a system sand based on a programmed approach greatly reduces system variations. Additives are consumed at identifiable rates. Core sand dilution can be determined as well as any raw virgin sand additions. Losses due to sand carry-out, dust collection loss and material handling can be calculated or approximated. By monitoring sand system variations, a predictable quantity of bonding material can be determined and added to the system. This approach helps minimize system variations and also reduces the necessity for clay analysis as a control tool.

New or reclaimed sand additions to a system sand are of critical importance. Their most important function is to reduce the concentration of contaminants in the system sand. The origin of these contaminants may be alloy by-products or contamination from a core process. A second function is to maintain the total system volume.

All ingredients added to a system sand should be added gravimetrically. Volumetric or timed additions of dry additives are generally not consistent enough to ensure adequate control and only contribute to overall consistency problems. This applies to the addition of a new or reclaimed sand as well as to the return system sand for a batch system.

Most system sands contain additives other than clays; monitoring those additions is critical to the production of quality castings. Carbon additives are either single- or multiple-component. The relative concentration of the carbon additive must remain constant for a laboratory-derived measurement to be of any value. For example, casting finish produced in a system sand with a total combustible value of 3.50% derived from a carbon additive based totally on seacoal can differ drastically from a similar system sand with an equivalent total combustible value derived from a multiple-component carbon additive. In cases in which the benefits can be justified, the use of preblended sand additives is recommended.

Compactibility is the only physical characteristic of a system sand that a molding machine realizes, and it is of paramount importance that it be controlled within a tight band. The desired range will be specific to each foundry. The range chosen should allow optimum strength of the clay as well as adequate moisture levels to minimize sand friability while satisfying the requirements of the molding equipment. The secondary control parameters are as important as the primary, but must be looked at over a period of time. It is necessary to realize that problems develop gradually in a system sand. With this in mind, the use of trend line analysis technique as a tool to a better understanding of the effects of subtle changes in a system sand can be of significant benefit. The specific secondary tests that should be run on a system sand include green compressive strength, permeability, moisture, AFS clay, screen distribution, and AFS washed fineness tests (use the AFS *Mold and Core Test Handbook*). The mulling efficiency should be monitored and charted on an ongoing basis.

While testing a system sand is very important, of equal importance is knowledgeable and responsible review of the data and corrective actions when necessary. Routine review of all test results should include representation from all the various disciplines within the foundry.

Included in the control program for a green sand system should be routine monitoring of the dust collection system. Particular attention should be given to the screen distribution, methylene clay content test, and the total combustible level test. Deviations from normal operating levels indicate equipment malfunctions that require corrective action.

Screen distribution is important. For system sands comprised of only base sand (plus new-sand additions and core sand dilution), if the grain shape remains constant, changes in screen distribution will occur slowly, a major contributor being the condition of the dust collector system. On the other hand, in those systems that have an influx of various types of base sand from varying core processes and sand sources, changes in the base sand distribution will be more dramatic and will cause dimensional problems unless preventive measures are implemented. For these systems, screen distribution should be tested more frequently.

Influence of Molding Equipment. The type of molding equipment used is also critical in the selection of a green sand system. Green sand molding can be divided into three basic types:

- Low-density and low-pressure molding includes manually operated jolt-squeeze units. The green

- compressive strengths of the sand for these units is generally in the low to mid teens (given in pounds per square inch)
- Medium-density units include automatic or semiautomatic units with rigid flasks that combine jolting action and hydraulic squeeze pressures
- High-pressure or high-density units produce molds with hardness values in the high 90s*. These units incorporate flaskless molding technology and use hydraulic pressure and other energy sources for sand compaction

The third group, that is, the high-pressure or high-density molding methods, dominate the high-production and highly automated foundry today. This type of green sand molding lends itself to both flask and flaskless system designs. Some of the major criteria that dictate whether a system is designed as a flask or a flaskless unit is the amount of metal to be poured in each mold and the total mold area that is required. It is not within the scope of this article to deal with all the factors that influence the selection of a molding system. However, all of the systems in this category can be used for high-production repetitive work. Dimensional control of castings with these processes is quite good, and the economics of their operation have yet to be matched by any other. Unfortunately, these systems represent a significant capital investment.

As automation and production rates have increased, the capability for the precise placement of the sand on the pattern has diminished. Thus, a critical characteristic for today's high-production sands is the capability of uniformly covering the pattern surface before application of the compaction energy. Therefore, sand flowability and consistency are of utmost importance in the formulation of a system sand.

Sand Reclamation

The economics of a foundry operation require sand reclamation to reduce the costs associated with new sand and the costs of landfill use, and to reduce the problems associated with the control of environmentally undesirable contaminants in the discarded sand.

In addition, tangible operational advantages result from sand reclamation. These begin with the ability to select the best sand for the casting process, knowing that most of it will be reclaimed during operation. In addition, the use of reclaimed sand reduces the number of variables that must be controlled, and provides operational consistency over a period of time. Sand grain shape and distribution and binder system bonding are more uniform, thus reducing sand defects. A properly designed sand reclamation system begins with green sand and converts it to a product very similar to new sand. Figure 5 shows the appearance of sand before casting, after molding, and after reclamation.

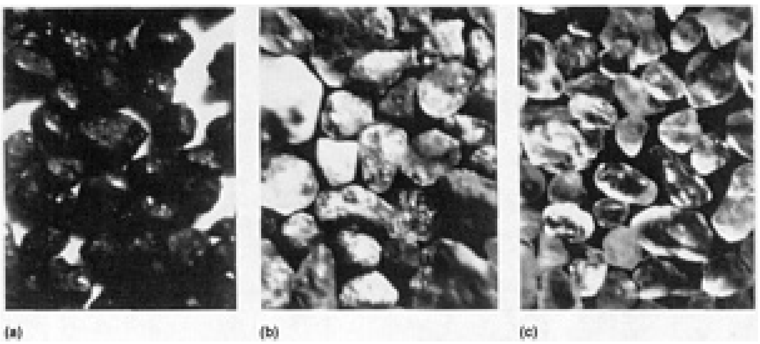

Fig. 5 Influence of sand reclamation on the appearance of green sand. (a) After molding (no reclamation). (b) After thermal reclamation. (c) New sand.

Sand reclamation begins with the removal of tramp and foreign materials, such as core rods, metal spills, slag, and paper, and the disintegration of lumps of sand. Then organic and inorganic binders are removed by attrition (scrubbing) and/or thermal methods. Dead clay is removed as fines. The sand is then brought up to specification by the addition of new sand, clay, and other sand additives.

Sand reclamation systems must be selected with regard to their cost, the specifications for the system sand, system capacity, compatibility with the sand system, metal being poured, and core mixes being used. It is important for the foundry to have a clear understanding of its needs in sand reclamation before calling in vendors. A variety of reclamation systems are described below. More detailed information can be found in the article "Sand Processing" in this Volume (see the section on "Sand Reclamation").

Wet Washing/Scrubbing. The cores of large castings can be removed by high-velocity jets of water. In the process, the cores are broken down into grains, and some binder is removed. Excess molding sand can be added and washed simultaneously. If the shakeout system is dry, the sand is charged into an agitator system where the solid content is held between 25 and 35%. Excess molding sand may be blended with the core knockout material. A similar system uses intensive scrubbing with a solids content of 75 to 80% and units in series. This latter method is superior because of closer and more frequent grain-to-grain contact. After washing, the sand is classified and may be used either wet (naturally drained to 4 to 5% moisture) and added to a system sand, dried for cores, or used for facing sand. Facing sand mixes derive their name from the fact that they are used in limited quantities against the face of the pattern or core box. They have properties usually different from those of the backup or system sand and contain additives not otherwise present. Facing sands are designed to perform special functions, such as providing higher green strength for lifting deep pockets, higher deformation for limited draft patterns, and special carbons that enhance skin drying.

The wet system has limitations in that only a portion of the binder, clay, and carbon is removed. The product, however, is excellent for use as a makeup sand in systems.

Dry Scrubbing/Attrition. This method is widely used, and there is a large variety of equipment available in price ranges and capacities adaptable to most binder systems and foundry capacities. Dry scrubbing may be divided into pneumatic, mechanical, and combined thermal-calcining/thermal-dry scrubbing systems.

In pneumatic scrubbing, grains of sand are agitated in streams of air normally confined in vertical steel tubes called cells. The grains of sand are propelled upward and rub and impact each other, thus removing the binder. In some systems, grains are impacted against a steel target. Banks of tubes may be used depending on capacity and degree of cleanliness desired. Retention time can be regulated, and fines are removed through dust collectors.

In mechanical scrubbing, the equipment available offers foundrymen a number of techniques for consideration. An impeller may be used to accelerate the sand grains at a controlled velocity in a horizontal or vertical plane against a metal plate. The sand grains impact each other and metal targets, thereby removing the binder. The speed of rotation has some control on impact energy. The binder and fines are removed by exhaust systems, and screen analysis is controlled by air gates and/or air wash separators. Additional equipment options include:

- A variety of drum types with internal baffles, impactors, and disintegrators to reduce lumps to grains and to remove binder
- Vibrating screens with a series of decks for reducing lumps to grains, with recirculating features and removal of dust and fines
- Shot-blast cleaning equipment that may be incorporated with other specially designed units to form a complete casting cleaning/sand reclamation unit
- Vibro-energy systems that use synchronous and diametric vibration. Separation of the binder from the sand grains is caused by frictional and compressive forces. One special, advantageous feature of these systems is the small number of moving parts

Thermal-Calcining/Thermal-Dry Scrubbing Combinations. These systems offer the best reclamation for the organic and clay-bonded systems. Grain surfaces are not smooth; they have numerous crevices and indentations. The application of heat with sufficient oxygen oxidizes the binders or burns them off. In attrition, only because there is no contact in the crevices, the binder remains. Heat offers the simplest method of reducing the encrusted grains of molding sand to pure grains. Both horizontal and vertical rotary kiln and fluidized bed systems are available.

In the horizontal rotary kiln, material is fed into one end (usually the cold one) and moved progressively through the heat zone by rotation assisted by baffles, flights, or other mechanical means. Some mechanical scrubbing also occurs. Some systems incorporate heat exchanger technology to considerably reduce the energy required. The latest technology also

includes provision for recovery of metal entrained in the sand and collection and detoxification of the process wastes for suitable nonhazardous waste disposal.

Several fluidized bed system designs are available. Some use preheating chambers and hot air recuperation. A drying compartment may also be added. Sand is introduced into the top (preheating) chamber of the reactor and is lifted by the hot air stream from below until it assumes some of the characteristics of a fluid. The hot air coming in contact with the sand grains burns the organics and calcines the clay. At the same time, some attrition takes place. A correct pressure differential must be maintained between the compartments if more than one is used in order to ensure downward flow of sand; otherwise gravity flow must be provided. Fluidizing is a very good method for cooling sand when using cool air.

Multiple-Hearth Furnace/Vertical Shaft Furnace. The multiple-hearth furnace consists of circular refractory hearths placed one above the other and enclosed in a refractory-lined steel shell. A vertical rotating shaft through the center of the furnace is equipped with air-cooled alloy arms containing rabble blades (plows) that stir the sand and move it in a spiral path across each hearth. Alternate hearths are "in" or "out." That is, sand is repeatedly moved outward from the center of a given hearth to the periphery, where it drops through holes to the next hearth. This action gives excellent contact between sand grains and the heated gases. Material is fed into the top of the furnace. It makes its way to the bottom in a zigzag fashion, while the hot gases rise countercurrently, burning the organic material and calcining clay, if one or both are present. Discharge can be directly from the bottom hearth into a tube cooler, or other cooling methods may be used The units are best suited to large tonnages, that is, five tons or more. They are extremely rugged and relatively maintenance free.

Combinations of systems may also be used, for example, thermal methods followed by dry attrition scrub to remove calcined clay from molding sand or undesirable chemicals and oxides from core processes. Also, commercial centers for sand reclamation are in operation and may be used by smaller foundries.

Note cited in this section

* Hardness in this situation refers to green surface hardness as measured by the C scale hardness tester described in the AFS *Mold and Core Test Handbook.* It should be noted that this scale is not related to the Rockwell C scale hardness indication.

Dry Sand Molding

The essential difference between dry sand and green sand molding is that the moisture in the mold sand is removed prior to pouring the metal. Dry sand molding is more applicable to medium and large castings than to small castings. The molds are stronger and more rigid than green sand molds. They can therefore withstand more handling and resist the static pressure of molten metal, which may cause green sand molds to deform or swell. In addition, they may be exposed to the atmosphere for long periods of time without detrimental effect. Such exposure may be necessary for placing and fitting a large number of cores.

Seacoal is the most common carbon material used in green sand; pitch is the most common in dry sand. Other materials in dry sand are gilsonite, cereal (corn flour), molasses, dextrine, glutrin, and resin. These additives thermoset at the baking/drying temperature (150 to 315 °C, or 300 to 600 °F) to produce high dry strength and rigid mold walls. The base sand is normally coarser than in green sand to facilitate natural venting and mold drying.

Dry Sand Molding Methods. As described below, dry sand molds are made by a variety of methods.

Large sand compaction machines of the jolt, roll-over, and draw-type or jolt-only-type compact the sand in conjunction with tucking, hand peening, and air ramming.

Sand Slingers. These machines throw and compact the sand by means of centrifugal force. A variety of sizes are available. Some supplemental hand ramming may be required.

Floor Molding. This molding method uses larger flasks normally requiring the services of an overhead crane. The molds are made by a combination of mechanical equipment (slinger), hand peening, and pneumatic hand-operated

rammers. Sand must be placed in the flasks in layers, and care must be taken by the molder to make certain that each layer knits and adheres to the other and is of uniform hardness.

Pit Molding. This method is used for very large castings when flasks are impractical. Pits are normally constructed of concrete walls and sometimes floors to withstand great pressures during pouring. Because the drag part of a pit cannot be rolled over, the sand under the pattern must be rammed or bedded in, or the bottom must be constructed with dry sand cores. A bed of coke, cinders, or other means of venting the pit bottom must be provided. Once the pattern is in place, mold-making procedures are the same as those for floor molding.

Curing Sand Mixtures. The sand mixture for dry sand molds can be cured (hardened) by baking in an oven or using forced hot air or stoves placed in the mold.

Mold Coating. Dry sand molds are coated with refractory washes. Water and/or solvent carriers using graphite, silica, or zircon are the most frequently used. It is common to apply several coats. An example of a dry sand mold being coated is shown in Fig. 6.

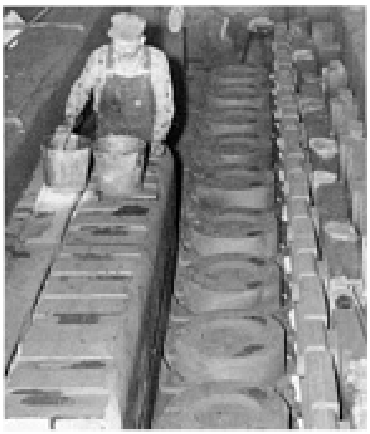

Fig. 6 Dry sand pit mold for stationary diesel engine.

Equipment used for dry sand molding must be strong and rigid. Flasks are equipped with crossbars that normally extend to within several inches of the pattern. The molding sand is reinforced with hooks and gaggers (L-shaped steel bars) that are usually coated with a clay slurry to enhance bonding to the sand. Cores may be suspended in the cope by means of threaded rods and bolts. Venting of the molds and cores is important. Drilling holes in the side walls of flasks facilitates venting. Large flasks and pit molds must be tightly secured with heavy clamps and weights to prevent run-out, which could be extremely dangerous and cause casting loss as well.

Cooling of Castings. Large castings should be cooled slowly in order to prevent internal stresses and/or cracking of the casting. It is sometimes possible to have the molds or cores so rigid that castings will hot tear. The use of inert filler materials placed a safe distance from the casting surface and/or the hollowing out of heavy mold sections will help to prevent such problems.

Skin-Dried Molds

Almost all dry sand molding has been replaced by the no-bake molding (see the article "Resin Binder Processes" in this Volume). Sometimes the pattern may be faced with a no-bake sand mixture and then backed up with a green/dry sand mixture. An intermediate (between green sand and dry sand) type of molding referred to as skin drying is sometimes used. The process is similar to dry sand molding in that the same type of sand mixtures and equipment are used. After coating the surface with a refractory wash, the molds are dried to a depth of 6 to 12 mm (0.25 to 0.5 in.). Skin-dried molds have some characteristics of green sand molds and some of dry sand molds such as ease of shakeout and firm mold face, respectively.

Loam Molding

Loam molding is one of the oldest methods known. It requires the skill of an experienced craftsman, and is seldom used today because of the lack of these craftsmen and the advent of the no-bake systems that have a number of advantages over loam molding, especially greatly reduced production time. Loam molding is particularly adapted to medium or large castings, usually those of circular shape.

The equipment required is relatively simple. No pattern is used; however, a flask or pit may be necessary to support the finished mold. Replacing the pattern is one or more sweeps conforming to the shape of the mold/core. The sweep is attached to an upright, rotating spindle. A bed plate, a cover plate, and arbors for cores are also necessary items.

Materials for making the molds consist of:

- Soft bricks capable of absorbing water

- Molding sand that is quite coarse (sometimes referred to as gravel) and containing a high percentage of clay
- Sawdust, straw, hay, hair, or cloth clippings may be used. These materials contribute to mold strength and burn during casting, thus enhancing collapsibility (disintegration of mold/core)

The molding sand is mixed with water to which molasses may be added until a thick loam slurry resembling concrete is obtained. This mixture is used along with the bricks to build up the general shape, using the same technique that a mason would use. Once the general shape is attained, the bricks are covered with a layer of loam, and the sweep is used to form the outside surface. A layer of loam from 6 to 25 mm (0.25 to 1 in.) thick remains. The mold/core is then baked until thoroughly dry, after which a refractory coating is applied. During the drying process, numerous small cracks form on the surface of the low moisture content clay. These small cracks produce a surface that is very receptive to the refractory coating, which may be brushed, swabbed, sprayed, or actually troweled on. After application, the coating is brushed with molasses and water. A camel hair brush may be used to impart an exceptionally smooth surface. The coating must be dried prior to assembly. Loam molds impart a superior peel to castings.

Before the advent of spun cast pipe in metal molds, large-diameter pipe was made in pits (pit cast pipe). The cores for these molds were made from loam. Hay rope was wrapped around a metal mandrel and the loam slurry was applied, smoothed, and dried, after which a refractory coating was applied.

A typical screen analysis of a loam molding sand is given in Table 1. A casting made from a loam molded cope is shown in Fig. 7.

Silicate and Phosphate Bonded Molds

Sodium Silicate/CO_2 System. Typical silicate binders are odorless, nonflammable, suitable for all types of work (high production to large molds), and applicable to all types of aggregates. They produce no noxious gases on mixing/molding/coring and only a minimum of volatile emissions at pouring/cooling/shakeout.

The amount of silicate binder used for cores and molds varies from 3 to 6%, depending on the type of sand, grain fineness, and degree of sand contaminants. The type of metal poured and its temperature, and the amount of erosion resistance the core or mold will have to withstand are additional factors. A clean, rounded sand grain of 55 fineness requires approximately 2.5 to 3% of binder. As the sand fineness increases, the amount of binder that must be used to coat each grain increases. Thus, a sand of 120 to 140 fineness requires from 1.5 to 3.0% more binder than a sand of 55 fineness.

Either continuous-type or batch-type mixers can be used with sodium silicates. Overmixing should be avoided. Mixtures normally have a good bench life, which becomes shorter when higher-ratio silicates are used. Hoppers of mixed sand should be covered with plastic sheets or damp sacking to prevent premature hardening (crusting).

The initial tensile strength of cores gassed for 5 s with CO_2 varies from 255 to 310 kPa (37 to 45 psi), depending on the binder used. When the core stands, strength increases to a maximum of about 670 to 1380 kPa (100 to 200 psi) in 24 h. This increase is due to some dehydration of unreacted silicates and continued gelling of the silicate. Under normal conditions, cores and molds do not deteriorate and can be stored. An exception may occur during periods of high humidity when sand mixtures are unable to achieve maximum strength by dehydration during storage after gassing. Strength deterioration in high humidity conditions is even more prevalent when the binder formulation or the sand mixture contains organic additives such as sugars, starches, or carbohydrates. Under these conditions, a short heating cycle is necessary to obtain the desired strength. When a core is hardened by carefully controlled gassing, and further hardened by dehydration and polymerization during the subsequent 24 h, good strengths are maintained over a long storage period.

Washes may be necessary on cores and molds made by the silicate/CO_2 process to prevent burned-on sand and metal penetration. Alcohol-base and solvent-type washes are normally used; isopropyl alcohol is preferred to methyl alcohol because it is less toxic and has a higher boiling point. Specially prepared graphite and zircon refractory pastes, which may be diluted with alcohol or solvent in the foundry, are commercially available. Washes on cores and molds promote peel, aid collapsibility, improve casting surface finish, and aid in resisting moisture absorption during periods of high humidity. Water-base washes can be used if care is taken to dry the core thoroughly immediately after coating. This procedure must be carried out with care due to the softening effect of the water on the silicate bond.

Additives may be used in sodium silicate bonded sand mixtures to improve shakeout or collapsibility. Sugars are commonly used for this purpose; they can be compounded with the silicate binder or added separately to a sand mixture.

Small cores and molds are successfully made with core blowers or shooters combined with gassing stations operating on predetermined cycles and automatically controlled. For these applications, CO_2 gas is injected through a hollow pattern or double-wall corebox, or by means of a mandrel in a core, or through a hood covering the box.

Larger cores can be cured by means of lance pipes of about 5 mm ($\frac{3}{16}$ in.) in diameter that are open at the lower end. Using a rod, holes are made about 150 mm (6 in.) apart; the lance is inserted into each hole successively, and the gas is

applied for 10 to 15 s at about 170 kPa (25 psig). The gas permeates and cures an area of sand having about a 75 mm (3 in.) radius around the hole. Large cores and molds may be gassed using specially designed, gasketed covers or hoods that fit over the flask or box. It is important to place vents properly to ensure the flow of gas through all parts of the mass.

Coreboxes and patterns may be made of wood, metal, or plastic and should be washed regularly to prevent sticking problems caused by a buildup of sodium silicate.

The silicate-bonded sand, after pouring and shakeout, may be reclaimed by mechanical means; up to 60% of the reclaimed sand can be reused. Wet reclamation of the silicate sand system is possible, but requires a significant amount of water to scrub the sand. Recently, new methods of attrition reclamation combined with low-temperature thermal methods have shown some promise (see the discussion on sand reclamation in this article).

Phosphate-Bonded Molds. This inorganic binder system, which consists of an acidic, water-soluble, liquid phosphate binder and a powdered metal oxide hardener, was designed to comply with air quality control regulations. Because its components are inorganic, fumes, smoke, and odor are reduced at pouring and shakeout. The phosphate no-bake binder system has shakeout properties superior to those of the silicate/ ester catalyzed no-bake systems described in the article "Resin Binder Processes" in this Volume. The bonded sand can be reclaimed easily by either shot blast or dry-attrition reclamation units.

The hardener component is an odorless, free-flowing powder. It must be kept dry; in contact with water, it slowly undergoes a mildly alkaline hydration reaction that alters its chemical reactivity and physical state. Under normal ambient conditions, the material is not hydroscopic. Flow properties of the powdered hardener are good. Standard powder feeding equipment can be used to disperse the hardener into sand mixers.

Curing characteristics of the phosphate no-bake binder system depend on the ratio of hardener to binder. Varying the level of hardener can typically control strip times from 25 min to more than 1 h. Recommended phosphoric acid-base binder levels are from 2.5 to 3.0% for molds and 3.5 to 4.0% for core production. The hardener level should be kept within 18 to 33% of the binder weight for best results.

Sand type also affects cure speed. Strongly alkaline sands such as olivine tend to accelerate the cure rate. Zircon forms an extremely strong and stable bond with phosphate binders, and as a result shakeout is more difficult.

High-quality defect-free castings can be produced using the phosphate binder system for molds and cores with a variety of metals, including gray and ductile irons and various steels. Erosion resistance of both washed and unwashed molds is excellent. Veining resistance is good on unwashed surfaces and can be controlled with the proper coating selection.

Unbonded Sand Molds

Murray Patz, Lost Foam Technologies, Inc.; Thomas S. Piwonka, University of Alabama

Casting processes that use unbonded sand molds are viable alternatives to conventional green sand molding processes. This section will review lost foam casting and vacuum molding both of which offer considerable advantages. A brief description is also provided for the magnetic molding process, which borrows from lost foam technology. Additional information on these processes can be found in Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12.

Lost Foam Casting**

The lost foam casting process originated in 1958 when H. F. Shroyer was granted a patent for the cavity-less casting method using a polystyrene foam pattern imbedded in traditional green sand, which was not removed before pouring of the metal (patent 2,830,343). The polystyrene foam pattern left in the sand mold is decomposed by the molten metal. The metal replaces the foam pattern, exactly duplicating all of the features of the pattern. Early use of the process was limited to one of a kind rough castings because the foam material used was coarse and hand fabricated and because the packed green sand mold would not allow the gases from the decomposing foam pattern to escape rapidly from the mold (the trapped gases usually resulted in porous castings).

The most significant breakthrough in the lost foam process came in 1964 with the issuance of a patent to T.R. Smith for the utilization of loose, unbonded sand as a casting media (patent 3,157,924). With this development, it was becoming clear to the foundry industry that the lost foam casting process was an emerging technology deserving of attention.

In the 1960s and 1970s, most of the lost foam casting activity took place in automotive company research facilities. Very few production castings were produced during this time. However, use of the lost foam casting process has been increasing rapidly since the expiration of the Smith patent in 1981. Currently, many casting facilities are dedicated strictly to the lost foam process.

Process Technique

Because the casting is an exact representation of the polystyrene foam pattern, the first critical step in the lost foam process is to produce a high-quality foam pattern. As will be described below, surface quality, fusion, dimensional stability, and foam pattern density are key control areas.

The foam pattern is prepared for casting by attaching it to a gating system (sometimes molded as part of the pattern) of material of the same type and density. The pattern system with gating is then coated inside and out with a permeable refractory coating. Once the coating is dry, the pattern system is ready for investment into a onepiece sand flask. Investment of the pattern is achieved by positioning the pattern system in the flask, which has a 25 to 75 mm (1 to 3 in.) bed of sand in the bottom of the flask.

Once the pattern system is properly positioned, loose, unbonded sand is introduced in and around it (Fig. 8). The flask is vibrated to allow the loose sand to flow and compact in and around all areas of the pattern. A pouring basin or sprue cup is usually positioned around the exposed foam downsprue. When compaction (sand densification) is complete, the flask is moved into the pouring area, and molten metal is poured into the pouring basin (sprue cup). The metal vaporizes the foam pattern, precisely duplicating all the intricacies of the pattern (Fig. 9). The casting is then allowed to cool for approximately the same amount of time as with green sand. The flask is usually tipped over, allowing the loose sand to fall away from the casting (Fig. 10a). This sand is collected for reuse and the casting is ready for degating and cleaning (Fig. 10b).

Processing Parameters

The Foam Pattern. Expandable polystyrene (EPS) has been, and will probably continue to be, the preferred material for manufacturing lost foam patterns. There are other foam materials under development that show some promise, but to date their use is quite limited. There are several grades of EPS, as indicated in Table 2. Grades T and X are preferred because they give the foam pattern molder the ability to produce the smoothest surfaces and the thinnest sections possible for lost foam patterns.

Table 2 Grades of expandable polystyrene

Bead grades	**Raw bead diameter**		**Diameter at 24 kg/m^3 (1.5 lbf/ft^3)**		Typical use
	mm	**in.**	**mm**	**in.**	
A	0.83-2.0	0.033-0.078	2.5-5.9	0.097-0.231	**Insulation**
B	0.58-1.2	0.023-0.047	1.7-3.5	0.068-0.138	**Packaging**
C	0.33-0.71	0.013-0.028	1.0-2.1	0.040-0.082	**Cups (coffee)**
T	0.25-0.51	0.010-0.020	0.74-1.5	0.029-0.058	**Cups/lost foam**

Expandable polystyrene weighs approximately 640 kg/m^3 (40 lb/ft^3) in its raw state. For the EPS to be useful in the manufacture of lost foam patterns, its bulk density must be reduced to a level between 16 and 27 kg/m^3 (1.0 and 1.7 lb/ft^3), as indicated in Table 3. This is achieved through a process known as preexpansion. The raw EPS is introduced into a heated chamber and kept in constant motion for even distribution of heat throughout the batch of material. The plastic beads soften, and the gas within the beads expands; this increases the diameter of each individual bead and thus reduces the bulk density (a good analogy is popping corn).

Table 3 Typical pattern density requirements for lost foam casting

Metal	**Metal pouring temperatures**		EPS pattern density	
	°C	**°F**	**kg/m^3**	lb/ft^3
Aluminum	705-790	1300-1450	24-27	**1.5-1.7**
Brass/bronze	1040-1260	1900-2300	20-21.6	**1.25-1.35**
Gray iron	1370-1455	2500-2650	$\leq$20	**$\leq$1.25**

The volume ratio at a finished density of 16 kg/m^3 (1.0 lb/ft^3) is approximately 40:1. After a period of time in the preexpander, the material is discharged and weighed to check density. The density of the foam pattern for a given cast product is critical. For consistent casting results, EPS density must be controlled within ±2% of target density. This is achieved by monitoring and adjusting time and temperature in the preexpander.

Once the preexpanded EPS is discharged from the preexpander, it is placed in intermediate storage to cool and stabilize. After the stabilizing process is complete (usually 6 to 12 h, depending on the type of bead used), the preexpanded EPS is conveyed to a hopper attached to a pattern-molding press. This sequence is illustrated schematically in Fig. 11.

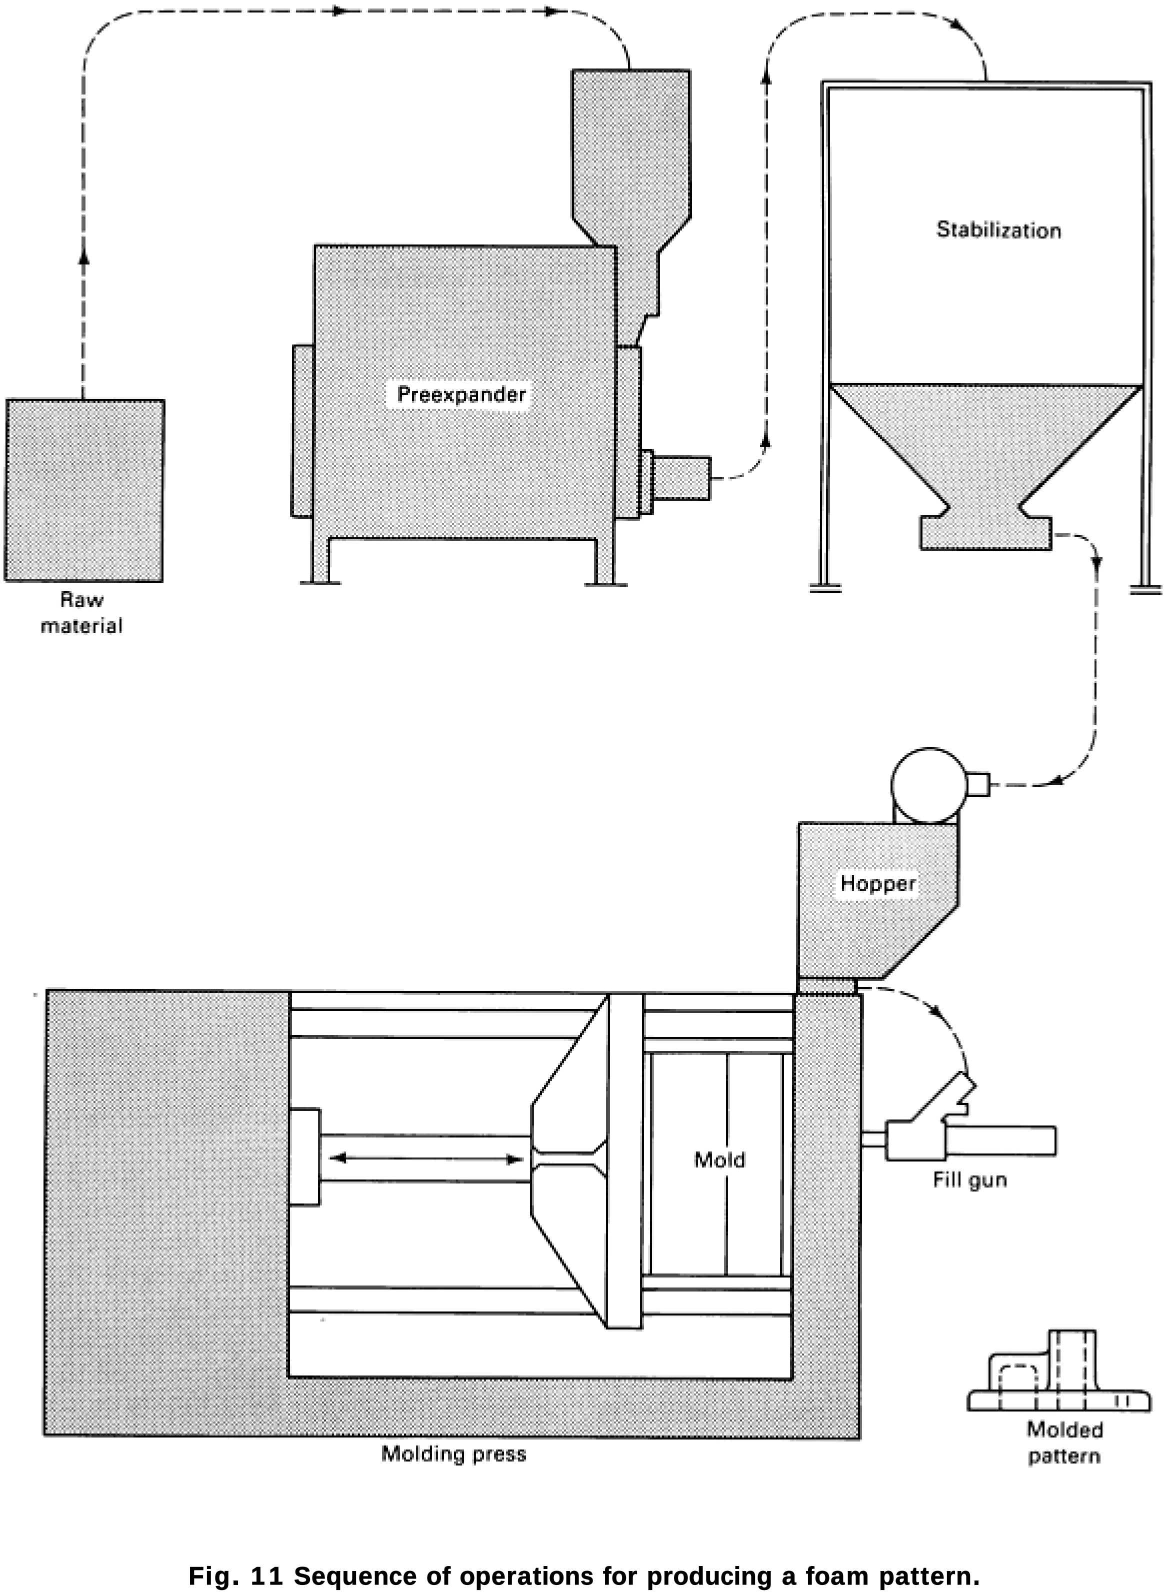

Fig. 11 Sequence of operations for producing a foam pattern.

Pattern molding for the lost foam process can be grouped into four major functions: filling, fusion, cooling, (stabilization), and ejection.

Filling. The preexpanded stabilized material at the desired density is fed from the hopper on the press to the mold (or pattern die). A vented fill gun is used to feed the material, as illustrated in Fig. 12.

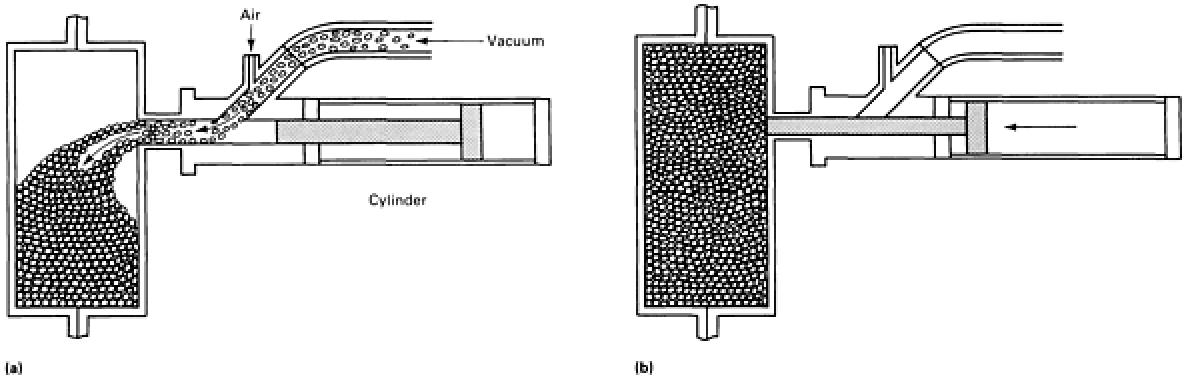

Fig. 12 Fill gun used to feed preexpanded stabilized material to molding press. (a) Open cylinder with pattern material transported by air/vacuum. (b) Cylinder closed prior to fusion.

Fusion. After the mold cavity is full, heat is added by passing steam through the material in the cavity; this reinitiates the expansion process and softens the material as in the preexpansion process (Fig. 13a). The material expands again, filling the air voids between the individual EPS beads and fusing the beads together into a solid mass to form the desired foam pattern.

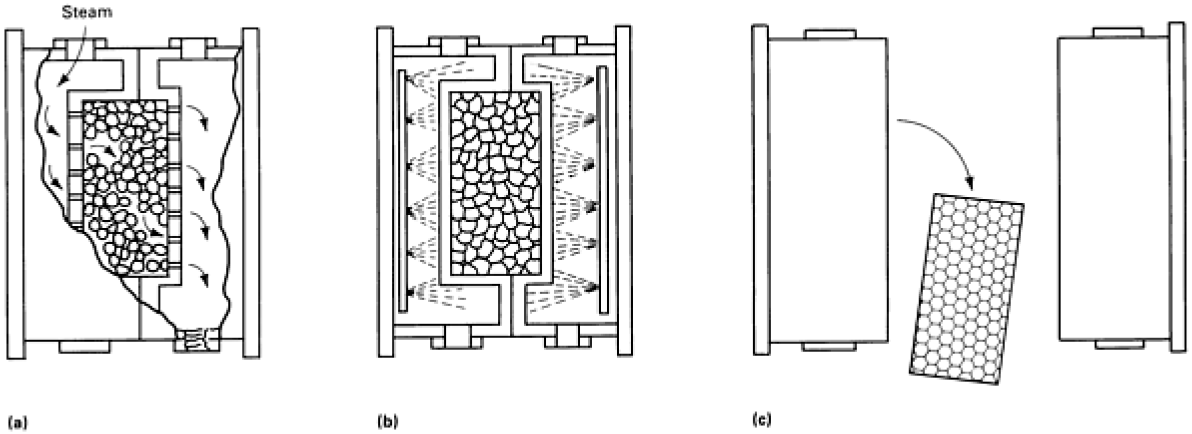

Fig. 13 Schematic showing fusion (a), cooling (b), and ejection (c) of lost foam pattern material.

Cooling. During the fusion portion of a molding cycle, the molded part exerts pressure against the cavity walls. If the part has not been cooled to reduce the internal pressure of the molded part, the part will continue to expand after ejection. This condition is known as postexpansion. To eliminate postexpansion, it is necessary to cool the mold cavity, thus reducing the internal pressure of the molded part to a point at which it can be ejected and still maintain its dimensional integrity. Cooling is usually accomplished by spraying water on the back of the mold wall cavity (Fig. 13b).

Ejection. Once the part has been cooled, the press can be opened and the part ejected (Fig. 13c). This can be done pneumatically or mechanically.

Pattern Assembly. Lost foam patterns typically consist of multiple pieces that must be assembled to form a completed pattern and gating system. The most widely accepted method of assembling patterns is to glue them together with a hot melt adhesive. The adhesive used is specifically formulated for the lost foam process. The temperature at which it is applied to the foam patterns is much lower than the application temperatures of other commercial hot melt adhesives. Lost foam hot melts are generally applied between 120 and 130 °C (245 and 270 °F). To ensure consistent dimensional control and adhesive joint quality, an automatic or semiautomatic gluing procedure is preferred. Figure 14 illustrates a typical pattern assembly sequence.

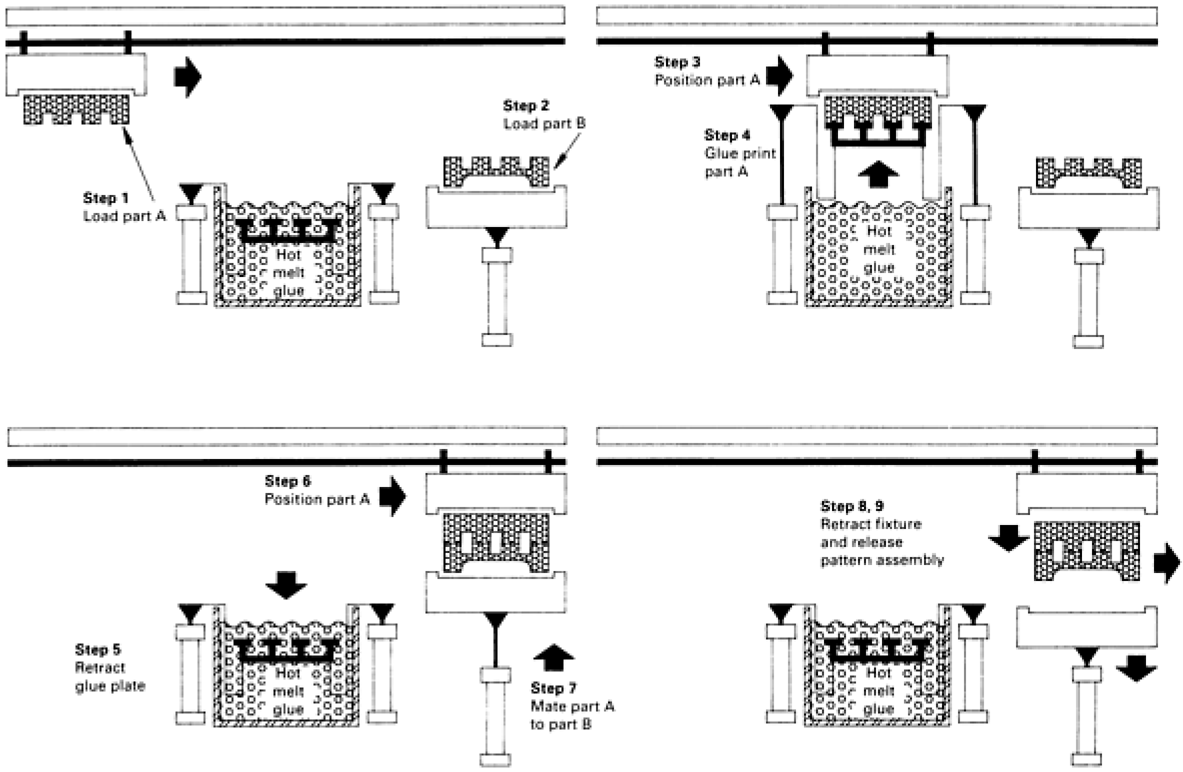

Fig. 14 Pattern assembly sequence showing nine steps performed in the pattern assembly machine.

For prototypes and short run quantities, hand-operated glue printing and assembly jigs can be used. Other methods of pattern assembly can be used in specific applications. These may include hand-applied rubber cement, liquid and contact adhesives, robotically applied airset adhesives, and foamed hot melt procedures. Whichever adhesive material is chosen, it must be suitable for use with lost foam patterns and must be compatible with the molten metal during the casting operation.

The vaporization rate and ash content of the adhesive must be approximately the same as those of the EPS pattern. The adhesive must not adversely affect the dimensional integrity of the pattern. Care must be taken to control all aspects of pattern assembly to maintain consistency. Poor assembly techniques will result in increased casting scrap and dimensional control problems. Thorough inspection of the completed foam pattern system is essential before proceeding to the next step in the process.

Coating Types. It is possible to produce a lost foam casting without using a refractory coating on the foam pattern, but for maximum process latitude, it is advantageous to coat the pattern system. This specialized coating serves two purposes. First, it provides a barrier between the smooth surface of the pattern and the coarse surface of the sand. Second, it provides controlled permeability, which allows the gaseous products created by the vaporizing foam pattern to escape through the coating and into the sand away from the cast metal (Fig. 15).

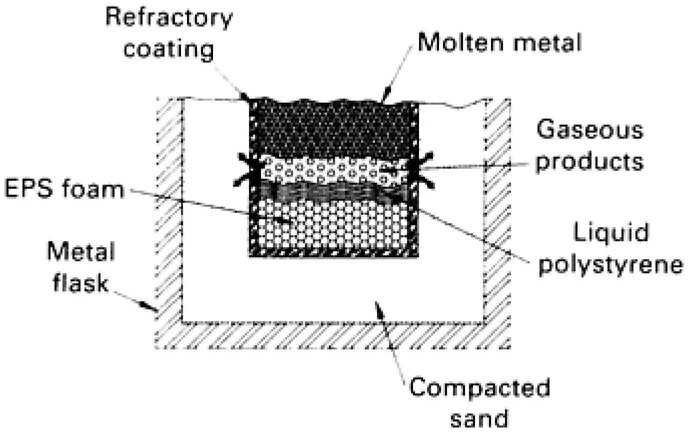

Fig. 15 Reactions taking place during a lost foam pouring operation.

Lost foam coatings are available in various permeabilities. Lower-permeability coatings are preferred in aluminum castings with high surface-area-to-volume ratios--for example, intake manifolds. Heavy-section aluminum castings and other nonferrous castings may require medium- or high-permeability coatings. Ferrous castings generally require higher permeability than nonferrous castings. Silica is the refractory of choice. Its combination of low cost and excellent heat transfer characteristics makes it attractive for use with most metals.

Zircon and olivine coatings are also available, but are not widely used. The choice of coating carrier is limited because the carrier must be compatible with the foam pattern. Hydrocarbons and chlorinated solvents will attack the EPS. Water is the most widely used carrier.

Application of the Coating. Proper preparation and control of the coating is absolutely essential for the consistent production of high-quality lost foam castings. The coating, when mixed properly, can be applied to the pattern system by dipping, brushing, spraying, or flow coating.

Brushing, spraying, and flow coating are used on very large patterns. Dipping is the preferred method for small- and medium-size patterns. Because of the extreme difference in density between the foam pattern system and the coating slurry, large patterns are sometimes difficult to immerse.

Pattern orientation and coating fluidity must facilitate pattern coverage in blind areas. The entire pattern system must be covered inside and out with the exception of the exposed downsprue area, on which molten metal will be poured.

Foam pattern cluster systems must be handled carefully during coating and drying. The weight of the wet coating may cause the patterns to distort or break. Medium- and high-production lost foam facilities find automated coating systems very helpful in controlling the consistency of the coating.

The next step is to dry the coated pattern. This can be done at ambient conditions within 24 h, or the pattern can be force dried in a drying oven or heated room. Forced drying is done at oven temperatures of 50 to 65 °C (120 to 150 °F), along with numerous changes of air per hour and possibly dehumidification. This method of drying coated foam patterns usually takes 2 to 6 h. Microwave drying in the final stage can be used in very high production applications.

Investing the Foam Pattern in Sand. As indicated in Table 2, the coated pattern system is placed in a one-piece flask. Loose, dry, unbonded sand is introduced into the flask generally through a sand raining system. This system gently fills the flask with sand, minimizing the possibility of pattern distortion due to side movement of the sand against the pattern. During the filling of the flask, the flask is isolated from the flask conveying system and vibrated with a high-frequency compaction system either from the bottom or the side of the flask. Variable frequency and amplitude may be required to compact the sand fully in both the internal and external areas of the foam pattern system.

Sand System. The sand most commonly used is silica sand--subangular to round. Different sizes are used for different applications. Generally, AFS grain fineness number 35-3 screen distribution is used in ferrous applications, while AFS 45-3 screen distribution is used in most nonferrous systems (methods for determining sand grain fineness number are discussed in the article "Aggregate Molding Materials" in this Volume). Most sand systems, in addition to the compaction and sand fill stations, incorporate a pouring area, cooling area, dump-out area, sand return system, and sand cooler classifier system. To maintain consistent sand permeability, it is necessary to screen or separate the fine particles that accumulate. The sand must be cooled before being returned to the flask fill area. Foam pattern distortion and adhesive softening may occur if the temperature of the sand introduced in the flask is higher than 50 °C (120 °F).

Pouring a lost foam casting is much like pouring metal in other sand casting methods. The pouring basin or pour cup must remain full throughout the pour. Metal feed is controlled by the vaporization rate of the foam pattern system. A positive head of metal must be maintained (Fig. 9). Failure to do so may result in a mold collapse and scrapped castings

or a partial mold collapse, thus providing the opportunity for sand and coating inclusions in the casting. Metal temperature at the time of pouring is critical and must be controlled tighter than with most other sand casting methods.

After pouring, the castings are allowed to cool at approximately the same rate as green sand castings. The flasks are moved into the dump-out area, sand and castings are separated (Fig. 10), and the castings are ready for degating and cleaning. Conventional cleaning methods, such as sandblasting or shotblasting, can be used. Vibratory media cleaning systems may be necessary to remove the coating, which adheres to internal cast surfaces. Water quenching will greatly assist the cleaning of aluminum castings. Methods for cleaning castings are reviewed in detail in the article "Blast Cleaning of Castings" in this Volume.

Advantages of Lost Foam Casting

The benefits of lost foam processing are numerous, and most are obvious to those who have witnessed the simplicity of the process. In lost foam casting, there is no mold parting line and there are no cores. One-piece flasks are readily moved.

The use of untreated, unbonded sand makes the sand system economical and easy to manage. There is less maintenance on sand handling equipment. Less sand is needed in the system, and the recycling of the sand is an ecological advantage.

These advantages lead to others that are equally desirable. Casting cleaning is greatly reduced and is sometimes eliminated except for removal of the wash coating that transfers from the pattern to the casting. Casting yield can be considerably increased by pouring into a three-dimensional flask with the castings gated to a center sprue.

Another advantage of lost foam casting is its ability to reduce the labor and the skill required in the casting process. In addition to reduced cleaning and the elimination of the need for core setting or parting line matches, handling of the flasks and castings is more readily automated with the lost foam process because locations are predictable.

A lost foam casting facility has the ability to produce a variety of castings in a continuous and timely manner. Lost foam foundries can pour diverse metals with very few changeover problems, and this adds to the versatility of the foundry. Response to customer demands can also be very rapid with this type of manufacturing system.

Further benefits of lost foam casting result from the freedom in part design offered by the process. Assembled patterns can be used to make castings that cannot be produced by any other high-production process. Part development costs can be reduced because of the ability to prototype with the foam. Product and process development can be kept in-house.

Finally, cast-in features and reduced finishing stock are usually benefits of using the lost foam process. Inserts can be cast into the metal, and bimetallic castings can be made.

Note cited in this section

** Lost foam casting is also referred to in the literature as evaporative pattern casting, evaporative foam casting, the lost pattern process, the cavity-less expanded polystyrene casting process, expanded polystyrene molding, or the full mold process.

Magnetic Molding (Ref 12)

Magnetic molding is similar to the lost foam process in that an EPS pattern is used. However, the unbonded sand used as the mold backing aggregate is replaced with magnetic iron or steel shot that is bonded by a magnetic field. The process consists of positioning the EPS pattern in the flask and encasing it with iron particles between 0.5 and 0.1 mm (0.02 and 0.004 in.) in diameter (supported by periodic vibrating and/or tilting), then magnetizing the molding material and pouring the molten metal while the evolving gases are drawn off through the base of the flask. The magnetic field is turned off after solidification and cooling, resulting in immediate shakeout. The free-flowing magnetic shot molding material is returned to its point of origin after cooling, dedusting, and metal splash removal.

The increased heat conductivity of the molding material results in a finer grain structure in the cast metal. Other advantages include the absence of a chemical binder, reductions in dust and noise levels, full mechanization or automation of the process, and the elimination of molding activities normally used (such as ramming and jolting).

To date, most of the research on magnetic molding has been carried out in the Soviet Union and Germany on cast irons, carbon and low-alloy steels, high-chromium steels, and copper-base alloys (Ref 5, 6, 7, 8). Investigations are still being conducted to determine the influence of process variables such as vibration time, magnetic field strength, and time of application on the dimensional accuracy of the castings produced. In addition, work is required to establish more clearly the magnetic properties of the iron powder to provide accurate information on the values of magnetic field strength required for the process (Ref 4).

Vacuum Molding (Ref 10, 11, 12)

The vacuum molding process, or V-process, is a sand molding process in which no binders are used. Instead, the sand is positioned between two sheets of thin plastic and is held in place by the application of a vacuum. Originally developed in Japan for the production of castings with high surface-area-to-volume ratios, the process is now licensed for use worldwide, and it has been successfully used to cast all metals that are normally cast in conventional green sand mold mixes.

Sequence of Operations. The steps in the process are shown in Fig. 16. A specially constructed pattern is built on a hollow carrier plate. The pattern contains a number of small vent holes. A thin (0.05 to 0.10 mm, or 0.002 to 0.004 in.) plastic film is then heated and stretched over the pattern and the sprue pin. A moderate vacuum (27 to 53 kPa, or 200 to 400 torr) is applied to the pattern plate, and this draws the film tightly to the pattern by suction through the vent holes.

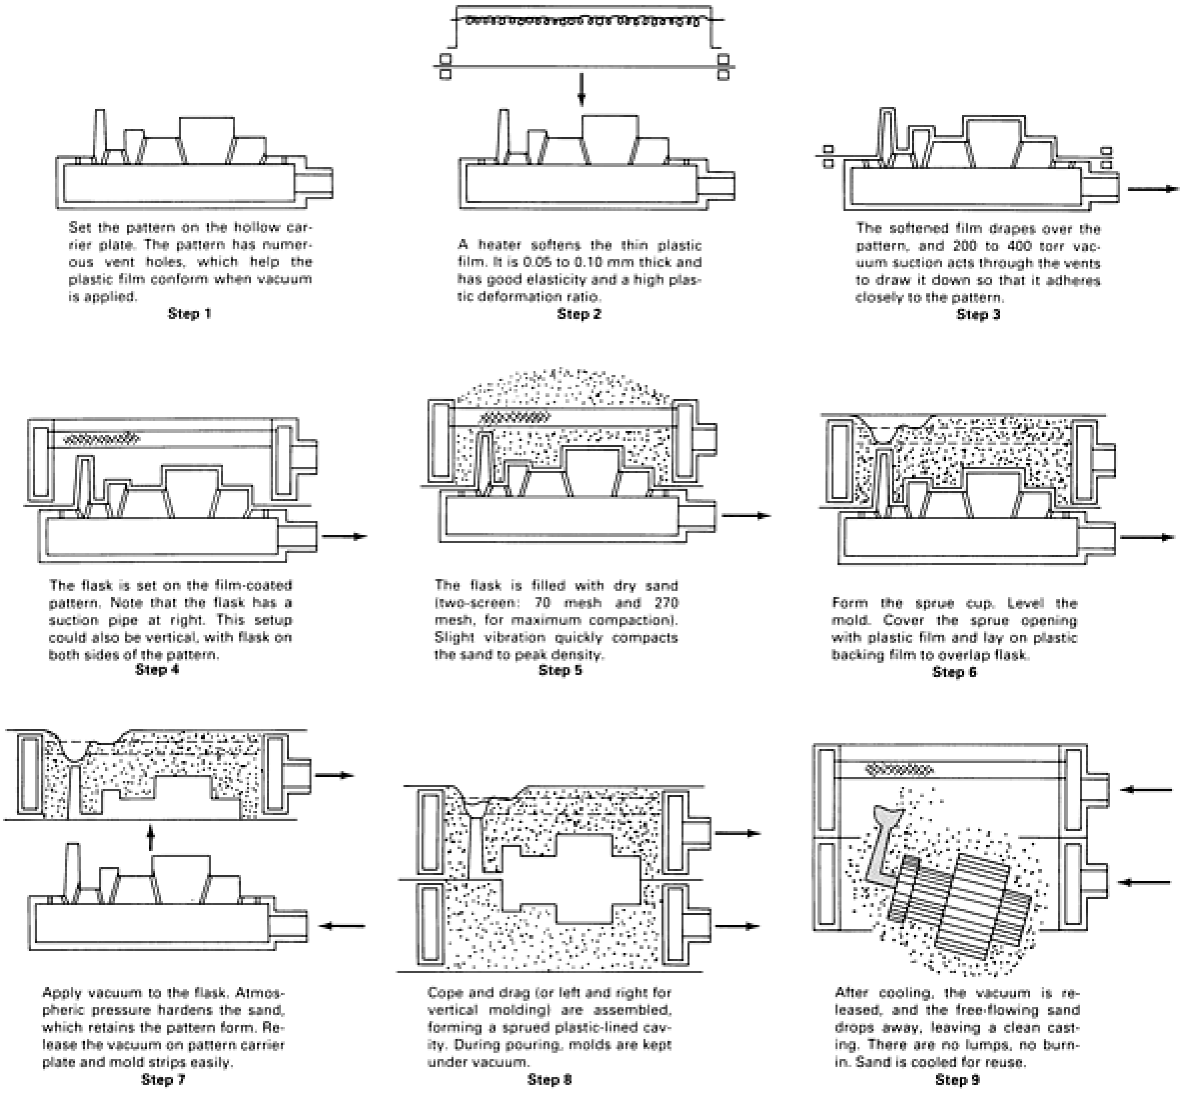

Fig. 16 Elementary sequences in producing V-process molds.

A specially constructed hollow-wall flask containing a vacuum connection is placed around the pattern, filled with sand, and vibrated at a low power level. A two-screen sand (70 and 270 mesh) is recommended for producing high-density molds. The excess sand is then struck off, and the top of the sprue pin is wiped clear of sand. A sheet of plastic film is placed over the top of the sand, and vacuum is applied to the flask. The vacuum holds the sand tightly in place, producing an extremely hard (AFS mold hardness 90+) dense mold. When the vacuum is released on the pattern carrier plate, the pattern is easily withdrawn.

Cope and drag are assembled while maintaining the vacuum, and the casting is poured. After the casting cools, the vacuum is released in the flasks, and the casting and loose sand are removed. The castings separate easily from the sand, which requires only cooling and screening for reuse.

Before pouring, the plastic that covers portions of the mold cavity that would normally be open to the atmosphere (such as the tops of risers, vents, and sprues) is removed to ensure that the mold cavity remains at atmospheric pressure during pouring in order to maintain the pressure differential between the mold and the mold cavity (otherwise the mold will collapse). Care must be taken to ensure that the gases generated during pouring exit to the atmosphere not to the sand and vacuum system.

Plastic Film Characteristics. The plastic films used for vacuum molding are thermoplastic compositions, while thermosetting resins are used as foundry sand binders (see the article "Resin Binder Processes" in this Volume). Plastics that have been evaluated for their applicability to vacuum sealing are listed in Table 4, along with some representative

properties. The most commonly used material is an ethylene-vinylacetate co-polymer (EVA) with vinylacetate contents ranging from 14 to 17%.

Table 4 Plastic films used for the V-process

Type of film	**Density, g/cm³**	Melting point	
		°C	°F
Low-density polyethylene	0.920	88-90	**190-194**
High-density polyethylene	0.960	94-97	**201-207**
Nylon	1.13	215-222	**419-432**
Polypropylene	0.90-0.91	160-170	**320-338**
Ionomer	0.93-0.94	72-75	**162-167**
EVA[a]	0.940	58	**136**
Polyvinylchloride	**1.450**	**56-90**	**133-194**

(a) Ethylene-vinylacetate co-polymer.

The characteristics of the plastic film must be suitable for vacuum forming so that pattern contours will be closely replicated without film shape defects (folds and creases) or rupturing, and the original sheet should be free of pinholes, tears, air bubbles, or blemishes. The important characteristics for easy shaping to pattern contour are both elastic and plastic behavior in proper balance. These properties are a function of film composition, temperature, thickness, stress, rate of loading, direction of loading, and the presence of notch inducers. More detailed information on the film characteristics and test methods used to evaluate these properties is available in Ref 10.

Advantages. The V-process offers a number of benefits. The lack of a binder means that fumes and dust are reduced and that no sand mixing system is necessary. No moldmaking machines are needed, and shakeout and sand reclamation are simplified. Patterns are identical to those used for green sand molding, except that vent holes must be judiciously placed around the patterns for plastic film adhesion. Pattern wear is reduced because the sand never makes contact with the pattern surface. Casting surfaces and dimensions are excellent.

The V-process is not normally used for high-production runs, because of the number of functions that must be performed; however, production rates of 60 to 100 molds per hour have been achieved. Figure 17 shows the layout for a high-speed automated vacuum molding line for the production of medium-size castings at a rate of 60 molds per hour. Vacuum molding is often used in the floor molding of relatively large patterns (flask sizes ≥750 × 750 mm, or 30 × 30 in., are typical) in jobbing foundries, where production rate is five to ten molds per hour.

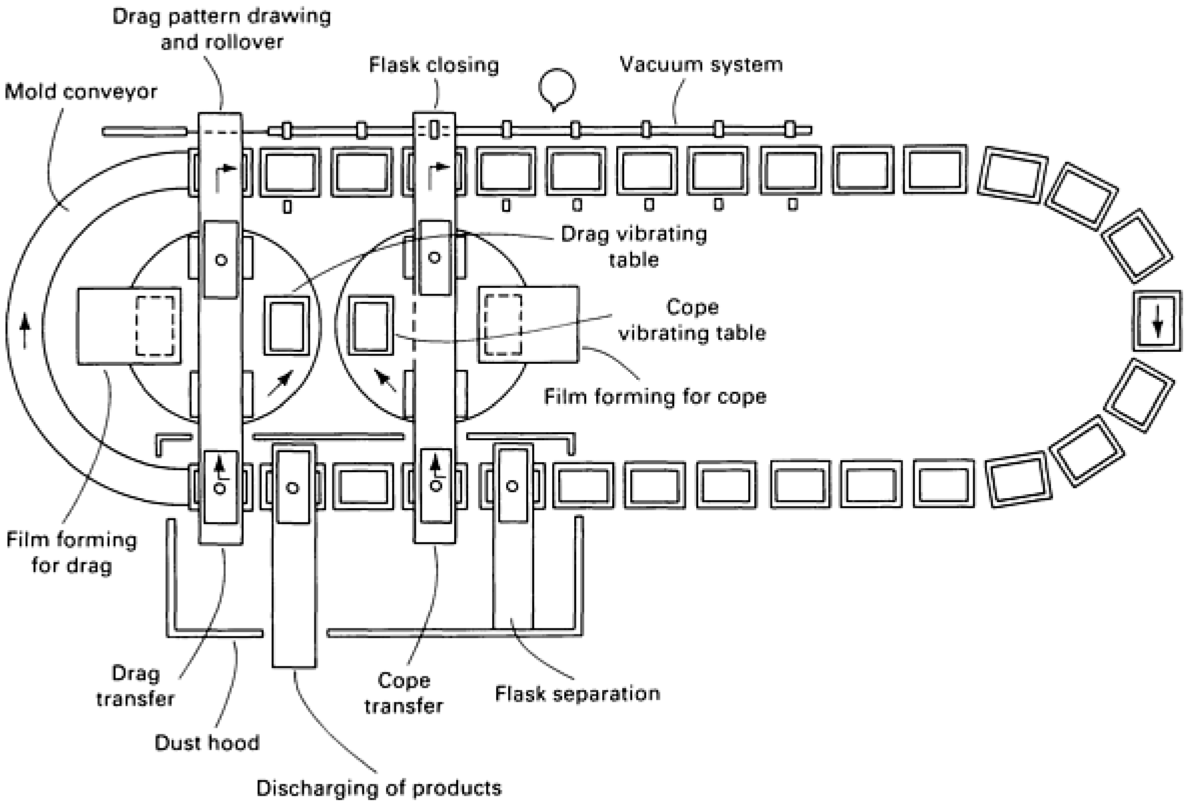

Fig. 17 High-speed automatic V-process production line. Production: 60 complete molds per hour. Flask size: 1300 × 1100 × 400 mm (50 × 40 × 15 in.). Amount of sand: 120 Mg (130 tons/h). Number of operators: 5.

As the plastic film vaporizes with a reducing gas, metal fluidity is often improved in V-process molds. However, because the molds contain no moisture, solidification rates are slower. The high mold rigidity increases riser efficiency because there is virtually no mold wall movement.

Coremaking

Larson E. Wile, Consultant; Ken Strausbaugh, James J. Archibald, and Richard L. Smith, Ashland Chemical Company; Thomas S. Piwonka, University of Alabama

---

Introduction

COREMAKING involves coating a refractory aggregate with binder, compacting the coated sand into the desired shape, and then curing (hardening) the compacted mass so that it can be handled. Refractory coatings are also often applied to the core surface to prevent sand-adhering defects on the casting and to yield a smoother casting finish.

Selection of a Core System

Although a wide variety of methods and materials are used for making cores, coremaking processes are generally categorized according to curing method and binder type. Detailed information on these processes can be found in the article "Resin Binder Processes" in this Volume. The three major systems used for coremaking are listed below:

Cold Box Processes

- Phenolic urethane/amine
- Furan/SO_2
- (Acrylic/epoxy)/SO_2 (free radical cure process)
- Sodium silicate/CO_2
- Phenolic ester

Heat-Cured Processes

- Shell process
- Core oil (oven bake)
- Phenolic hot box
- Furan hot box
- Furan (furfuryl alcohol) warm box

No-Bake Processes

- Furan/acid
- Phenolic/acid

- Alkaline phenolic/ester
- Silicate/ester
- Phenolic urethane/amine
- Polyol isocyanate
- Alumina phosphate

The cold- and heat-cured (heat-activated) processes lend themselves exceptionally well to medium- and high-production applications. Examples of high-production operations are foundries that cast automotive, pipe fitting, air conditioning, and refrigeration components (Fig. 1). The no-bake processes are generally used for short-run production quantities.

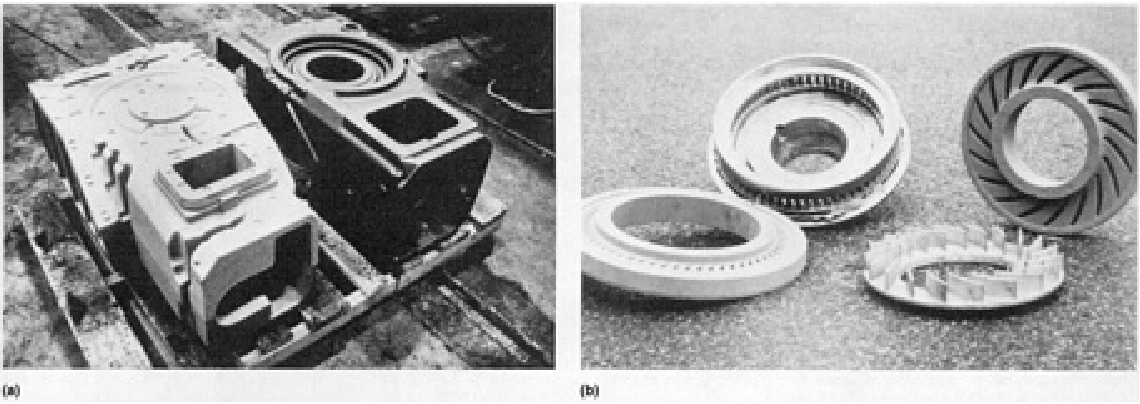

Fig. 1 Cores and corresponding castings produced by the cold box process. (a) Large transmission case and resulting gray iron casting for an agricultural equipment manufacturer. (b) Disk brake rotor and turbine cores and castings. Courtesy of Ashland Chemical Company

Both cold- and heat-activated cores are cured in the core box, thus maintaining excellent dimensional accuracy. Cold processes utilize gases that are forced through the compacted sand mixture to cure the core (Fig. 2). Heat-cured processes require the core box to be heated to 175 to 290 °C (350 to 550 °F) prior to introduction of the prepared sand. The no-bake process uses binder systems that consist of chemicals that, when mixed together in sand, cure without the introduction of an external agent, such as heat. The process is well suited to the fabrication of larger cores.

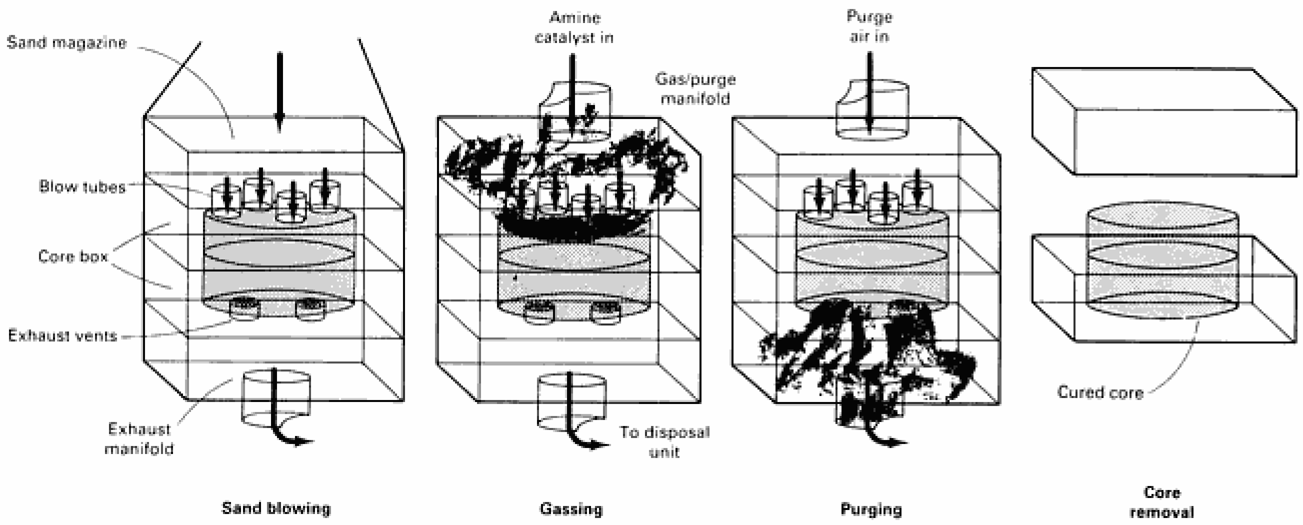

Fig. 2 The cold box coremaking process. The wet sand mix, prepared by mixing sand with the two-component liquid resin binder, is blown into the core box. The core box is then situated between an upper gas input

manifold and a lower gas exhaust manifold. The catalyst gas enters the core box through the blow ports or vents and passes through the core, causing almost instantaneous hardening of the resin-coated sand. The core is ready for ejection from the core box after purging with clean air for a few seconds. After the catalyst gas passes through the core, it leaves the core box through vents into the exhaust manifold. From the gas exhaust manifold, the catalyst gas is piped to an appropriate disposal unit.

In the core-oil (oven-bake) process, sand is mixed with corn flour and/or clay and water along with the binder to give sufficient strength to the mass of sand so that it can be immediately removed from the core box onto core plates. The cores are then hardened by baking at 200 to 260 °C (400 to 500 °F). The oven-bake process does not require complicated curing equipment, and materials are inexpensive; but dimensional accuracy is more difficult to maintain.

The type of metal to be poured must be considered in selecting a core process. For example, steel and certain high-alloy cast irons are sensitive to urea because of the tendency to form gas defects due to the amount of nitrogen present. In making aluminum castings, the pouring temperature may not be high enough to break down the binder system adequately for easy removal from the castings. Although silicate cores usually collapse sufficiently when used with aluminum and steel, their use in cast iron may be a problem because of a secondary bond that forms at iron-pouring temperatures. Cores for magnesium castings require inhibitors that must be compatible with the binder system.

Wood, plastic, and metal core boxes can be used with the cold processes, while only metal can be used with the heat-activated systems. However, once a system is established, metal core boxes and machines designed for one type of heat-activated process can usually be used for alternate heat-activated processes. The same is true for cold processes.

Although equipment is available for blowing or shooting core weights of up to 540 kg (1200 lb), most cores of this size and above use one of the no-bake processes. Smaller cores are usually made using cold, warm, or hot box techniques unless they have high surface-area-to-volume ratios, in which case the required equipment would be cumbersome.

Elevated temperatures accelerate chemical reactions. Summer temperatures may adversely affect some of the hot systems to the point where they actually harden prematurely. In cold systems, the silicon dioxide (SO_2) types possess the longest working times.

The core sand will eventually become system sand. Therefore, suitability for reclamation and compatibility with the sand reclamation and sand system used must be considered.

Mixing

Sand mixing is easily accomplished for all of the processes except the oven-bake and shell processes. Special mullers are required to mix the sand and dry ingredients adequately with water and binders to develop the necessary strength to permit baking process cores to be removed from the core boxes in the uncured state.

Most shell process sands are hot coated in paddle/plow-type mixers using solid or liquid novolac resins. Cold and warm coating, both of which utilize powdered or liquid novolac resins, have declined.

With the hot coating process, a solid flake or liquid novolac resin is dispersed into a sand that has been preheated to 130 to 175 °C (265 to 350 °F). Hardener (contents ranging from 10 to 17% based on the weight of the resin) is first dissolved in water, and this solution is added after the resin is dispersed, and a lubricant is added near the end of the cycle.

The moisture content of the sand mix will range from 1.5 to 2.5%. Immediately after the addition of the water/hardener solution, cold air is blown into the mixer to cool and dry the sand. Whatever process is selected, the coating process is carried out in a paddle-type mixer that is usually equipped with a system (fluid bed, screen, or cyclone) to cool and complete the drying of the coated sand.

Various types of blending equipment are used to disperse the binders uniformly over the sand used in the other processes. Batch or continuous mixers can be employed to coat the sand used in the cold or heat-activated processes. If a batch mixer is used, the sand and additives are weighed or volumetrically measured before being introduced into a mix. There the mixture is agitated by a revolving mixer or by vibratory motion for 20 s to 5 min. Prepared sand is then discharged and transferred to the coremaking station.

A continuous mixer is almost a necessity for a no-bake coremaking operation, but is also adequate for mixing sand for the cold or heat-activated processes, with the exception of the shell process. Sand and additives are continuously metered into a mixing trough or chamber that contains revolving mixers of various designs, and prepared sand is discharged. In the no-bake process, the sand is discharged directly into the core box, where it is immediately compacted. Prepared sand for the cold and heat-activated processes is generally discharged into a storage hopper above a coremaking machine.

Compaction

Cores must be sufficiently dense to obtain good grain-to-grain bonding of the sand mass and to prevent metal penetration between the sand grains. Prepared sand can be hand rammed into the core box, and this is the usual procedure for no-bake cores; but mechanical methods are required for high-production operations.

Core blowing machines are commonly used to compact sand into the core boxes. Prepared sand is added to a chamber, which is then sealed except for exit ports (blow ports) that are placed directly over inlet ports (investment areas) of the core boxes. The core boxes are equipped with air relief vents. A large volume of compressed air at 275 to 700 kPa (40 to 100 psi) is suddenly introduced above the sand in the chamber, forcing the sand into the core box through the investment area. The carrier air is exhausted through the vents in the core box. The blow air is then turned off, the excess pressure in the blow chamber is exhausted, and the core boxes are disengaged from the blow ports. All these steps are generally electrically or mechanically controlled and require only seconds to complete.

Release Agents

All core binders are sticky, but some are less so than others. It is this characteristic that requires the use of release agents/parting compounds on core boxes, regardless of the type of core box material. The desirability of having a dense core compounds the problem of core release, because binder-coated sand is packed or blown against the surface with force, which enhances sticking. In the heat-activated processes, the binder melts or softens and migrates to the heated surface.

It is necessary to start with a good core box; no amount of release agent will overcome roughness and scoring. The core box should be chromium plated if it is to be used for high production, and it should be broken in gradually. If a release agent is functioning properly, some buildup will occur; it should be removed frequently because it adversely affects core dimensions and quality. One method of removing buildup is blasting with ground walnut hulls, corn cobs, or other soft media. Solvents can also be used. Minimum amounts of release agents should be used, and when adding them during mixing, they should be added near the end of the cycle. The release agent should be chemically compatible with the binder system.

Oleic acid diluted with kerosene (usually 10:1) is used as a release agent for core-oil cores. It is added to the sand mixture and used to keep the core boxes clean. The amounts used are 125 to 250 mL/450 kg (1 pt to 1 qt/1000 lb) of sand.

Shell and other heat-cured processes use emulsified silicone release agents diluted in water. A low surface tension silicone should be used for spraying core boxes. Stearates, usually calcium, are added to shell sand during the coating process. Amounts recommended are 2 to 5%, based on resin solid weight. Small amounts of core oil or silicone emulsion can be added to hot box sand during mixing.

The no-bake and cold box processes use a wide variety of release agents. Small-to-medium size high-production core systems will normally use liquid types, which can be sprayed through jet nozzles and integrated into an automatic cycle or sprayed with a hand gun. No-bake systems normally use liquids, suspensions in liquids, or dry materials for larger cores. The suspension systems usually use a solvent carrier that evaporates readily. Materials can be sprayed, brushed, dusted, or hand rubbed onto the core boxes. Ingredients include (in many combinations) water, alcohol, chlorinated solvents, mica, talc, silicones, aluminum powder, graphite, and soybean oil (lecithin).

Curing

Curing of the compacted mass of sand and binders varies according to the process chosen. In the cold box processes, the appropriate gas for the process (carbon dioxide, sulfur dioxide, tertiary amines, or methyl formate) is forced through the compacted sand (Fig. 2). Chemical reactions then occur that create rigid bonds between sand grains. Excess curing gas is purged from the cured core with compressed air, and the cores are removed from the core box as hardened cores.

In the heat-activated process, prepared sand is blown into a heated core box. The heat releases curing agents from latent hardeners in the sand mix, and these curing agents then cure the binder.

Time alone is required for the binders in the no-bake cores to react, and after sufficient time, generally from 30 s to 1 h, the cores are rigid enough to be removed from the boxes. Additional curing may continue for several hours.

Cores from the core-oil process are placed in ovens after stripping from the core box and are baked for 1 h or longer, depending on section thickness. They are removed from the oven when thoroughly cured and allowed to cool to ambient temperature.

Coating

Coatings are frequently applied to cores to enhance the casting surface finish and to reduce casting defects at the mold/metal interface. Coatings accomplish this by having a higher refractory value than the sand and/or by forming an impermeable barrier between the metal and the core. Most coatings are formulated with five major components:

- Refractory materials
- Carrier system
- Suspension system
- Binder system
- Chemical modifiers

Refractory materials for coatings can be made of any of the following materials:

Zirconium oxide
Zirconium silicate
Magnesium oxide
Olivine
Chromate
Pyrophyllite
Talc
Carbon (many forms)
Silicon dioxide
Magnesium/calcium oxide

Mullite (aluminum silicate)
Mica
Iron oxide
Magnesite

These materials are blended in many combinations to make up a broad selection of proprietary coatings. Silica, alumina, and carbon are the most commonly used, and water, alcohol (isopropyl, methanol), naphtha (petroleum distillate), chlorinated solvents (inhibited 1,1,1-trichloroethane, or chlorothene NU, and methylene chloride), and aliphatic hydrocarbon are used as liquid carriers.

The carrier allows the refractory to be applied evenly to the sand mold or core. After the coating has been applied, the carrier must be removed. When the carrier is water, it can be torched or oven dried. Alcohol carriers are commonly ignited and allowed to burn off. The volatile chlorinated hydrocarbons readily air dry and require neither torching nor oven drying.

Suspension System. The function of the suspension system is to maintain the refractory material uniformly dispersed in solution. With water carriers, sodium bentonite is commonly used, while organic bentonite or bentones are generally used with alcohol and chlorinated hydrocarbon carriers.

The binder system in a coating is usually an organic resin, and it behaves similarly to the resins used to bond sands. The amount of binder used depends on the density and fineness of the refractory. It is used sparingly to avoid casting surface defects.

Chemical modifiers to the coating include surfactants to enhance wettability, antifoaming agents, and bactericides.

Coating Benefits. Most of the reasons for using coatings center around reducing casting costs by improving sand peel and reducing mold/core reaction, reducing or eliminating metal penetration (burn-in and/or burn-on), and reducing or eliminating veining. These reasons are directly associated with casting cleaning costs. Coatings are also used to reduce machining time and tool wear by having a clean smooth surface, to improve casting appearance, to facilitate handling (especially where low-strength cores may be required because of shakeout conditions), or to promote chill or increase hardness in metal (for which selenium or tellurium paste is used). Coatings should not be used indiscriminately. No coating will compensate for a poor-quality core.

Blending and Applying Coatings. All the advantages of selecting the proper coating, or wash, can be lost if it is not properly blended. Coating ingredients are available in powder, paste, slurry forms, and ready-to-use forms.

In preparing a core wash, the ingredients are mixed to a slurry with an electric or air-driven mixer. The mixing tank should be twice as high as its diameter, should be equipped with flow-through baffles spaced at approximately 120°, and should have an impeller shaft with two blades. The slurry must be mixed until creamy and lump free, with ingredients in suspension/solution. The Baumé must be kept 25 to 30° higher than application requires and further diluted prior to use. The carrier should be added in steps to avoid overdilution, which will adversely affect suspension. Coatings should be mixed a specified time before use (usually 12 to 24 h) to permit tempering of the suspension and bonding agents, and over-mixing should be avoided.

The methods of application will depend on a number of factors, such as the size and shape of the core, plant layout (if a continuous process is used), and production requirements. For example, small cores would not lend themselves to spraying but to dipping in groups using fixtures and/or baskets. Conversely, large cores in a production line could move continuously on a conveyor through a dip tank to a drain station and then to a drying station. Regardless of the method of application, obtaining a smooth, even coat is of paramount importance.

Water- or solvent-based washes can be used for furan, furan/phenolic, urethane cold box and no-bakes, phenolic esters, and baked core-oil cores. However, water-based washes should not be used on silicate or phosphate-bonded cores, because such washes will degrade the binder.

The best practice for drying coatings is to apply coatings on cured cores and then dry them by appropriate means, such as ovens, burn-off, or warm air circulation. If cores are cold, they should be heated before or immediately after application. If cores are coated green (incomplete cure), heat should be applied immediately. Evaporation of the solvent is important for avoiding deterioration of the core binder.

Core Venting

Venting is necessary, and the general rule is to provide the maximum allowable venting. To understand the fact that gases must be dispersed, one need only consider the volume change that occurs in the transition of a liquid or solid to a gas.

The principal gases resulting from the breakdown of the chemical binder systems have been found to be hydrogen, carbon monoxide, carbon dioxide, methane, and nitrogen (Ref 1). In venting, however, the volume of gas is more important than its composition.

Care must be taken to lead all vents to core prints and to provide exits from the mold with minimum pressure buildup. In addition, vents must be kept far enough away from the surface to prevent metal breakthrough. As coarse a sand mix as good practice permits should be used. The permeability of sand is related to its coarseness, assuming a normal distribution. The coarser material will have the highest permeability and the most natural venting.

Cut, punched, filed, or scratched vent passages can be made by removing sand during coremaking, after curing, and before assembly. Mandrels can be used to hollow out cores, thus saving sand, or small holes can be drilled into cured cores.

Strands of wax and/or plastic tubing can also be used. These materials are available in a variety of sizes. In the heat-activated processes, some of these materials melt and are absorbed into the sand, leaving a passage. Permeable plastic tubes can be used in cold box processes. In very large cores, the center can be filled with dry unbonded sand, coke, slag, or gravel, thus avoiding gas generation. A secondary advantage of using these materials is that they replace the same volume of mixed sand and thus reduce cost.

Plaster Molding

Revised by Charles D. Nelson, Morris Bean and Company

Introduction

PLASTER MOLD CASTING is a specialized casting process used to produce nonferrous castings that have greater dimensional accuracy, smoother surfaces, and more finely reproduced detail than can be obtained in sand molds or coated permanent molds. The four generally recognized plaster mold processes are:

- Conventional plaster mold casting
- Match plate pattern plaster mold casting
- The Antioch process
- The foamed plaster process

Applications

Near-net shape castings such as compressor wheels, impellers, components of electronics gear, tire molds, aerospace fuel pump systems, and heat exchanger systems are examples of castings produced by plaster mold casting. Machining costs would be exceedingly high if these parts were cast in most other types of molds.

For many parts, only a small portion of the total area requires the capabilities of plaster molding. Composite molds are more suitable for such parts.

Although about 90% of the plaster mold castings weigh less than 9 kg (20 lb) each, castings weighing as much as 34 kg (75 lb) are being produced in substantial quantities. To illustrate the capabilities of the technique, an aluminum alloy casting weighing 1815 kg (4000 lb) has been successfully cast in a plaster mold.

Advantages. Most of the advantages to be gained from the use of plaster molds have to do with casting quality:

- As-cast surface finishes of 50 to 125 RMS are readily obtained. By using flexible rubber patterns and incorporating the advantages of lost wax techniques, slurry molding successfully produces intricate designs
- The dimensional accuracy of the castings is good (about equal to the accuracy of castings made in investment molds)
- Thin sections can be cast because the castings normally cool quite slowly due to the insulating qualities of the plaster; wall thickness limits are a function of casting design, bit selected areas 0.64 to 1.02 mm (0.025 to 0.040 in.) thick are typical
- Slow cooling minimizes warpage and promotes uniformity of structure and mechanical properties in the castings
- Plaster molds are especially well suited to the use of chills, which permit close control of thermal gradients in the molds; this optimizes mechanical properties desired in isolated areas of a complex casting

Disadvantages in using plaster molds are largely related to molding and casting procedures:

- Cost is high, partly because of the lengthy processing procedures and partly because the mold materials are not reusable
- Mold processing requires more equipment than is required for most other molding processes
- Because of the lengthy processing procedures needed to make plaster molds, duplicate (or multiple) pattern equipment, as well as duplicates of other processing equipment, may be required in order to meet production schedules
- With the exception of the foamed plaster process, the permeability of plaster molds is inherently low when compared to the sand casting process; therefore, it is usually necessary to apply pressure or vacuum during pouring or to provide greater permeability by a special procedure

Plaster Mold Compositions

In all of the processes for making plaster molds and cores, the principal mold ingredient is calcium sulfate. Other materials used to enhance such mold properties as green and dry strength, permeability, and castability include cement, ceramic talc, fiberglass, sand, clay, Wollastanite, pearlite, and fly ash.

Cores are typically made of the same material and by the same process as molds, but cores are sometimes made of other materials, such as shell molding sand. Cores for the match plate plaster mold process are made of sand. Specific mold and core formulations, as well as techniques for making the slurries, are discussed under each process in this article.

Characteristics of Calcium Sulfate. Calcium sulfate exists as two different hydrates and in an anhydrous form. In its dihydrate form ($CaSO_4 \cdot 2H_2O$), it is known as gypsum. (Commercially, all three forms of calcium sulfate are sometimes referred to as gypsum.) When heated above an equilibrium temperature of 128 °C (262 °F), gypsum loses three-fourths of its water to form the hemihydrate ($CaSO_4 \cdot \frac{1}{2} H_2O$), which is plaster of paris. Similarly, when the plaster of paris is heated above an equilibrium temperature of 163 °C (325 °F), all of the water of crystallization is removed, and anhydrous calcium sulfate ($CaSO_4$) is formed. The above temperatures are based on laboratory studies of pure calcium sulfate under equilibrium conditions. Temperatures at which the hydrates are formed depend greatly on vapor pressure. For practical purposes, temperatures well above equilibrium temperatures are generally used.

If it is exposed to moisture at a temperature lower than 100 °C (212 °F), the anhydride formed near 163 °C (325 °F) will absorb water and will revert to the hemihydrate; the anhydride produced by heating to about 540 °C (1000 °F) will absorb water less rapidly. Similarly, when plaster of paris (the hemihydrate) is mixed with water, gypsum (the dihydrate) is reestablished, yielding a coherent solid in a few minutes. This reaction is termed setting. Prolonged exposure of the hemihydrate to moist air at temperatures below 100 °C (212 °F) results in a slow conversion to the dihydrate.

In the production of a plaster mold, plaster of paris is mixed with water to form a slurry. This slurry is immediately poured over a pattern or into a core box, where it sets, forming a solid mold or core composed of gypsum with free water distributed throughout the plaster mold.

The next stage is to dry the plaster in an oven to remove the excess water. Various drying temperatures are used, depending on the plaster molding process. If partings and waxes are used, the temperatures must be high enough to remove any waxes.

Plaster molds have low heat capacity. Therefore, the cooling rates for castings made in such molds are low. Figure 1 shows that the freezing time for a test casting made in a conventional plaster mold is more than four times as long as that for one made in a hard-rammed green sand mold.

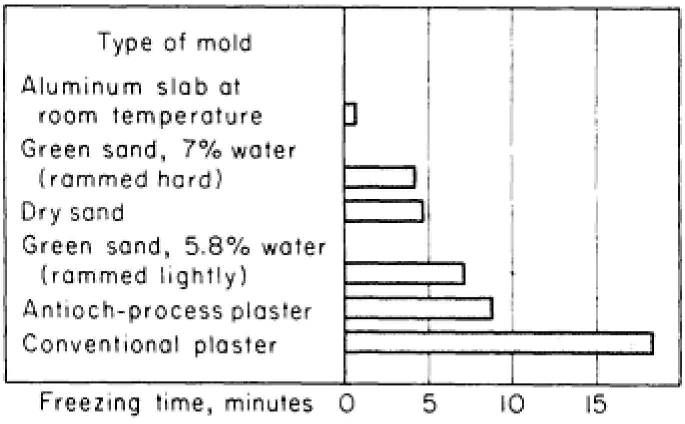

Fig. 1 Comparison of freezing times for identical test castings poured in various types of molds

Slow cooling has advantages and disadvantages. It permits better feeding, particularly in thin sections, as well as the replication of intricate detail that would be difficult to obtain with fast cooling. However, it slows production by lengthening the time between pouring and shake out, and for most alloys it results in castings of lower strength. This latter disadvantage can usually be eliminated by the use of chills in specific areas.

Patterns and Core Boxes

Metal and Rubber Patterns. Patterns and core boxes for plaster mold casting are commonly made of metal (aluminum alloy, brass, or zinc alloy). Flexible rubber patterns are widely used for producing intricate molds, such as the molds used for casting wheels having angular vanes. Flexible rubber patterns having as much as 30° negative draft can be withdrawn without damaging molds that have high green strength.

Cast epoxy resin patterns are useful for some purposes. For example, when several patterns are required, they can be made quickly by molding them from epoxy resin in metal master dies. Cast epoxy patterns also have greater dimensional stability and longer production life.

Wood Patterns. Because patterns for production casting by plaster mold processes must withstand repeated exposure to liquid slurries, wood patterns usually are not adequate. Wood patterns, although not extensively used in the production of castings, are specified as patterns for match plate pattern molds. Wood patterns must be sealed, or they will swell and distort.

Mold Drying Equipment

Plaster molds made by any process must be dried. The most common drying temperatures range from 120 to 260 °C (250 to 500 °F), but temperatures to 870 °C (1600 °F) have been used under carefully controlled conditions. Once the optimum temperature for a specific application has been determined, it must be closely maintained--usually within ±6 °C (±10 °F).

After this initial requirement has been met, the choice of equipment depends largely on the temperature to be used and the number of molds to be processed. For drying at 120 to 260 °C (250 to 500 °F), either batch-type or conveyor core ovens are satisfactory.

Higher-temperature drying requires furnaces similar to those used for the heat treating of steel. Either batch-type or conveyor furnaces can be used, but conveyor furnaces are generally preferred, especially for drying large quantities of molds. The molds must be cooled to at least 205 °C (400 °F) before they are removed from the furnace.

Flasks

Flasks are usually made of low-carbon steel and aluminum. They vary in size in accordance with the size of the pattern, the number of identical molds to be produced, and the number of patterns in a flask.

When the flask is to hold only one pattern half, especially when only a few molds are required, a simple, bottomless flask is placed on a mold board, and the pattern half is positioned within it on the board, ready to receive the slurry. When many identical molds are required, especially when two or more patterns are placed in a single flask, a flask with a flat bottom that serves as a mold board is used; the pattern halves are arranged on the flask bottom. In the Antioch process, for small single-pattern molds, pattern and flask are often an integral unit (see the section "The Antioch Process" in this article). The flask for a given application should be large enough to allow space for the same thickness of plaster surrounding the pattern as would be needed if the mold material were dry sand.

Standardization of flask sizes is important in production operations because this simplifies tooling, especially when vacuum pouring is used. Standardization of flask size is also desirable for pouring the slurry and drying the molds. In some foundries, it is common practice to select as standard a flask size that is suitable for the largest casting that will normally be poured. When smaller castings are to be made, a family mold practice is often used. In this practice, two or more patterns (sometimes as many as 16) are positioned in the flask.

Metals Cast in Plaster Molds

Only nonferrous metals are cast in plaster molds. Ferrous alloys are not suitable, because most of them are poured at temperatures that would melt the calcium sulfate the molds are made of. Calcium sulfate undergoes a phase transformation at 1195 °C (2180 °F) and melts at 1450 °C (2640 °F).

Aluminum. All of the aluminum alloys that can be successfully cast in sand molds are suitable for casting in plaster molds. The more readily castable alloys--43, A344, 355, 356, and 357--are preferred.

Copper. Most of the coppers and copper alloys that can be successfully cast in sand molds can be cast in plaster molds; again, the more castable alloys are preferred (see the article "Copper and Copper Alloys" in this Volume). Copper alloys containing more than approximately 5.0% Pb are generally not recommended for casting in plaster molds, because the higher-lead alloys react with some mold compositions, resulting in poor surfaces on the castings and defeating one of the objectives of plaster mold casting.

Magnesium alloys are not recommended for plaster mold casting. A reaction is likely between the magnesium alloys and the mold material. In particular, magnesium alloys will react with any free water that remains in the mold and will cause an explosion.

Zinc alloys are frequently cast in plaster molds, most often for prototype castings. The die casting alloys AG40A and AC41A are often used, but a proprietary alloy whose coefficient of thermal expansion is very close to that of aluminum alloys is frequently cast. Master patterns appropriate for this zinc alloy or for aluminum can be made according to a single shrinkage rule.

Nominal compositions of the three zinc alloys mentioned are:

Alloy	Composition, %			
	Al	**Cu**	**Mg**	Zn
AG40A	4.10	0.10 max	0.035	**rem**
AC41A	4.10	1.00	0.055	**rem**

Except for allowances for shrinkage, the technique for making the molds is the same as that for aluminum and zinc alloys.

Conventional Plaster Mold Casting

Melting practice equipment and methods for metal to be poured into plaster molds are the same as those used for preparing the metal for pouring into other types of molds. A brief outline of conventional plaster molding is given in the following sequence of operations for producing conventional plaster molds.

- Mix dry ingredients
- Add dry ingredients to water
- Soak (2 to 4 min)
- Mix (2 to 5 min)
- Coat patterns (or core boxes)
- Pour slurry
- Set at room temperature (15 min)
- Remove pattern
- Dry molds (or cores)
- Assemble cores and mold halves

Composition and Preparation of Dry Ingredients. Dry ingredients ready to mix with water are available as proprietary compositions. For small operations, it is usually cost effective to purchase these ready-to-mix dry ingredients. Compositions vary considerably, but the gypsum content (typically, a blend of gray and white gypsum) is commonly 50 to 60%, by weight, of the dry mixture. The rest of the mixture consists of two or more filler materials, such as wollastanite, ceramic talc, fly ash, pearlite, and sand. Portland cement, hydrocals, fiberglass, and terra alba are also sometimes used to enhance the strength of the mold and to improve setting behavior.

Mixing the Slurry. Equipment requirements for mixing the slurry are very precise. The principal components of a batch-type mixer are a bucket and a propeller (Fig. 2). The bucket height should be equal to or slightly greater than the top diameter, and the bottom diameter should be approximately two-thirds of the top diameter.

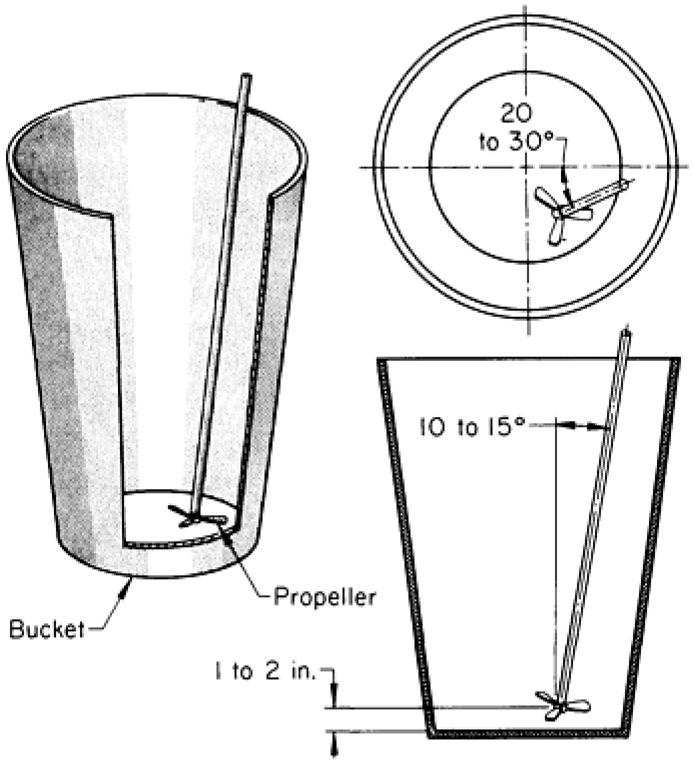

Fig. 2 Preferred shape of bucket and position of propeller used in the batch mixing of plaster slurries for conventional plaster molds

Preparing the Pattern. Because the slurry begins to set as soon as it is mixed, it must be poured over the pattern (or into the core box) almost immediately, and the pattern must be ready to receive the slurry.

Pouring the Slurry. When the slurry is poured into the flask, the lip of the bucket should be kept close to the pattern. The slurry should be poured at a constant rate and made to flow over the pattern rather than splash on it.

Set time varies somewhat, depending on the slurry composition, but 30 min is usually the maximum set time. After the slurry has set, the pattern and flask are removed, and the drying cycle is started as soon as is practical.

Drying the Molds. All conventional plaster molds must be dried enough to expel the free water and most of the water of crystallization to a depth of at least 13 mm ($\frac{1}{2}$ in.) below the surface. Some foundries prefer to have the molds completely calcined.

Oven drying should begin as soon as is practical after the mold has been removed from the flask. Molds that have partially dried by standing at room temperature are more susceptible to cracking than those that are oven dried

immediately after setting. If the molds must stand at room temperature for some time (such as over a weekend or even overnight), they should be covered with a damp cloth or stored in a humid atmosphere.

During drying, the mold should be uniformly supported on its edge or face. Common practice is to place the mold on a perforated flat metal plate, a rigid metal grid, or some other type of level support. If smooth plates are used for support, they should be covered with a thin layer of talc or similar material to allow movement of the mold during drying without the danger of its cracking or warping.

Time and temperature cycles used for drying conventional plaster molds vary widely among foundries. Temperature may vary from about 175 to 870 °C (350 to 1600 °F), and time from 45 min to 72 h. The fact that furnaces are operated at high temperatures (760 to 870 °C, or 1400 to 1600 °F) does not mean that all areas of the mold must reach this temperature range, but the interior of the mold must be at a temperature of at least 105 °C (220 °F), to ensure removal of the free water. (Mold temperatures are measured by thermocouples in the center of mold sections.) The specific time and furnace temperature required for drying a specific mold usually must be determined by experimentation. Once established, the time-temperature cycle must be rigidly controlled for best reproducibility.

Mold Assembly. After the mold has been removed from the oven, cores are placed in the drag half. Depending on mold complexity, this can be done while the molds are still hot or after they have cooled to room temperature. Ceramic or plaster pins are placed in the holes provided in the drag half. The cope half is then lowered so that the pins protruding from the drag enter the matching pin holes in the cope, as shown in Fig. 3.

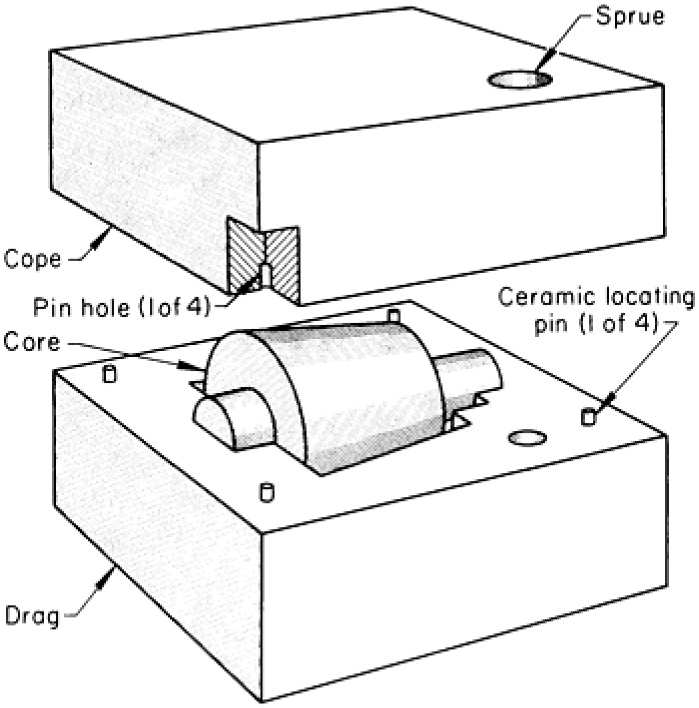

Fig. 3 Plaster mold and core showing location pins for matching the cope and drag sections

Preheating. Following assembly, the mold is ready for preheating. Some foundries preheat all conventional plaster molds to a preestablished temperature (commonly 120 °C, or 250 °F) before pouring the metal. Other foundries preheat the molds only in specific applications for which preheating has proved advantageous. Preheating of the mold can help to minimize defects or to obtain better replication of fine detail in the casting.

Pouring Practice. A dried plaster mold made by the conventional process has extremely low permeability--about 1 to 2 AFS, compared with 80 and upward for sand molds. Because of this low permeability, either vacuum assist or pressure is usually required for the pouring of molds. Simple gravity pouring is rarely done.

Most foundries use vacuum assist for pouring conventional plaster molds. A typical setup for vacuum-assist pouring is shown schematically in Fig. 4(a). In this setup, the mold is supported by a fixed bottom plate (plate B, Fig. 4a).

Casting of Match Plate Patterns

Match plate patterns are cast by a particular adaptation of the conventional method of plaster molding. Changes in details of the conventional method ensure high accuracy and smooth surface finish, which are required in metal match plate patterns.

Common dimensional requirements for match plate patterns are:

- Match between the cope and drag, within 0.25 mm (0.010 in.)
- Parallelism between the two halves, within 0.51 mm (0.020 in.)

A surface finish of 2.5 μm (100 μin.) or better is obtained.

Sizes and Weights of Match Plate Patterns. A match plate pattern consists of a cope section and a drag section separated by a plate. These three components are cast as an integral unit. A typical match plate pattern is shown in Fig. 5.

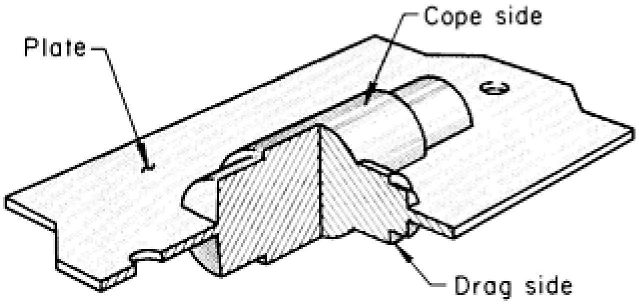

Fig. 5 A typical metal match plate pattern

Metal match plate patterns vary considerably in size and weight. Patterns weighing as much as 180 kg (400 lb) each have been cast, although these are unusually large. Match plate patterns seldom weigh more than 45 kg (100 lb) each, and most weigh from 8.2 to 16 kg (18 to 35 lb).

A single plate may hold one pattern or many patterns. The thickness of the plate for small patterns having one pattern per plate is usually 9.5 mm ($\frac{3}{8}$ in.). The plate thickness increases as the size and weight of the pattern increase; a thickness of 19 mm ($\frac{3}{4}$ in.) would be used for a plate measuring 1.1 × 1.1 m (44 × 44

in.). Plate thickness is also increased to provide adequate stiffness and bend resistance in designs involving a stepped parting line separating cope and drag mold sections.

Mold Composition. Materials for molds for match plate patterns are available as proprietary dry mixtures ready for mixing with water. However, some foundries prefer to make their own mixtures.

Master patterns for match plate patterns are usually made of wood (for economy), but they can be made of metal. Wood patterns must be lacquered or otherwise coated to prevent the absorption of water from the slurry.

Separate master patterns are made for the cope and the drag. The plate portion is developed by the technique described in the section "Mold Assembly" in this article, rather than by means of a pattern. Before the slurry is poured, the patterns are coated with a release agent.

Flasks for the casting of match plate pattern molds are bottomless boxes. They differ from flasks for conventional plaster mold casting in two respects. First, standardization of flask size is seldom feasible in match plate pattern mold work because pattern sizes vary widely. However, standardization is less important because molds are not required in production quantities. Second, because the mold remains in the flask through the drying and metal-pouring operations, provision for matching the cope and drag sections must be incorporated into the flask rather than the pattern as in conventional operations. The use of guide pins for the matching of mold sections is illustrated in Fig. 6.

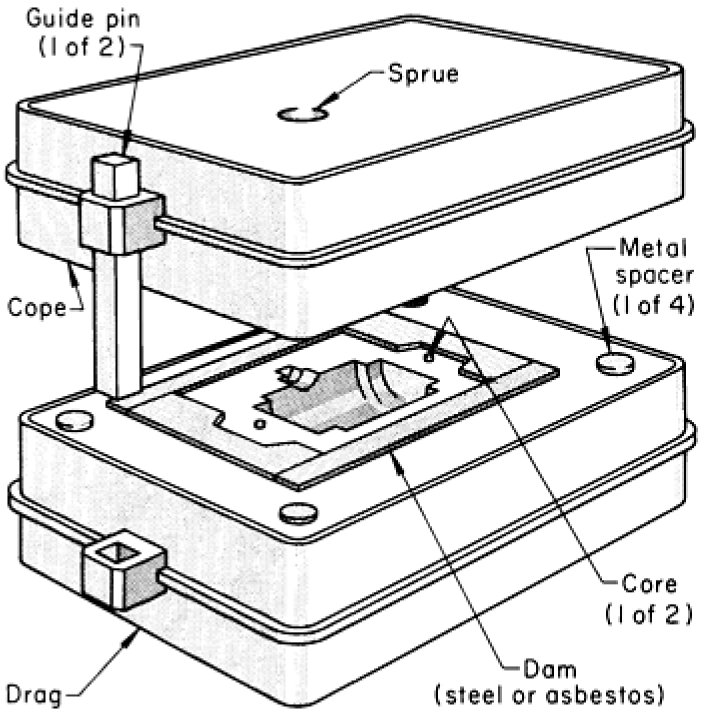

Fig. 6 Assembly details of a match plate mold

Mixing and Pouring the Slurry. Equipment and procedures for mixing the slurry and pouring it over the patterns are essentially the same as those for the conventional process (see Fig. 2 and accompanying text). Common practice is to make several vents in the mold with a nail or wire immediately after the slurry has been poured. The vents serve two purposes. Vent holes traversing the entire mold sections of dry molds provide openings for the escape of steam and other gases when the metal is poured. Through-vents in wet molds facilitate the separation of mold halves and the removal of patterns by acting as channels for the injection of compressed air.

Set Time. A slurry will set in 20 to 35 min. After the slurry sets, the patterns are removed, and the molds are dried.

Drying. Molds for match plate patterns, like molds for conventional plaster castings, should be dried as soon as possible after the plaster has set. High-temperature drying cannot be used for match plate molds, because it results in unacceptable distortion and size change. Match plate molds are usually dried at 120 to 205 °C (250 to 400 °F) for 12 to 72 h. Size and section thickness of the molds determine the length of time in the drying ovens. The center of the thickest section of the mold should reach at least 105 °C (220 °F) before drying is stopped. The permeability of a match plate mold at this stage is approximately the same as that of a conventional mold (1 to 2 AFS).

Mold Assembly. After the mold halves have reached room temperature, the cope and drag sections are matched as shown in Fig. 6. The assembly of a match plate mold is significantly different from that of a conventional plaster mold. Cores, if used, are positioned in the drag mold section. Cores are used if holes are required in the plate. Internal cores are used only in large match plate molds, so that the patterns will be lighter and can be handled more easily. Cores are made of sand.

In heavy sections, it is common practice to insert aluminum chills with nail-like protrusions into the plaster to make an internally cast chill. It is common to have 50 to 100 chills in a large mold with varying sections. The cope section, aligned by guide pins, is lowered onto the drag (Fig. 6). It is then raised for a distance equal to the desired thickness of the plate.

Metal spacers of this thickness are inserted at each corner, and dams of steel or Fiberfrax are placed so as to form the desired outer contour of the plate (Fig. 6). When the metal is poured, it flows outward in the space between the cope and drag sections and forms the plate portion of the match plate pattern.

Metals Used. Match plate patterns are cast from aluminum alloys, most frequently Alloys 355 and 356. One foundry using a blend of equal quantities of 356 and 319 reported greater ductility and better machinability than could be obtained if either alloy were used alone. Ductility is important in making match plate patterns because the patterns often require straightening.

Pouring Practice. Because of the low permeability of a match plate mold, some assistance is required to fill the mold quickly and completely. Pressure assist is used rather than vacuum, partially because pressure equipment is more adaptable to a wider variety of flask sizes than vacuum equipment is. However, some foundries use a combination of pressure and vacuum assist.

The equipment for pressure casting is illustrated in Fig. 7. The first step in its use is to place a diaphragm of sheet Fiberfrax (about 3.2 mm, or $\frac{1}{8}$ in., thick) over the sprue in the mold. A ceramic-lined cylinder is then placed on the diaphragm, as shown in Fig. 7. A predetermined amount of metal is poured into the cylinder, and a cap is placed on the cylinder and clamped tight. The cap is attached to a source of compressed air. After the cap has been secured in position, the air valve is opened. Air pressure against the molten metal ruptures the Fiberfrax diaphragm and forces the metal into the mold cavity. A pressure of 10 to 17 kPa ($1\frac{1}{2}$ to $2\frac{1}{2}$ psi) is kept on the sprue for about 30 min.

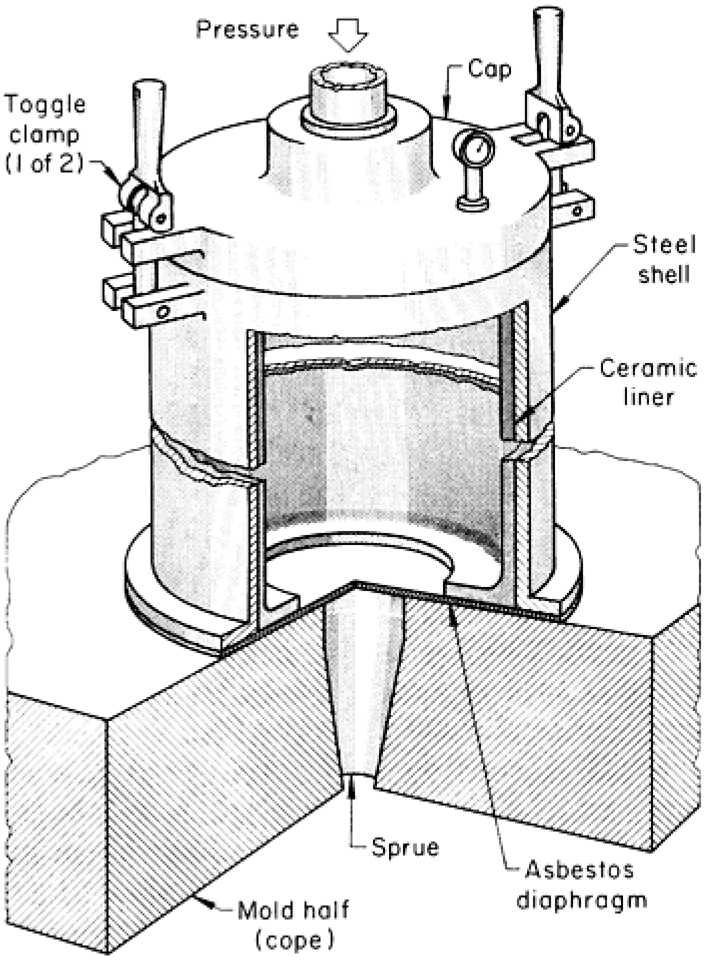

Fig. 7 Cylinder used for pouring a casting with pressure assist

The Antioch Process

The Antioch process (U.S. Patent 2,220,703) was developed to overcome the principal limitations of conventional plaster molds and cores without sacrificing the advantages of the plaster mold process. If undried molds are partially dehydrated and then allowed to rehydrate without being disturbed, gypsum crystals slowly recrystallize into granules about the size of sand grains, and the mold acquires a porous structure of relatively high permeability. Permeability is held within a range of 15 to 30 AFS; the permeability of conventional plaster molds is 1 to 2 AFS. Recrystallization does not take place at the surface of the mold, because not enough water is present. Therefore, the surface remains smooth.

In addition to the greater permeability developed by the dehydration-rehydration process, the molds produced have greater heat capacity than conventional plaster molds because they are composed of approximately 50% sand. Figure 1 shows that the freezing time for a casting in an Antioch process mold is only about 20% longer than the freezing time for an identical casting in a lightly rammed green sand mold and is less than half the time required for a casting in a conventional plaster mold.

Unlike conventional molds, Antioch process molds do not shrink. In fact, they expand slightly--from 0.001 to 0.0025 mm/mm (0.001 to 0.0025 in./in.)--during processing.

Because of their porous structure, the molds have low dry strength. This characteristic, in promoting early collapse of cores as the casting cools, minimizes hot tears in the castings. For very large molds, the low dry strength sometimes necessitates the use of internal reinforcement, which is achieved with hardware cloth or core rods such as those used in making sand cores. When possible, reinforcement is avoided because of the difference in expansion between the reinforcing metal and the molding material.

After setting, but before the dehydration-rehydration treatment, Antioch process molds have relatively high green strength. When flexible rubber patterns are used, this high green strength permits the withdrawal of patterns having a severe back draft without damage to the mold. This makes the Antioch process particularly well suited to the production of molds for parts having angular, bladelike sections--rotor sand nozzles, for example.

In addition to the cost, which is high for all plaster molds, the major disadvantage of Antioch process molds is the long processing time required to make the mold. This occupies expensive equipment for long periods.

Mold and Core Materials. The dry mixture for Antioch process molds and cores consists of silica sand, white molding plaster, talc No. 2, and a small amount of material (such as portland cement) for expansion control. The typical mixture given in Table 1 varies somewhat among different foundries. However, once a formulation has been established in a specific foundry, it is retained for all castings, regardless of their size and shape. Optimum results are obtained by weighing all ingredients accurately. Only by consistent use of a specific formulation is it possible to obtain maximum reproducibility.

Table 1 Typical composition of dry material for Antioch process molds

Ingredient	Weight	
	kg	lb
Washed silica sand (AFS 50 is typical)	20.4	**45**
White molding plaster	18.6	**41**
Talc No. 2	3.6	**8.0**
Portland cement	0.2	**0.4**
Sodium silicate	0.4	**0.8**
Western bentonite	1.1	**2.5**
Terra alba	**1.5**	**3.4**

Processing. The sequence of operations for producing Antioch process molds is given below:

- Mix dry ingredients
- Add dry ingredients to water
- Soak (1 to 3 min)
- Mix (2 to 4 min)
- Coat patterns (or core boxes)

- Pour slurry
- Set at room temperature (15 to 20 min)
- Remove pattern
- Dehydrate in autoclave (6 to 12 h)
- Rehydrate in air (14 h)
- Dry molds (or cores)
- Assemble cores and mold halves

The set time for a slurry formulated from a composition such as that shown in Table 1 will be approximately 15 to 20 min. Set time can be decreased by adding up to 3% terra alba and heating the water. For example, the minimum set time of 6 to 7 min is achieved by adding 3% terra alba and using water at 32 °C (90 °F). The temperature and humidity of the surrounding atmosphere have very little influence on set time, although an atmospheric temperature of 21 to 27 °C (70 to 80 °F) is preferred.

Dehydration. The time between setting of the slurry and the beginning of the dehydration cycle is not extremely critical if steps are taken to prevent the mold from drying out. If the set molds are covered with damp cloths, they can be held overnight, or sometimes even over a weekend, without a significant impact on subsequent dehydration. If the molds are placed in humidity cabinets, they can be stored for longer periods before dehydrating. However, the dehydration cycle should begin soon after the pattern is removed if the mold cannot be kept moist.

For dehydration, the molds are placed on suitable racks in a standard autoclave. The autoclave is sealed, and steam is admitted. The autoclave is operated with a steam pressure of 105 kPa (15 psi) for 6 to 8 h. For extremely large molds, it is operated for 12 h. The autoclave is then opened, and the molds are removed.

Rehydration. The mold is permitted to remain at room temperature for 14 h. After rehydration, the mold is ready for drying.

Drying temperature ranges from 175 to 230 °C (350 to 450 °F), and drying time from 1 to 70 h. Drying time depends mainly on the size of the mold and the temperature used. The center of the mold must reach a temperature of at least 120 °C (250 °F). This can be accomplished considerably more quickly at an oven temperature of 230 °C (450 °F) than at 175 °C (350 °F).

Regardless of the cycle used, it is important that the same cycle be used for all molds of the same size. Maximum reproducibility (of dimensions, in particular) can be achieved only through close control of the cycle.

Mold assembly is essentially the same as that described for conventional plaster molds. After the molds have cooled to room temperature, cores (if used) are placed in the drag, and the cope is placed over the drag and core assembly. Matching is done by means of locating pins. The pins used for matching Antioch process molds are usually 13 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$ in.) in diameter. Even when molds are permitted to remain in their flasks, guide pins on the sides of the flasks are seldom used for matching.

Metals Cast. All of the aluminum alloys that can be cast in other types of plaster molds can be cast in Antioch process molds. Most copper-base alloys can be cast in Antioch process molds. Yellow brass is the copper alloy most often cast. The Antioch process is seldom used for alloys that must be poured at temperatures above about 1040 °C (1900 °F).

Pouring Practice. It is generally possible to pour castings in Antioch process molds by gravity, using gating systems that are similar to those used for sand molding. Molds are usually at room temperature when pouring begins. Vacuum assist can be applied when difficulty is encountered in replicating fine detail or when thin sections have not filled properly. The technique is generally the same as that for pouring conventional molds with vacuum assist.

Foamed Plaster Molding Process

The foamed plaster process offers a means of achieving greater mold permeability than can be obtained in conventional plaster molds and at much improved dry strength over Antioch plaster molds. This gain is achieved by adding a foaming

agent, such as alkyl aryl sulfonate, either to the dry ingredients before mixing or to the liquid slurry, as a separately generated foam mix. A special method of mixing foams the slurry with many fine air bubbles, thus decreasing the density and increasing the volume of the slurry. In general, with regard to the composition of the metal poured, casting size, and casting shape, the applicability of foamed plaster molds is the same as that of plaster molds made by other procedures.

Characteristics. Foamed plaster molds have smooth surfaces with air cells just below the surface. During setting and subsequent drying of the molds, these air cells become interconnected, thus permitting the escape of gases as the metal is poured. The permeability of a foamed plaster mold depends mainly on the volume increase from the addition of air when the slurry is mixed. For most molds, a volume increase of 50 to 100% is recommended. This increase usually results in a mold permeability of approximately 15 to 30 AFS for dried molds.

Equipment for mixing will vary somewhat with the slurry used. The type described below has proved suitable for mixing a proprietary dry mixture with water.

The mixer must be capable of beating air into the slurry and producing air cells no larger than about 0.25 mm (0.01 in.) in diameter. Large air cells are not permitted, because they break under pressure from molten metal, resulting in casting defects. Proper mixing can be accomplished with several types of mixers. Regardless of the type of mixer used, the greater the power input, the finer the mold structure (the smaller the air cells) and the smoother the surface of the mold.

The bucket should be similar to that shown in Fig. 2, but the mixing device is a round, two-ply, 3 mm thick ($\frac{1}{8}$ in. thick) rubber disk (which can be made from 3 mm, or $\frac{1}{8}$ in., two-ply rubber belting) attached to a shaft, as shown in Fig. 8. The diameter of the shaft is not critical. Other mixer designs that are successfully used for mixing air into foamed plaster incorporate a 127 to 152 mm (5 to 6 in.) diam perforated disk mounted on a shaft that is tilted slightly from normal.

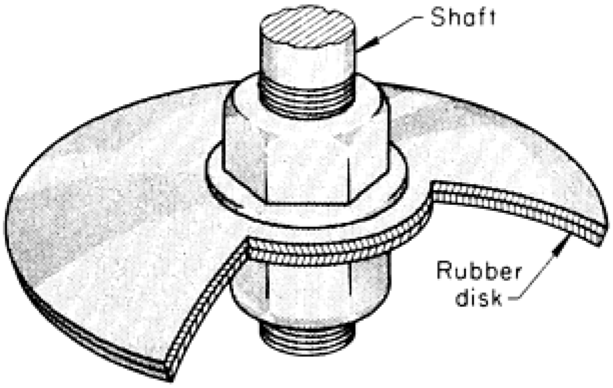

Fig. 8 Two-ply rubber disk attached to shaft for the high-speed mixing of foamed plaster slurries

Processing. The following sequence of operations is typical of the routing required to produce a component by the foamed plaster molding process:

- Mix foamed plaster dry mix with 32 to 43 °C (90 to 110 °F) soft water to a consistency of 80 to 100 AFS. The mixer used should have two speeds: a high speed (~1750 rpm) to mix the dry material and water thoroughly and a slower speed (~800 to 1000 rpm) to beat air into the slurry and to obtain a smooth, creamy slurry. Mixing time is varied to obtain 100% volume increase
- Pour slurry
- Set time varies from 20 to 40 min. Set time is a function of water temperature, mixing time (high speed), dry material setting characteristics, and consistency. Changes in variables to decrease set time also serve to decrease working time
- Strip patterns
- Dry in standard type dryers at temperatures from 175 to 260 °C (350 to 500 °F) for 8 to 16 h depending

on mold size. Foam plaster is very insulating, and thermal gradients can set up dimensional change, thus causing mold cracking. Avoid conditions that will cause thermal shock at mold temperatures above 120 °C (250 °F)

- Assemble and cast; molds can be poured from room temperature up to the dryer temperature

Metals Cast. For the most part, all aluminum alloys can be cast, but the aluminum-magnesium alloys are the most compatible.

Pouring Practice. All conventional foundry pouring techniques are applicable to foamed plaster molds. The insulating qualities of foamed plaster make it very suitable as a riser insulation material.

Ceramic Molding

Introduction

CERAMIC MOLDING techniques are based on proprietary processes (two of which are discussed in this article) that employ permanent patterns and fine-grain zircon and calcined, high-alumina mullite slurries for molding. Except for distribution of grain size, the zircon slurries are comparable in composition to those used in ceramic shell investment molding (see the article "Investment Casting" in this Volume). Like investment molds, ceramic molds are expendable. However, unlike the monolithic molds obtained in investment molding, ceramic molds consist of a cope and a drag or, if the casting shape permits, a drag only.

Both investment molding and ceramic molding can produce castings with fine detail, smooth surfaces, and a high degree of dimensional accuracy. The ceramic mold surface has refractory properties that enable it to withstand high metal pouring temperatures (such as those necessary for steel and heat-resistant alloys), give it excellent thermal stability, and do not permit burn-in.

Applications

Ceramic molding has two principal applications. The first is the production of precision castings that require patterns too large and unwieldy for molding with expendable wax or plastic patterns. The second principal application is the production of castings in limited quantities for which permanent wood patterns may be more economical and require less lead time to make than the metal pattern dies required for molding wax or plastic patterns.

Ceramic molding is intended for the production of castings of high quality, not only in terms of their dimensional accuracy and surface finish but also in terms of soundness and freedom from nonmetallic inclusions. In general, the capabilities of ceramic shell investment molding and ceramic molding are similar, and the selection of one process over the other is largely dependent on the size of the casting, the quantities required, and the molding costs involved. In some applications, depending on casting shape, permanent patterns used in ceramic molding may provide greater dimensional accuracy than wax patterns, primarily because wax expands during melt-out. Permanent patterns are also less susceptible to damage and distortion in handling than wax or plastic patterns.

The principal disadvantage of ceramic molding in its early stages of development was the high cost of the molding materials. These materials were used in large quantities for making the slurry for all-ceramic molds and could not be reclaimed. This disadvantage was greatly diminished by the development of less expensive, composite ceramic molds, in which chamotte (an aluminous fireclay) serves as a backup for a ceramic facing, thus greatly decreasing the amount of binder and zircon or mullite required. Furthermore, as much as 80 to 90% of the backup molding material can be reclaimed.

Suitable Work Metals. Both ferrous and nonferrous alloys are cast in ceramic molds, but ferrous applications are more numerous and account for the major tonnage of castings produced. Alloys of aluminum, copper (especially beryllium copper), nickel, and titanium are nonferrous alloys that are suitable for ceramic mold casting; suitable ferrous alloys include ductile iron, carbon and low-alloy steels, stainless steels, and tool steels.

Types of Parts Cast. The range of products cast in ceramic molds is closely related to the alloy used. For example, among the products cast from tool steels (especially H12, H13, and A2) are forging dies and punches; trimming dies; die inserts; dies for hot upsetting; extrusion bridges, spiders, and cups; and inserts for die casting dies. Products cast from stainless steel include food-machinery components; valves for the chemical, pharmaceutical, and petroleum industries; glass molds; aircraft structural components; and hardware for atomic reactors and aerospace vehicles. Typical copper alloy castings include food-machinery parts, marine hardware, and decorative trim items used in architectural applications.

Complex castings with thin sections ($\leq$1.6 mm, or $\frac{1}{16}$ in.) can be cast in ceramic molds, using special techniques. Casting surfaces have excellent smoothness--usually 3.2 μm (125 μin.) or better.

Dimensional accuracy depends primarily on the accuracy of the pattern. Metal contraction can normally be predicted closely enough to provide castings within the following tolerances:

- ±0.08 mm (±0.003 in.) on dimensions up to 25 mm (1 in.)
- ±0.13 mm (±0.005 in.) on dimensions over 25 to 75 mm (1 to 3 in.)
- ±0.38 mm (±0.015 in.) on dimensions over 75 to 203 mm (3 to 8 in.)
- ±0.76 mm (±0.030 in.) on dimensions over 203 to 381 mm (8 to 15 in.)
- ±1.14 mm (±0.045 in.) on dimensions over 381 mm (15 in.)

For dimensions across the parting line, an additional tolerance of ±0.25 to ±0.51 (±0.010 to ±0.020 in.) must be provided.

Closer tolerances are readily obtainable by reworking the pattern after a test casting has been compared dimensionally with the pattern. Reproducibility is excellent; once the pattern has been established, subsequent castings will be extremely consistent throughout the life of the pattern.

Shaw Process

The Shaw process relates to two distinctly different types of ceramic molds: a one-piece all-ceramic mold and a composite ceramic mold consisting of an inexpensive fireclay backup material with a relatively thin facing of ceramic slurry. Selection of mold type depends almost exclusively on the size of the casting and the cost of the mold material. Many small castings can be produced economically in one-piece all-ceramic molds, because the amount of expensive ceramic slurry needed for the mold is moderate and the additional pattern and labor costs for composite molding cannot be justified.

Patterns. Two sets of patterns are commonly required for the production of composite molds: a set of oversize preform patterns for molding the coarse backup material and a second set of patterns, representative of the dimensional accuracy desired in the casting, for molding the ceramic facing. Thus, for cope and drag molding, a total of four patterns may be required.

The preform patterns are made 2.4 to 9.5 mm ($\frac{3}{32}$ to $\frac{3}{8}$ in.) oversize to allow for the thickness of the ceramic facing. In some applications, the preform pattern can be eliminated by using the final pattern, backed with a sheet of plastic, cardboard, or felt of suitable thickness, to mold the preform impression in the coarse fireclay backup. Because solid ceramic molds are made without backup material, only the final patterns are required for molding.

The pattern materials used for ceramic molding are conventional: wood, epoxy, aluminum, brass, tool steel, and cast iron. Wood, epoxy, and aluminum are most widely used. Prior to use, wood patterns are coated with a sealant that will not dissolve in alcohol.

To ensure a high degree of accuracy in the alignment of cope and drag, by mechanically meshing certain surfaces, it is common practice in ceramic molding to incorporate parting blocks and locators in the cope and drag halves of patterns. These are molded into both the backup and the ceramic facing, together with the casting contours.

Preparing the Backup. The backup refractory commonly consists of a coarse-grain chamotte (an aluminous fireclay that has been calcined at a high temperature) and a sodium silicate binder. A typical screen analysis for the chamotte is as follows:

Mesh	Cumulative percentage
6	**Trace**
8	**5-9**
12	**27-41**
16	**60-68**
30	**94**
70	**99**

The refractory and binder are mixed in a muller or an auger to the desired consistency and are rammed or vibrated over a pattern assembly. The pattern assembly consists of a preform pattern (or a final pattern covered with a suitable spacer material) mounted on a molding board and carefully located in a conventional flask, together with the required sprues. Before use, the preform pattern and other elements of the pattern assembly are coated or sprayed with a wax-silicone mixture to facilitate parting.

Carbon dioxide gas is diffused into the mold material for hardening. One method of doing this consists of piercing the mold material in several locations with small-diameter rods, thus creating channels into which the gas can be introduced. More uniform gassing can be accomplished in a vacuum chamber. After the gassing and hardening operation, the preform pattern is removed from the mold.

Preparing the Ceramic Facing. The principal ingredient of the ceramic facing is usually finely pulverized zircon, calcined mullite, or a mixture of both, although fused silica, magnesium oxide, and other refractory flours have also been used. Typical screen analyses for two calcined mullite flours are:

Mullite flour	Cumulative % on mesh size of:		
	100	**200**	325
A	3	35-65[(a)]	...

(a) Remainder passes through this mesh size.

A typical slurry contains a mixture of 75% zircon and 25% calcined mullite combined with a hydrolyzed ethyl silicate binder in proportions of approximately 0.91 kg (2 lb) of refractory blend to 100 mL (3.4 oz) of binder. To this mixture is added a small amount of gelling agent, which causes the slurry to set in a predetermined period of time, usually 3 to 4 min. Immediately after this addition, the slurry is ready for pouring.

Pouring the slurry over the pattern is always a gravity operation. However, when pattern detail is critical, the pattern and slurry are placed in a vacuum chamber, where the ungelled slurry is vacuumed to remove entrapped air bubbles.

Immediately prior to use, the final pattern is coated with a wax-silicone mixture to facilitate parting, and the backup mold is placed over it. The slurry is poured through pouring gates until the level rises to invest the final pattern. In a few minutes, the chemical gelling action is complete, leaving the green ceramic with a consistency like that of vulcanized rubber, and the pattern is stripped from the mold. The rubberlike consistency is critical because it facilitates the separation of molds from patterns that have no draft, straight sides, extremely fine detail, protruding pins, or holes. Stripping is sometimes done mechanically to ensure that withdrawal of the pattern will not damage the mold. Removal of the pattern does not cause the mold to expand or contract. After stripping, the mold is ready for burn-off.

All-Ceramic Mold Casting. An unbacked, all-ceramic mold is made entirely from slurry of the type used for facing a composite ceramic mold. The procedure for pouring an all-ceramic mold is shown in Fig. 1. The pattern, affixed to a flat plate, is surrounded by a flask, into which the ceramic slurry is poured. After the chemical gelling action is complete, the green mold is stripped from the pattern, and the flask, which is built with a small amount of draft, is removed from the mold. The mold is then ready for burn-off.

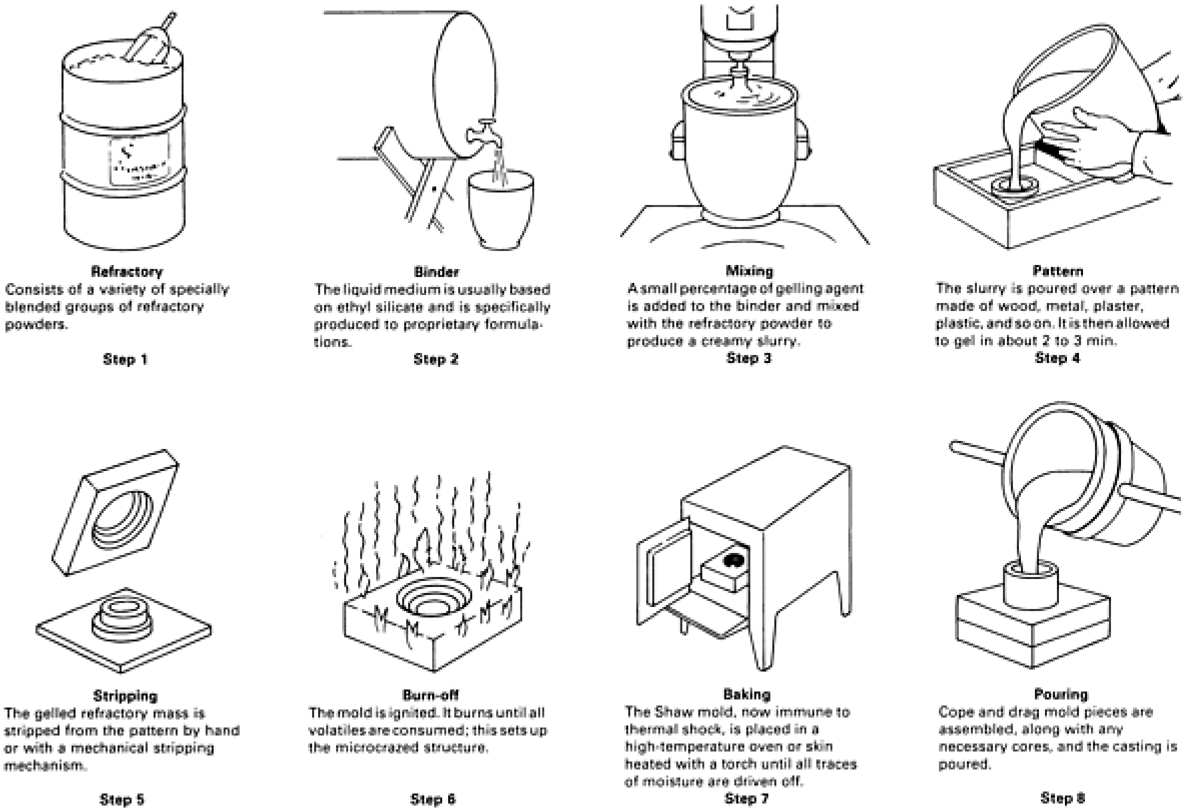

Fig. 1 Sequence of operations used in the Shaw all-ceramic mold process.

Burn-off (Mold Stabilization). After gelling, the ceramic mold or mold facing is ignited with a torch and burns until most volatiles are consumed. During burn-off, the ceramic develops a microcrazed pattern, which is a three-dimensional network of microscopic cracks induced by the rapid evaporation of the alcohol in the slurry and by solid-phase reactions. Microcrazing is characterized by jagged ceramic particles separated by minute fissures or air gaps. These fissures are small enough to prevent molten metal from penetrating the mold surface, but they are large enough to permit the venting of air and other gases and to accommodate the expansion of the ceramic particles when they are in contact with the molten metal. Thus, microcrazing is advantageous in promoting dimensional stability without detracting from surface finish (see the section "Mold Stabilization" in this article).

Baking is the final stage of processing. All remaining volatiles are removed, and the colloidal silica left by the hydrolyzed ethyl silicate binder forms a high-temperature bond of SiO_2 that is stable nearly to its melting point (1710 °C, or 3110 °F), thus providing enough mold strength to resist washout, or erosion, by molten metal. To perform these functions satisfactorily, baking must be done at not less than 480 °C (900 °F). Baking composite molds at more than 650 °C (1200 °F) may cause a differential expansion between the facing and backup layers due to the contraction of the soda-rich silica bond in the backing material. This can produce distortion in the mold cavity. Nevertheless, some foundries bake composite molds at temperatures as high as 815 to 980 °C (1500 to 1800 °F) without harmful effects.

Two methods of baking are currently in use. In one method, termed skin heating, the mold is directly heated from above with electric or gas-torch heaters. This method has the advantage of fully curing the ceramic facing without overheating the backup material. It is a rapid technique, and it permits molds to be cured in conventional steel flasks.

Heating the molds in an electric or gas-fired furnace is the other method of baking. Furnace baking has the advantage of removing all moisture and volatiles from the backup material as well as from the facing, thus minimizing the risk of bleeding moisture from the backup to the facing after mold assembly. Such bleedback can produce surface defects in the casting.

The normal baking period for molds is 4 to 6 h at the prescribed baking temperature. After baking, molds are allowed to cool to an appropriate temperature for pouring.

Pouring. Before pouring, molds are usually checked for cleanliness and temperature. Mold temperature at the start of pouring ranges from 40 to 540 °C (100 to 1000 °F), depending on casting shape and the alloy being poured. Cope and drag halves are assembled, and a layer of cement is usually troweled on to seal the mold around the parting line. For safety, heavier molds are reinforced by fastening a steel band around the outside of the mold. This assists in handling of the mold and prevents seepage of hot metal in the event that the mold wall cracks during pouring. Finally, ceramic pouring tubes and exothermic or insulating riser sleeves are set up in the cope.

The mold is clamped firmly, and metal is poured either directly from the melting furnace or from a ladle. Pouring must proceed as rapidly as possible to avoid cold shuts and gas voids. After the metal has been poured, additional exothermic material is sprinkled on the risers to keep them fluid and to prevent shrinkage tears.

Composite Ceramic Mold. This type of mold is a sodium silicate/carbon dioxide cured and fired chamotte backing that significantly decreases the cost of refractory materials. A preform pattern and a finish pattern are needed to make composite molds (Fig. 2). Cope and drag preforms are made 2.4 mm ($\frac{3}{32}$ in.) oversize on all mold cavity surfaces to allow for the thickness of the ceramic facing material.

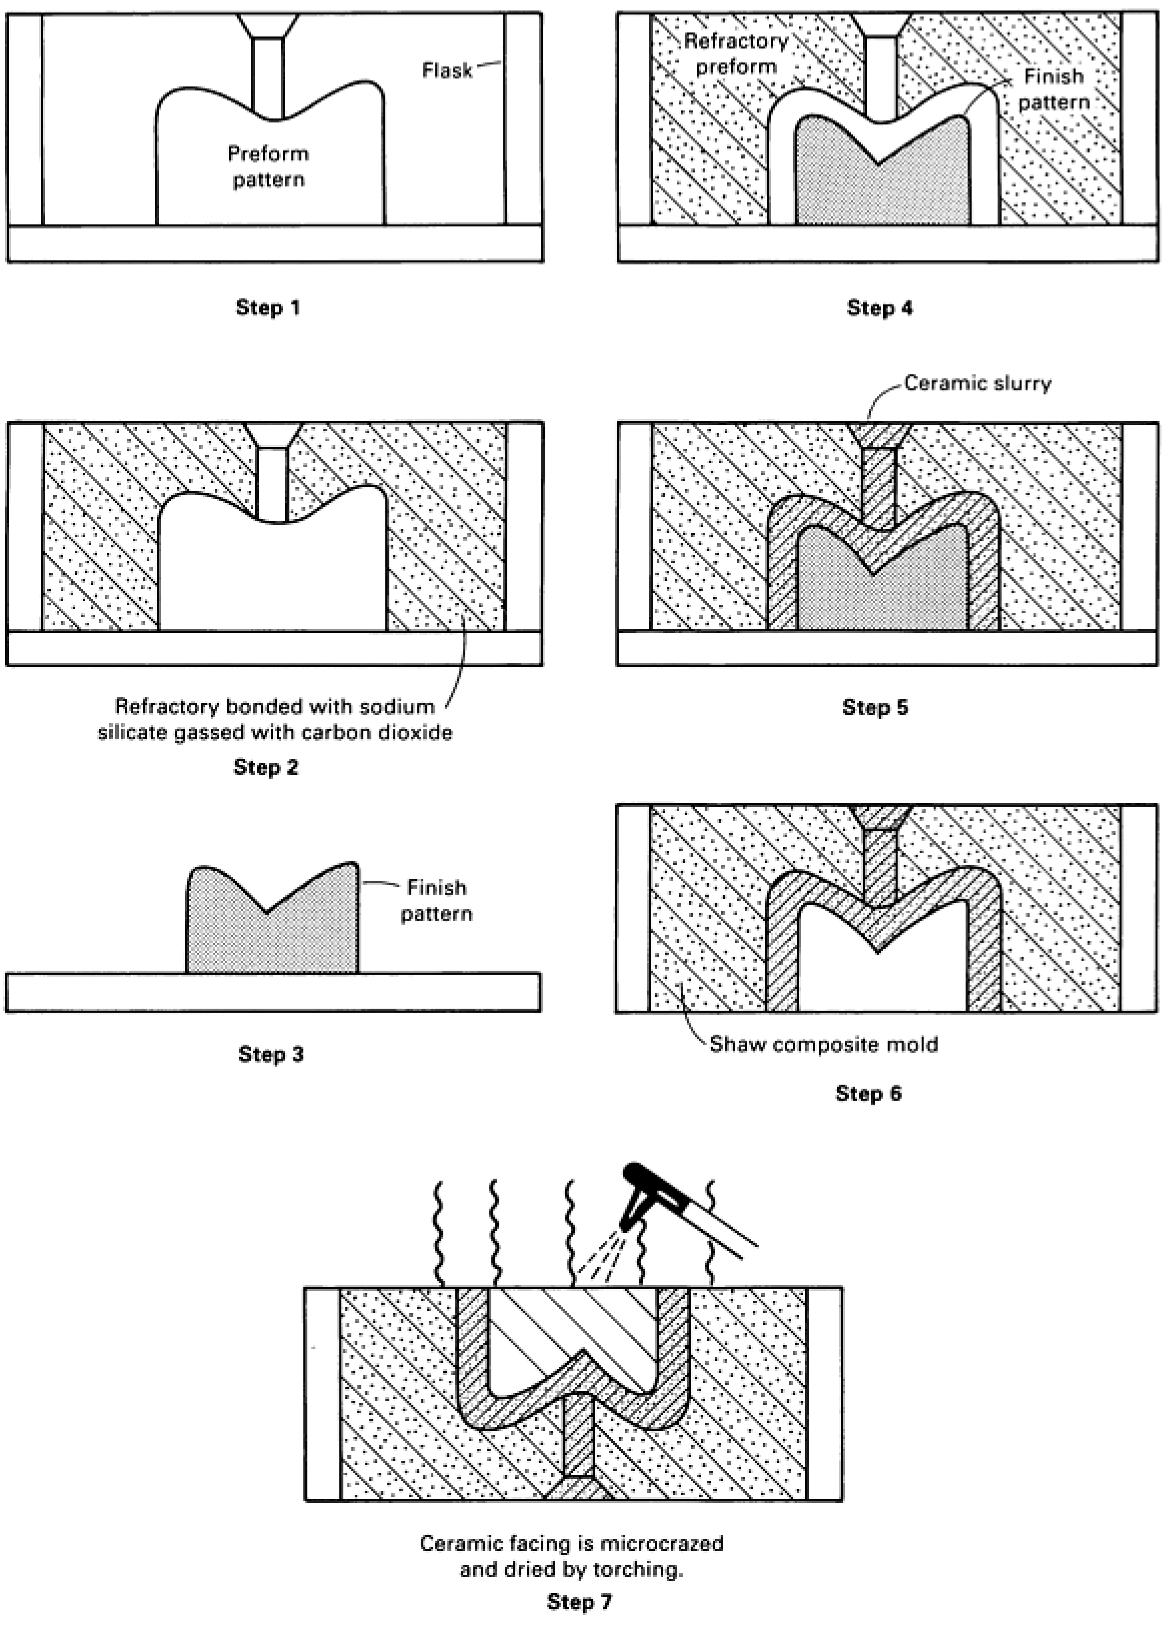

Fig. 2 Diagram of Shaw composite mold process. See text for details.

The cope and drag flasks must be accurately aligned, and at each stage of mold production, alignment holes are drilled and reamed to a jig. As a further safeguard, a sand strip is cast into the insides of the flasks to keep the hardened preforms from shifting during handling. Preform patterns are then mounted on a pin lift molding table. The flasks are aligned by dowel pins and the alignment holes on the table before they are fastened to the patterns by quick-acting clamps.

The sodium silicate refractory mixture contains a percentage of invert sugar, which aids shakeout of the mold after pouring. The refractory mixture is rammed around a preformed pattern (step 1, Fig. 2), and the rammed half mold is placed in a bell jar for 10 to 20 s, during which it is gassed with a commercial grade carbon dioxide (step 2). While the first preform is being gassed, the operator rams the second flask with the composite mixture. By this time, the first preform is hardened and is removed from the bell jar. The operator repeats the gassing procedure for the second preform. The gassed preform mold halves are then stripped from the preform patterns, and each hardened preform mold is aligned with the final pattern bolted to the molding table. The flasks are fastened to the patterns by the quick-acting clamps.

The Shaw ceramic slurry needed for the facing of the composite mold is virtually the same as that used for the solid body mold--a specially blended formula of refractory aggregates, ethyl silicate-base binder, and a gelling agent. The thick, creamy slurry is then poured into the gap between the final pattern and the hardened preform material (steps 3 to 6). The slurry not only fills all of the details of the mold cavity but also penetrates the aggregate voids of the surface of the porous backing, creating a strong mechanical bond.

Gelling of the slurry requires 2 to 3 min, and the fine ceramic facing of the composite mold is formed. The composite cope and drag are unclamped and lifted from the patterns by a foot-operated stripping plate. The molds are then placed on a conveyor for movement through a torching zone, where the volatiles are ignited and consumed (step 7). The microcrazed structure of the Shaw mold occurs during this burn-off period. The cope and drag molds are moved directly into a high-pressure torching zone for 5 to 10 min; in this zone, the molds are brought to incandescence. The copes and drags are assembled using the alignment pins to ensure accuracy. The molds can be assembled either hot or cold.

Unicast Process

The Unicast process differs from the Shaw process principally in the method of mold stabilization employed. Mold stabilization refers to the treatment given the fine ceramic facing of a composite mold, or the total mass of an all-ceramic mold, shortly after it has set and while it is still green.

Advantages. The Unicast process provides accurate dimensional control, and warpage or distortion is almost entirely eliminated. As a result of the stabilized molecular growth, the mold develops a cellular or spongelike structure caused by the interstitial separation of particles. This structure provides for gas venting and particle expansion during casting. The advantages of this structure are metal soundness, ease of casting long, thin sections, and reductions in traditional mold venting. Molds can be poured hot or at room temperature without any change in thermal characteristics. Directional solidification of the cast alloy is fully controlled, resulting in high physical properties and outstanding metal soundness.

The major advantages of solid ceramic mold casting include the following:

- Only a short lead time is necessary due to simple tools and a fast mold build cycle
- A modest installation cost can be maintained using simple equipment
- The manufacturing cost is considerably lower than that of machining or other alternate methods
- Patterns are usually inexpensive and quickly prepared
- The die life of cast tooling is longer than that of dies made from wrought materials
- Cast tooling can frequently be used as-cast without further machining
- The process is suitable for impossible-to-machine grain and texture details for large injection mold bodies
- The process is feasible for casting sizes ranging from small to very large

Composite Mold. Another difference between the Shaw and Unicast processes relates to the sequence followed in preparing composite molds. In the Shaw process, preparation of the coarse mold backup precedes pouring of the fine ceramic facing. In the Unicast process, this sequence is reversed (see the section "Typical Process Sequence" in this article). The castings produced by the two processes are comparable in quality and surface finish, and several foundries are licensed to use both processes.

Although the Unicast process commonly uses a solid ceramic mold for smaller and short-run castings, it generally employs a composite-ceramic mold for large parts and for those produced in high volume. In this case, the Unicast

ceramic is used as a 6.4 to 13 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) facing backed by a specially blended, coarse-sand aggregate for support. This technique sharply reduces mold cost by conserving the ceramic material, and it permits the mechanized production of molds.

Patterns and Flasks. The Unicast process employs conventional pattern equipment throughout. The patterns must be of good quality because the slightest flaw or defect in the pattern will be reproduced on the final casting. The reproduction of detail is such that even fingermarks on a pattern coating are likely to be transferred to the casting. Most of the common pattern materials are used, including the denser hardwoods, plaster, aluminum, plastics, and hard rubber.

Alloys Cast. Alloys normally poured in Unicast molds are about evenly divided between ferrous and nonferrous. Of the ferrous alloys, about 60% are irons, and the rest are principally stainless steels and tool steels. Of the nonferrous alloys, about 30% are alloys of cobalt, titanium, or uranium, and about 20 to 30% are alloys of aluminum, magnesium, or zinc. The rest are principally copper alloys, with beryllium copper predominating.

Slurries. The fine ceramic slurries used in the Unicast process are comparable to those used in the Shaw process and consist of mixtures of a finely pulverized ceramic, such as zircon, and an organic gelling binder, such as hydrolyzed ethyl silicate. Accordingly, the chemical reactions that take place during gelation are the same as those in the Shaw process. Backup slurries, used in composite mold preparation, are coarse and less expensive ceramic grains mixed with a refractory binder that will harden in the presence of carbon dioxide.

Mold stabilization refers to the treatment given the fine ceramic slurry after it has gelled but while it is still green. The methods used for mold stabilization in the Shaw and Unicast processes are distinctly different, although the chemical reactions involving the binder are the same.

When the binder becomes a hard, rubbery gel, it consists of a liquid and a solid phase. The liquid phase is largely free alcohol, and the solid phase is a form of polysilicic acid. By itself, polysilicic acid is unstable and rapidly forms new chemical chains that are of larger mass than the original molecule. Molecular growth in the green state causes the suspended ceramic particles to move or separate, thus producing a pattern of microscopic cracks. Unless molecular growth is arrested in a short period of time, the cracks can become excessive and form macrocracks.

In the Shaw process, rapid evaporation of the alcohol resulting from hydrolysis or gelling reaction is accomplished immediately after (or very soon after) gelling by ignition or firing of the mold. This operation, referred to as burn-off, is usually performed by igniting the mold facing with a torch, as shown in Fig. 1. Burn-off follows removal of the pattern from the mold. It arrests excessive molecular growth, which may be catalyzed by moisture in the air or by other contaminants. This reaction must be avoided to ensure optimum binding properties and to avoid excessive cracking of the mold.

In the Unicast process, the gelled mold is immersed in a liquid hardening bath or vapor atmosphere that permits aging and internal stabilization of the mold. Various hardening media can be used, depending on the composition of the mold binder and the final curing step. Thus, commercial ethyl alcohol can be used with an ethyl silicate binder because the binder evolves ethyl alcohol as a result of the hydrolysis action.

Alternatively, the bath can be a liquid such as acetone, kerosene, benzene, or other hydrocarbon with which the evolved alcohol is readily miscible. The hardening bath is more reactive when hot; the heat provides good results even when the bath liquid is not chemically identical to the evolved alcohol. Even boiling water can be used; the temperature of the water drives the volatiles out of the mold to be dissolved in the water.

A typical aging period for the mold in the bath is 10 to 15 min. The aging reaction is enhanced when the pH of the hardening bath or atmosphere is maintained at a level somewhat higher than that of the mold and, preferably, on the alkaline side of neutral pH. Decreasing acidity serves to accelerate setting and gelation. Organic amines or other generally alkaline ammonium compounds can be added to the bath for this purpose.

The precise function of the hardening medium is not completely understood. Aging is enhanced when the gelled mold material is entirely immersed in a liquid or vapor that is substantially identical to the evolved alcohol, as compared to burn-off or to isolation of the mold surface from air by application of a wax or other suitable impermeable coating.

Final curing, which follows the hardening bath, is usually done in an oven maintained at about 980 °C (1800 °F), but direct flame heating can be used. The cured molds are then transferred to the melting station for pouring.

Typical Process Sequence. In a typical molding and casting sequence (Fig. 3), a pattern, mounted on a baseplate, is enclosed within a flask. A thin (4.8 to 9.5 mm, or $\frac{3}{16}$ to $\frac{3}{8}$ in.) coating of fine-grain ceramic slurry is applied to exposed pattern surfaces by spraying or similar means. The coating becomes tacky almost upon contact and is ready to receive backing material. An inexpensive, coarse backup slurry is poured rapidly over the facing coat until the flask is filled. The slurry is chemically controlled to set to a semirigid state within 2 to 3 min, at which time the upper surface of the mold is leveled with the flask edges with a striking tool. The flask is removed, and a vacuum clamping plate is placed in position on top of the mold. The entire assembly is inverted on a stripping machine, the pattern is stripped from the mold, and the clamping vacuum is released.

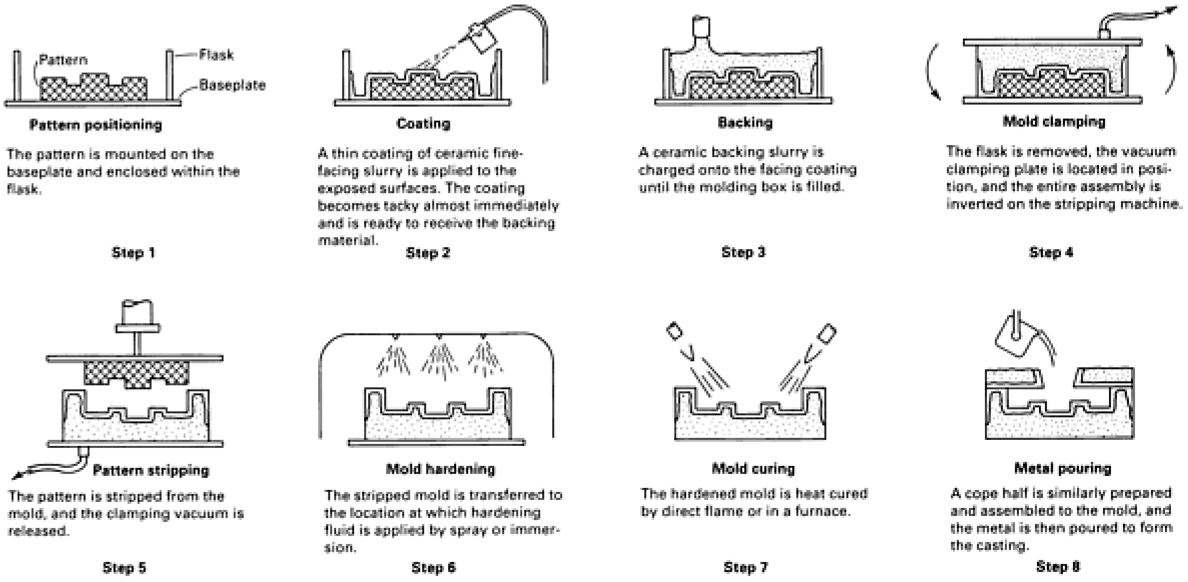

Fig. 3 Steps involved in producing a Unicast process casting

The stripped mold is transferred to the chemical hardening tank or chamber, where it is immersed in, or sprayed with, hardening fluid. It is then cured by heating with direct flame impingement or in a furnace.

Introduction

IN INVESTMENT CASTING, a ceramic slurry is applied around a disposable pattern, usually wax, and allowed to harden to form a disposable casting mold. The term disposable means that the pattern is destroyed during its removal from the mold and that the mold is destroyed to recover the casting. Related processes, in which ceramic slurries are poured against permanent patterns to make cope and drag molds, are covered in the articles "Plaster Molding" and "Ceramic Molding" in this Volume.

There are two distinct processes for making investment casting molds: the solid investment (solid mold) process and the ceramic shell process. The ceramic shell process has become the predominant technique for engineering applications, displacing the solid investment process. By 1985, fewer than 20% of non-airfoil investment castings and practically no airfoil castings (the largest single application of investment casting) were being made by the solid investment process (Ref 1). Today the solid investment process is primarily used to produce dental and jewelry castings and has only a small role in engineering applications, mostly for nonferrous alloys. Because of its declining role and because it was discussed in the article "Molten Salt Bath Cleaning" in *Surface Engineering*, Volume 5 of the *ASM Handbook*, the solid investment process will not be covered in this article. Only the ceramic shell process will be described. The basic steps in this process are illustrated in Fig. 1.

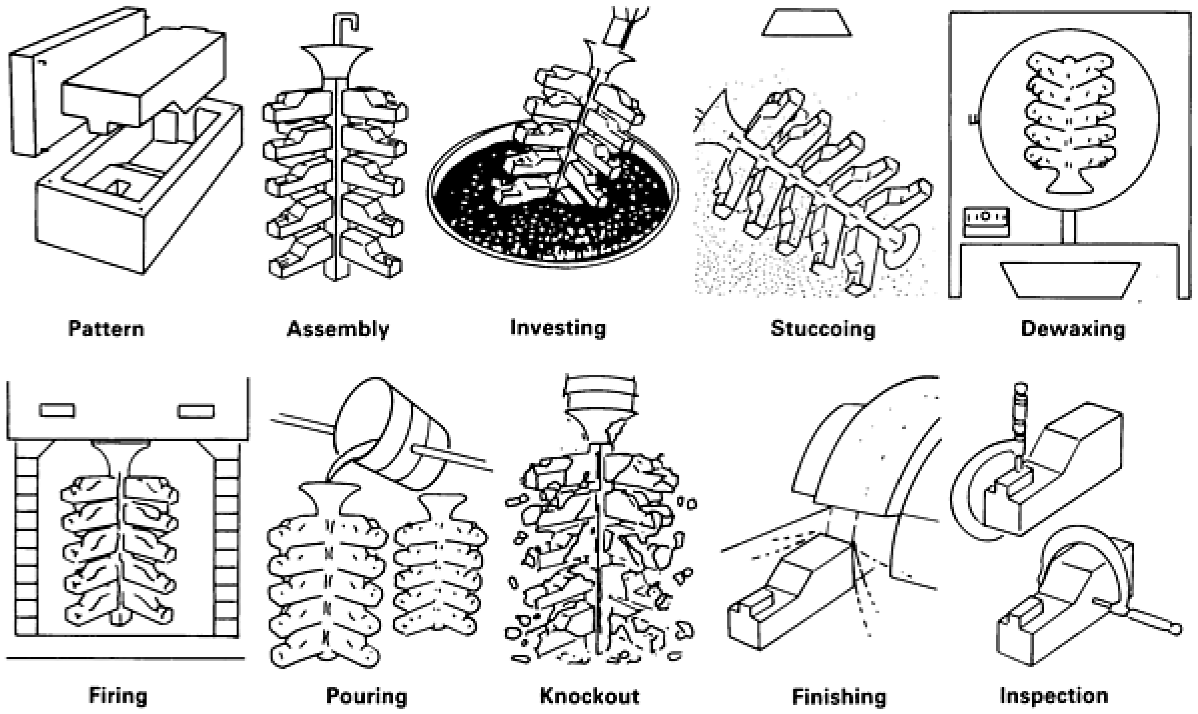

Fig. 1 Steps in the investment casting process.

Pattern Materials

Pattern materials for investment casting can be loosely grouped into waxes and plastics. Waxes are more commonly used. Plastic patterns (usually polystyrene) are frequently used in conjunction with relatively thin ceramic shell molds in a process known as Replicast CS (see the article "Replicast Process" in this Volume).

Waxes

Wax is the preferred base material for most investment casting patterns, but blends containing only waxes are seldom used. Waxes are usually modified to improve their properties through the addition of such materials as resins, plastics, fillers, plasticizers, antioxidants, and dyes (Ref 2).

The most widely used waxes for patterns are paraffins and microcrystalline waxes. These two are often used in combination because their properties tend to be complementary. Paraffin waxes are available in closely controlled grades with melting points varying by 2.8 °C (5 °F) increments; melting points ranging from 52 to 68 °C (126 to 156 °F) are the most common. The low cost of these waxes, combined with their ready availability, convenient choice of grades, high lubricity, and low melt viscosity, accounts for their wide usage. However, applications are limited somewhat by their brittleness and high shrinkage. Grades designated fully refined should be selected for pattern waxes. Microcrystalline waxes tend to be highly plastic and lend toughness to wax blends. Hard, nontacky grades and soft, adhesive grades are available. Microcrystalline waxes are available with higher melting points than the paraffins and are often used in combination with paraffin.

Ozocerite is an imported mineral wax that can serve a similar function. Fisher-Tropsch waxes are synthetic hydrocarbon waxes resembling paraffins, but are available in grades that are much harder and higher melting. They improve hardness and rigidity and promote faster setup in pattern-making operations. Polyethylene waxes (of much lower molecular weight

than the usual polyethylene plastics) function in much the same manner as the Fisher-Tropsch waxes, but are available in even higher melting grades (to over 132 °C, or 270 °F).

Candelilla is an imported vegetable wax that is moderately hard and slightly tacky. It has relatively low thermal expansion and somewhat less solidification shrinkage than the hydrocarbon waxes. Candelilla is useful for hardening paraffin and raising its softening point. Unfortunately, it has been subject to shortages and wide price fluctuations.

Carnauba is another imported vegetable wax. It has a fairly high melting point (83 °C, or 181 °F) and a low coefficient of thermal expansion. Carnauba is very hard, nontacky, and brittle. It is rather costly, which tends to limit its use.

Beeswax is a natural insect wax that melts at approximately 64 °C (147 °F). It is widely used for modeling and is also useful in pattern blends, contributing some of the same characteristics as comparable microcrystalline waxes. It is believed to be the original wax used for lost wax casting, but today its use is limited by its cost relative to other waxes.

Palmitic and stearic acids are fatty acids that have good wax properties. They have low viscosity when melted, relatively low thermal expansion in the solid state, relatively low solidification shrinkage, and good compatibility with a wide range of materials. Still other waxes that have been used are montan wax (both acid and ester types), fatty acid amides, ceresin, stearone, and hydrogenated castor oil.

The waxes listed represent those most commonly used for pattern blends. Of these, the paraffins and microcrystalline waxes are the most popular. Many other waxes are available and are at least potentially useful. In many cases, a particular wax is not used simply because a less expensive wax offers similar properties.

Waxes are reasonably priced, yet they provide a good balance of properties not readily obtainable in other materials. They are easily blended to suit different requirements and are compatible with other materials that can improve their properties still further. Their low melting points and low melt viscosities make them easy to compound, inject, assemble into clusters, and melt out without cracking the thin ceramic shell molds. These properties allow waxes to be injected at low temperatures and pressures, and this, combined with their lack of abrasiveness, leads to lower tooling costs.

Additives. Plain waxes possess many useful properties, but there are two important areas in which they are deficient:

- Strength and rigidity, especially where very fragile patterns need to be made
- Dimensional control, especially with regard to surface cavitation resulting from solidification shrinkage during and after pattern injection

Improvements can be made in these areas with nonwaxy additives.

The strength and toughness of waxes are improved by the addition of well-known high molecular weight plastics such as polyethylene, ethyl cellulose, nylon, ethylene vinyl acetate, and ethylene vinyl acrylate. These materials are highly viscous at wax-working temperatures, which tends to limit the amounts that can be used.

Nevertheless, these amounts are sufficient to make significant improvements in the handling characteristics of patterns and clusters. Polyethylene is widely used because it is economical and compatible with a wide spectrum of waxes. Ethyl cellulose has had some use, but it is much more limited in terms of compatibility and is more expensive. Polystyrene is rarely used because of its incompatibility with the commonly used waxes. Ethylene vinyl acetate and ethylene vinyl acrylate are newer materials that are finding increased application. Nylon has had only small usage.

Solidification shrinkage, which causes surface cavitation, is reduced somewhat by the plastics mentioned above. The effect, however, is limited by the low amounts that can be used before viscosity becomes excessive. Greater effects can be obtained by adding resins and fillers. Resins are used in most present-day pattern waxes. Fillers are used more selectively, and this leads to the description of pattern waxes as being either filled or unfilled.

The resins used for shrinkage reduction are of lower molecular weight than the plastics used for toughening[*]. The most useful resins soften gradually and continuously with increasing temperature, and they do not exhibit the large solid-to-liquid expansions during heating, or the reverse contractions during cooling, that characterize the solid-to-liquid

transformation in waxes. Thus, resins reduce this effect in direct proportion to the amount used. The amount used can be quite large because resins yield relatively low viscosity melts at wax-processing temperatures.

Suitable resins include the numerous rosin derivatives (esterified, polymerized, hydrogenated, and dehydrogenated) as well as such tree-derived resins as Burgundy Pitch, dammar, and the terpene resins. Additional resins include coumarone-indene, various hydrocarbon resins from petroleum, and a number of coal tar resins. The resins listed encompass a wide range of softening points and viscosity-versus-temperature relationships. They vary at room temperature from soft and tacky to hard and brittle, and they may have widely different compatibilities with particular waxes and plastics. All these factors must be considered and properly balanced in using resins in pattern waxes.

Fillers. The solidification shrinkage of waxes can also be reduced by mixing in powdered solid materials called fillers. These are insoluble in, and higher melting than, the base wax, and they produce an injectable suspension when the mixture is molten.

Because they do not melt, fillers do not contribute to the solidification shrinkage of the mixture, which is reduced in proportion to the amount used. Figure 2 shows the manner in which fillers reduce expansion during heating (as well as corresponding shrinkage upon cooling). Fillers that have been used in pattern waxes include polystyrene, various dicarboxamides and related compounds, isophthalic acid, pentaerythritol, and hexamethylenetetramine. The filler should preferably be in the form of small, equally sized spheres (Ref 5). Several such fillers have been developed, including spherical polystyrene, hollow carbon microspheres, and spherical particles of thermosetting plastic. In a variation of the filler concept, water has been emulsified into molten wax to serve the same function as the solid fillers (Ref 6). This type of wax is commercially available.

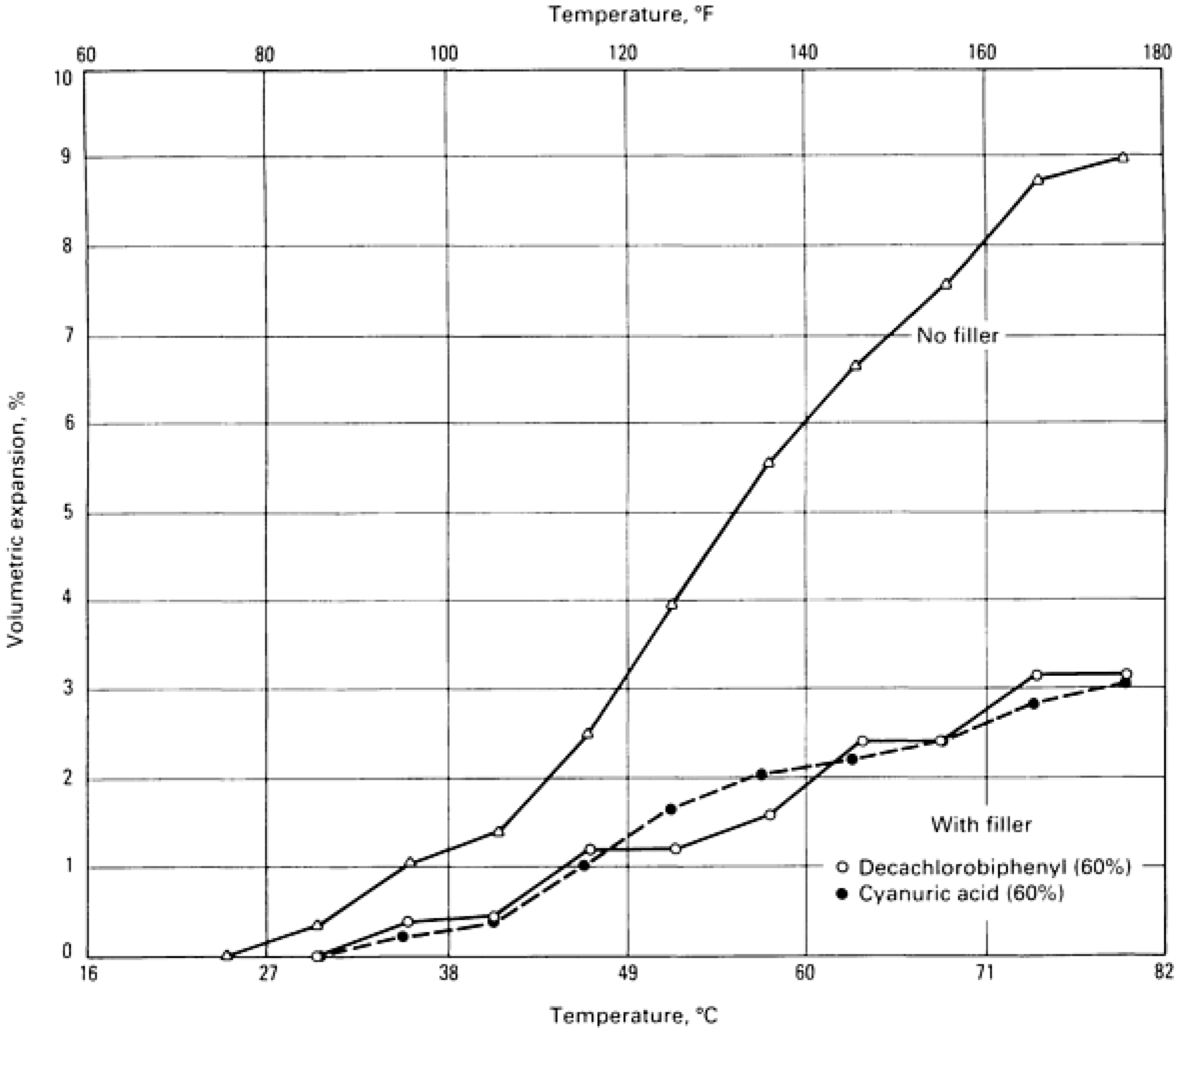

Fig. 2 Effects of filler materials on the volumetric thermal expansion of a pattern wax. Source: Ref 3, 4.

Several other additives can be used in pattern waxes. Colors in the form of oil-soluble dyes are used to enhance appearance, to provide identification, and to facilitate inspection of molded patterns. Antioxidants can be used to protect waxes and resins subject to thermal deterioration. Oils and plasticizers have been used to alter injection properties and, in certain cases, to reduce shrinkage.

As a result of the above considerations, the compositions of present-day pattern waxes (unfilled) typically fall into the ranges given below:

Ingredients	Composition, %
Waxes (usually more than one)	**30-70**
Resins (one or two)	**20-60**
Plastic (one)	**0-20**
Other	**0-5**

Filled waxes usually have similar base materials, with 15 to 45% filler added.

Wax Selection. In formulating wax pattern materials, a number of processing areas and other concerns must be addressed. These are listed below, along with the properties or considerations appropriate to each:

- *Injection:* Softening point, freezing range, rheological properties, ability to duplicate detail, surface, and setup time
- *Removal, handling, and assembly:* Lubricity, strength, hardness, rigidity, impact resistance, stability, and weldability
- *Dimensional control:* Thermal expansion/shrinkage, solidification shrinkage, cavitation tendency, distortion, and stability
- *Mold making:* Strength, wettability, and resistance to binders and solvents
- *Mold dewaxing and burnout:* Softening point, viscosity, thermal expansion, thermal diffusivity, and ash content
- *Miscellaneous:* Cost, availability, ease of recycling, toxicity, and environmental factors

Assistance in formulating pattern waxes can be found in Ref 2, 7, and 8. Reference 8 provides an extensive listing of pattern ingredients and their properties. A number of standard tests are available to facilitate the effort (Ref 9, 10, 11). The application of thermal analysis methods to wax testing is being investigated (Ref 7, 12), and this approach warrants extension for both control and development work. The Investment Casting Institute has provided a test die for evaluating waxes and wax injection presses (Ref 13, 14). No simple laboratory tests are available that can evaluate the suitability of a pattern wax. The best approach usually consists of laboratory tests for screening purposes combined with practical evaluation under such productionlike conditions as injection behavior, handling characteristics, dimensional consistency, and dewaxability.

Plastics

Next to wax, plastic is the most widely used pattern material. A general-purpose grade of polystyrene is usually used.

The principal advantages of polystyrene and other plastics are their ability to be molded at high production rates on automatic equipment and their resistance to handling damage even in extremely thin sections. In addition, because polystyrene is very economical and very stable, patterns can be stored indefinitely without deterioration. Most wax patterns deteriorate with age and eventually must be discarded.

A disadvantage that limits the use of polystyrene is its tendency to cause mold cracking during pattern removal, a condition that is worse with ceramic shell molds than with solid investment molds. Other common plastics, such as polyethylene, nylon, ethyl cellulose, and cellulose acetate, are similar in this regard. In addition, tooling and injection equipment for polystyrene is more expensive than for wax. As a result, polystyrene finds only limited use. A recent survey of 72 investment casting plants in the United States revealed that fewer than 20% had machines for injecting polystyrene and that wax machines outnumbered plastics machines by almost 13 to 1 (Ref 15).

Perhaps the most important application for polystyrene is for small, delicate airfoils. Patterns for such castings are incorporated into composite wax/plastic assemblies for integral rotor and nozzle patterns. These airfoils are extremely thin and delicate; they would be too fragile if molded in wax because even a single chip or crack will cause an expensive casting to be rejected. Polystyrene solves this problem, and the use of wax for the rest of the assembly makes it feasible to process such large patterns without excessive mold cracking. The other important use for polystyrene is for small patterns running in large quantities. However, this application has declined as ceramic shell molds have replaced solid investment molds.

Other Pattern Materials

Urea-base patterns were developed in Europe and have found some application there (Ref 16). They resemble plastics in that they are very hard and strong and require high-pressure injection machines. An advantage of urea patterns is that they can be easily removed without stressing ceramic shell molds; the pattern is simply dissolved out in water or an aqueous solution. Another water-soluble pattern material is based on mixtures of low-melting salts (Ref 17). Patterns based on paradichlorobenzene and naphthalene have found some application in Japan (Ref 18). Foamed polystyrene has long been used for gating system components, and it is also being used for patterns in the Replicast Process (see the article "Replicast Process" in this Volume).

* The terms resins and plastics are used in accordance with the definitions proposed for pattern wax technology in Ref 2.

Patternmaking

Patterns for investment casting are made by injecting the pattern material into metal molds of the desired shape. Small quantities of patterns can also be produced by machining (see the section "Machining of Patterns" in this article).

Injection of Wax Patterns

Wax patterns are generally injected at relatively low temperatures and pressures in split dies using equipment specifically designed for this purpose. Patterns can be injected in the liquid, slushy, pastelike, or solid condition. Injection in the solid condition is often referred to as wax extrusion. Temperatures usually range from about 43 to 77 °C (110 to 170 °F), and pressures from about 275 kPa to 10.3 MPa (40 to 1500 psi). Liquid waxes are injected at higher temperatures and lower pressures; solid waxes, at lower temperatures and higher pressures. In some cases, the same wax can be injected under some, or all, of these conditions, but it is often beneficial to tailor a wax for one particular condition.

Equipment for wax injection ranges from simple and inexpensive to sophisticated and costly. It can be as simple as a pneumatic unit with a closed, heated reservoir tank that is equipped with a thermostat, pressure regulator, heated valve, and nozzle and is connected to the shop air line for pressurization. A small die is held against the nozzle with one hand while the valve is operated with the other. Such machines are limited by available air pressure (usually <690 kPa, or 100 psi) and are therefore generally used to inject liquid wax. Such equipment is satisfactory for a large variety of small hardware parts that are commonly made as investment castings.

Parts that are more demanding in terms of size, complexity, or dimensional requirements are made on hydraulic machines. These machines provide higher pressures for improved injections as well as high clamping pressures to accommodate large dies and high injection pressures. They can also be operated with very low pressures, as is often necessary when injecting around thin ceramic cores. Hydraulic wax injection machines are sized according to their clamping force capability, with models ranging in capacity from 9.1 to 363 Mgf (10 to 400 tonf) or more.

Machines for manual or semiautomatic operation generally have horizontal platens that clamp the die closed (one stationary, one movable). Injection is horizontal along the parting line; a second vertical nozzle is sometimes available. Models are available with C-frame construction and with two-, three-, and four-post H-frame construction.

Machines for automatic injection have the platens mounted vertically, with injection through the stationary platen and one-half of the die or at the parting line. A reservoir tank is usually provided for liquid and slushy wax, having either slow agitation or recirculation to keep the wax uniform and to retain solid material (wax or filler) in suspension. Reservoir tanks are sometimes omitted, and the machines are connected directly to a central wax supply.

Machines for paste wax injection require preconditioned wax in a metal cylinder. The cylinder is inserted into the machine, and the wax is pushed out by a piston. Solid injection (extrusion) machines require pretempered wax billets.

Paste and solid injection both require a separate unit (oven or tempering bath) for tempering the cylinders or billets. Liquid injection usually requires separate units for melting and tempering the wax before it is introduced into the reservoir tank.

The parameters customarily controlled include wax and nozzle temperature, pressure, flow rate, and dwell time. Other available features, which may or may not be considered standard, include control of flow rate acceleration and deceleration, purging of the nozzle with fresh wax before each shot, nozzle drool control, unlimited shot capacity, die handling means, nozzle position adjustment, water-cooled platens, and multistation operation.

Reference publications that are available include a guide for troubleshooting wax injection operations (Ref 19) and an atlas of pattern defects (Ref 20). Other recommended publications are given in Ref 21, 22, 23, 24, 25, 26.

Injection of Plastic Patterns

Polystyrene patterns are generally injected at temperatures of 177 to 260 °C (350 to 500 °F) and pressures of 27.6 to 138 MPa (4 to 20 ksi) on standard plastic injection machines. These are hydraulic machines with vertical water-cooled platens that carry the die halves, and horizontal injection takes place through the stationary platen. Polystyrene granules are loaded into a hopper, from which they are fed into a plasticizing chamber (barrel). Modern machines have a rotating screw that reciprocates within the heated barrel to prepare a shot of material to the proper consistency and then inject it into the die. Some older machines having plungers instead of screws are still in use.

The use of multicavity dies, as well as the running of a number of dies at once, is commonplace. Coupled with automatic or semiautomatic operation, this results in extremely high productivity.

The same parameters are controlled as for wax injection. The development of wax-base compositions that perform well in plastic injection machines has permitted the advantages of wax patterns to be combined with the advantages of plastic injection for certain applications (Ref 27).

Machining of Patterns

When only one or a few patterns are required, as for prototype and experimental work, it is expedient to machine them directly from wax or polystyrene. This avoids the time and expense involved in making pattern tooling. Special waxes have been specifically developed for this application (Ref 28).

Pattern Tooling For Investment Casting

Investment casting permits various potential tooling options that are made possible by the low melting point, good fluidity, and lack of abrasiveness of waxes. This often represents an important competitive advantage. For a given part configuration, anticipated production requirements, choice of pattern material, and available patternmaking equipment, the selection is based on a consideration of cost, tool life, delivery time, pattern quality, and production efficacy. The methods in use can be grouped into three basic categories: machining, forming against a positive model (using a variety of methods), and casting into a suitable foundry mold.

Many materials can be used, including soft metals (lead-bismuth-tin alloys), zinc alloys, brass, bronze, beryllium copper, nickel-plate, steel, rubber, plastic, metal-filled plastic, plaster, and combinations of these. All of these are suitable for wax patterns, but plastic patterns usually require steel or beryllium copper tooling. Soft metals and nonmetallics are often used for temporary tooling.

Machined Tooling. Most production tooling is made by machining. The early investment casting industry favored tooling made from master models, but as parts became larger and more complex and production methods more demanding, machined tooling became dominant. Computer-aided design, electric discharge machining, and computer numerical controlled machine tools are commonly used.

Aluminum is preferred for most wax tooling, steel, for plastic tooling. Aluminum is economical to machine, has good thermal conductivity, and is conveniently light. Brass or steel inserts can be used in areas subject to wear. The higher strength of steel is not usually needed for wax injection; instead, steel is primarily used for plastic injection for small parts that run in sufficiently large quantities to justify its higher cost. For polystyrene, this quantity is usually around 10,000 pieces or more; for very small parts, perhaps as low as 5000.

Tool steels are most frequently used for plastic dies. AISI type P20 is extensively used because it can be purchased prehardened, then machined, and finally put into use without heat treatment. AISI A2 and O1 are also used. Both are machined in the annealed state, then hardened and tempered. Carbon steels such as 1020 are sometimes used for intermediate quantities. Holder blocks, shoes, and mold bases used to hold the plastic injection molds can be made of prehardened alloy steel (for example, 4140).

Tooling made against a positive model includes a variety of methods for forming metal or metal-faced tooling, such as spraying (Ref 29), pressure casting (Ref 30), cold and warm hobbing (Ref 31, 32), electroforming (Ref 33, 34), and (potentially) gas plating (Ref 35). It also includes the casting of such nonmetallic materials as plaster (usually used to back up a spray metal facing), plastics (Ref 36), and rubber (Ref 37), as well as the vulcanizing of solid rubber under pressure (Ref 38).

All these methods begin with a positive model in the shape of the final investment casting; the model is machined oversize to include the appropriate shrink factors. The methods are economical because it is generally (although not always) less expensive to machine a positive model than to machine a negative cavity of identical shape. Furthermore, with the exception of hobbing, the model can be made of a material that is easier to machine. The various methods of making dies from the master model are relatively inexpensive, so that the combined cost of machining the model and making the die is usually less than that for full machining. When multiple cavities are needed or where molds must be replaced, the same master can be used, resulting in further economies.

Cast Tooling. Steel and beryllium copper are frequently used for cast tooling. Aluminum and zinc alloys have also been used. Wax can be cast against a master model to produce a pattern, which is then used to make an investment cast cavity. Better as-cast accuracy can be achieved if the model is coated with only a thin layer of wax. This is used to investment cast a steel shell, which is then backed up with cast aluminum (Ref 39). The ceramic mold process can also be used to cast injection cavities (Ref 40).

Both casting and hobbing can produce excellent tooling that is suitable for the wax or plastic injection of relatively simple parts, such as many small hardware castings. Machined tooling is also used for many of the same applications, as well as for complex parts, such as airfoils, and for large structural parts. Soft metal tooling and nonmetallic tooling are primarily used for short runs and experimental work or for temporary tooling. However, under favorable conditions, runs of up to 40,000 parts have been reported for cast bismuth-tin tooling (Ref 41). Cast, hobbed, and machined dies used for wax injection often last indefinitely. Rubber molds are regularly used for making patterns for jewelry casting.

Pattern and Cluster Assembly

Large patterns for investment casting are set up and processed individually, but small-to-medium ones are assembled into multipattern clusters for economy in processing. Clusters of aircraft turbine blades, for example, may range from 6 to 30 parts. For small hardware parts, the number may run into the dozens or even the hundreds. Most patterns are injected complete, including their casting gates. However, very large or complex parts can be injected in segments, which are assembled into final form. The capacity of injection machines and the cost of tooling are important considerations. Gating components, including pour cups, are produced separately, and patterns and gating are assembled to produce the pattern cluster. Standard extruded wax shapes are often used for gating, especially for mock-up work. Preformed ceramic pour cups are often used in place of wax ones. Most assembly is done manually.

Pattern Assembly

Wax components are readily assembled by wax welding using a hot iron or spatula or a small gas flame. The wax at the interface between two components is quickly melted, and the components are pressed together until the wax resolidifies. The joint is then smoothed over. A hot melt adhesive can be used instead of, or in addition to, wax welding. A laser welding system was recently described for this purpose (Ref 42).

Manual wax welding requires a fair degree of skill and considerable attention to detail. Fixtures are essential to ensure accurate alignment in assembling patterns, and they are often useful for cluster assembly. Patterns must be properly spaced and aligned. Joints must be strong and completely sealed with no undercuts. Care must be taken to avoid damaging patterns or splattering drops of molten wax on them.

Polystyrene pattern segments can be assembled by solvent welding. The plastic at the interface is softened with the solvent, and the parts are pressed together until bonded. The polystyrene becomes very tacky when wet with solvent (such as methyl ethyl ketone) and readily adheres to itself. Frequently, only one of the two halves needs to be wet. The assembly of polystyrene to wax is done by welding, with only the wax being melted.

Automation. Most assembly and setup operations are still performed manually, but some automation is being introduced. In one application, a robot is used to apply sealing compound in the assembly of patterns for integrally cast nozzles having 52 to 120 airfoils apiece. In the area of cluster setup, a few units for automatic assembly are being offered commercially, one of which has been described in great detail (Ref 43). Clusters are assembled automatically by welding pairs of wax patterns on opposite sides along the length of a wax runner bar, using heated copper blades and spring pressure. Standard gate designs in a range of size increments eliminate the need for special fixturing. The unit is suitable for most small-to-medium size castings.

Cluster Design

The design of the cluster is a critical factor because it affects almost every aspect of the process. Factors to be considered include ease of assembly, number of pieces processed at a time, ratio of metal poured to castings shipped, handling strength, ease of mold forming and drying, wax removal, liquid metal flow, filling of thin sections, feeding of shrinkage,

control of grain size and shape (when specified), shell removal, ease of cutoff and finishing, and available equipment and processes.

Three requirements are essential:

- Providing a cluster that is properly sized and strong enough to be handled throughout the process
- Meeting metallurgical requirements
- Providing separate specimens for chemical or mechanical testing (when required)

Once these essentials are satisfied, other factors are adjusted to maximize profitability. The process is very flexible, and foundries approach this goal in various ways. Some tailor the cluster design to each individual part to maximize parts per cluster and metal usage. Others prefer standardized clusters to facilitate handling and processing. Where close control of grain is required, whether for equiaxed, columnar (directionally solidified), or single-crystal casting, circular clusters are often used to provide thermal uniformity. The specific casting process used, such as counter-gravity casting, directional solidification (see the articles "Counter-Gravity Low-Pressure Casting" and "Directional and Monocrystal Solidification" in this Volume), or centrifugal casting (see the article "Centrifugal Casting"), may dictate the basic features of cluster design.

The critical aspects of cluster design are gating and risering, which are discussed in the articles "Riser Design" and "Gating Design" in this Volume. Basic concepts of risering borrowed from sand casting, such as progressive solidification toward the riser, Chvorinov's rule and its extensions, solidification mode, and feeding distance as a function of alloy and section size, also apply to investment casting.

However, feeding distances tend to be longer in hot investment molds than in sand molds (Ref 44, 45). Separate risers are sometimes used, but more often the gating system also serves the risering function, especially for the myriad of small parts that are commonly investment cast. The use of wax clusters permits great flexibility in the design of feeding systems. Process development clusters are readily mocked up for trial. Extruded wax shapes are easily bent into feeders that can be attached to any isolated sections of the part that are prone to shrinkage. Once proved, they can be incorporated into tooling if this is cost effective. If not, they can be applied manually during cluster assembly. This capability makes it practical to cast very complex parts with high quality and makes it feasible to convert fabrications assembled from large numbers of individual components into single-piece investment castings at great cost savings.

Considerable effort is being directed toward applying heat transfer models based on finite-element and finite-difference methods to the analysis of solidification and the design of feeding systems for castings, including investment castings (Ref 46). Although this has not yet had a significant impact on production engineering activities, eventual implementation and widespread use is anticipated. A specific application to a complex investment casting has recently been described (Ref 47).

Manufacture of Ceramic Shell Molds

Investment shell molds are made by applying a series of ceramic coatings to the pattern clusters. Each coating consists of a fine ceramic layer with coarse ceramic particles embedded in its outer surface. A cluster is first dipped into a ceramic slurry bath. The cluster is then withdrawn from the slurry and manipulated to drain off excess slurry and to produce a uniform layer. The wet layer is immediately stuccoed with relatively coarse ceramic particles either by immersing it into a fluidized bed of the particles or by sprinkling the particles on it from above.

The fine ceramic layer forms the inner face of the mold and reproduces every detail of the pattern, including its smooth surface. It also contains the bonding agent, which provides strength to the structure. The coarse stucco particles serve to arrest further runoff of the slurry, help to prevent it from cracking or pulling away, provide keying (bonding) between individual coating layers, and build up thickness faster.

Each coating is allowed to harden or set before the next one is applied. This is accomplished by drying, chemical gelling, or a combination of these. The operations of coating, stuccoing, and hardening are repeated a number of times until the required mold thickness is achieved. The final coat is usually left unstuccoed in order to avoid the occurrence of loose particles on the mold surface. This final, unstuccoed layer is sometimes referred to as a seal coat.

Mold Refractories

The most common refractories for ceramic shell molds are siliceous, for example, silica itself, zircon, and various aluminum silicates composed of mullite and (usually) free silica. These three types in various combinations are used for most applications. Alumina has had some use for super-alloy casting, and this application has increased with the growth of directional solidification processes. Alumina is generally considered too expensive and unnecessary for commercial hardware casting. Silica, zircon, aluminum silicates, and alumina find use for both slurry refractories and stuccos. Table 1 lists the typical properties of these materials, and Fig. 3 shows thermal expansion curves.

(a) Poor: slight reaction in hot concentrated alkali; Good: soluble to very soluble in hot concentrated alkali or hydrofluoric acid; Moderate: reacts with hot concentrated alkali solutions.

(b) PCE, pyrometric cone equivalent.

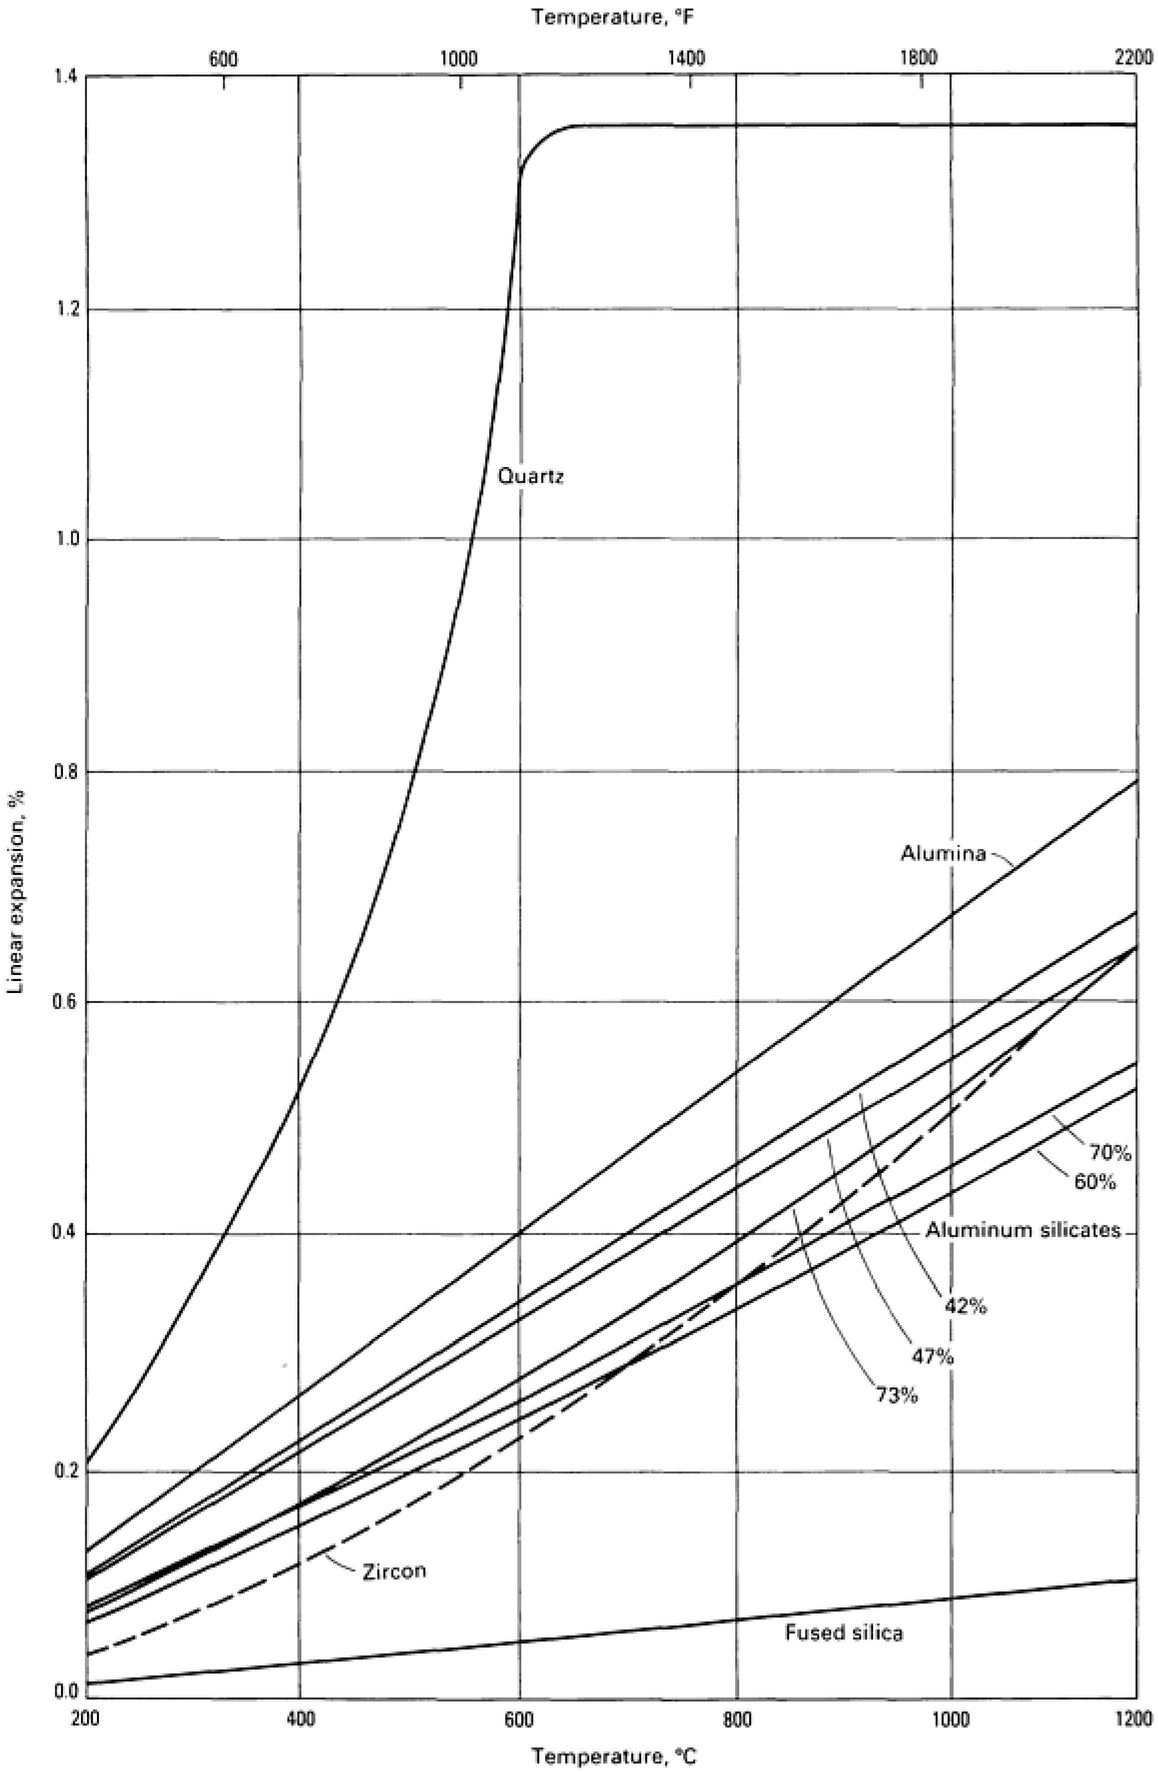

Fig. 3 Linear thermal expansion of some refractories common to investment casting. Source: Ref 48.

Other refractories, such as graphite, zirconia (ZrO_2), and yttria (Y_2O_3), have been suggested for use with reactive alloys. Still other materials have been proposed for specific purposes. These specialized applications are summarized in Ref 49.

Silica is generally used in the form of silica glass (fused silica), which is made by melting natural quartz sand and then solidifying it to form a glass. It is crushed and screened to produce stucco particles, and it is ground to a powder for use in slurries. Its extremely low coefficient of thermal expansion imparts thermal shock resistance to molds, and its ready solubility in molten caustic and caustic solutions provides a means of removing shell material chemically from areas of castings that are difficult to clean by other methods.

Silica is also used as naturally occurring quartz. This is the least expensive material used to any extent. However, its utility is limited by its high coefficient of thermal expansion and by the high, abrupt expansion at 573 °C (1063 °F) accompanying its α-to-β-phase transition. As a result, shells containing quartz must be fired slowly, a practice most foundries find inconvenient.

Zircon occurs naturally as a sand, and it is used in this form as a stucco. It is generally limited to use with prime coats because it does not occur in sizes coarse enough for stuccoing backup coats. It is also ground to powder (and sometimes calcined) for use in slurries, often in conjunction with fused silica and/or aluminum silicates. Its principal advantages are high refractoriness, resistance to wetting by molten metals, round particle shape, and availability.

Aluminum silicates for investment casting are made by calcining fireclays or other suitable materials to produce a series of products ranging in alumina content from about 42 to 72%, with the remainder being silica plus impurities. Refractoriness and cost increase with alumina content. The only stable compound between alumina and silica at elevated temperatures is mullite ($3Al_2O_3 \cdot 2SiO_2$), which contains 72% alumina. Mixtures containing less than 72% alumina produce mullite plus free silica. The latter is usually in the form of silica glass, although some crystalline silica in the cristobalite form may be present. As the alumina content increases, the amount of mullite increases and free silica decreases until, at about 72% alumina, the material contains only mullite. Fired pellets of these materials are crushed or ground and carefully sized to produce a range of powder sizes for use in slurries, and granular materials for use as stuccos.

Alumina is produced from bauxite ore by the Bayer process. It is more refractory than silica or mullite and is less reactive toward many alloys than the siliceous refractories. Its use is primarily confined to superalloy casting, in which these properties can be used to advantage. The usual grades are tabular, which has been calcined just below the melting point, and fused, which has been electrically melted. The latter is slightly denser and slightly purer.

Binders

The commonly used binders are also siliceous and include colloidal silica, hydrolyzed ethyl silicate, and sodium silicate. Hybrid binders have also been developed, and alumina or zirconia binders are used for some processes.

Colloidal silica is the most widely used. It is manufactured by removing sodium ions from sodium silicate by ion exchange. The product consists of a colloidal dispersion of virtually spherical silica particles in water. The dispersion is stabilized by an ionic charge, which causes the particles to repel one another, thus preventing agglomeration. The stabilizing ion is usually sodium (up to 0.6%), although ammonia can also be used. In either case, the product is alkaline.

Colloidal silica can also be stabilized at an acid pH, but such products are not widely used. The most popular grades are sodium-stabilized with a silica content of 30% and an average particle size of either 7 or 12 nm. They are either used at this 30% level or diluted with water to reduce the silica content to 18 to 30%. Coherent gels having excellent bonding properties are formed by adding ionic salts that neutralize the ionic charge or by concentrating the sol (as by drying a coating).

Colloidal silica is an excellent general-purpose binder. Its main disadvantage is that its water base makes it slow drying, especially in inaccessible pockets or cores.

Ethyl silicate is produced by the reaction of silicon tetrachloride with ethyl alcohol. The basic compound formed is tetraethylor-thosilicate ($Si(OC_2H_5)_4$). This corresponds to a theoretical silica content of 28.8%. The grade used for investment applications is designated ethyl silicate 40, and it consists of a mixture of ethyl polysilicates averaging five silicon atoms per molecule and having a silica content of around 40%.

By itself, ethyl silicate has no bonding properties. It is converted to ethyl silicate binder by reaction with water (hydrolysis). The reaction is usually carried out in ethyl alcohol, which serves as a mutual solvent, using an acid catalyst such as hydrochloric acid. The reaction is fairly rapid and highly exothermic. Its progress can be monitored with temperature measurements. The reaction forms complex silicic acids that are capable of condensing to form coherent gels having good bonding properties. This process is promoted by drying (concentrating) or by adding an alkali such as ammonia. The result is similar in many ways to that obtained using colloidal silica. Prehydrolyzed grades of ethyl silicate having reasonable shelf life are also available, making it unnecessary for foundries to perform this chemical operation themselves.

Ethyl silicate, with its alcohol base, dries much faster than colloidal silica. It is, however, more expensive and poses tire and environmental hazards. It is best used in applications involving rapid dipping cycles. Ethyl silicate slurries are readily gelled by exposure to an ammonia atmosphere; this permits dips to be applied very quickly, yet still provides proper drying because of the high volatility of the alcohol.

Hybrid binders have been developed in an effort to combine the advantages of colloidal silica and ethyl silicate. The water required for hydrolysis of the ethyl silicate is supplied by using colloidal silica, providing an additional source of silica for improved strength. Less flammable solvents can be substituted for alcohol. The resulting product presents a desirable combination of properties (Ref 50).

Liquid sodium silicate solutions are used where a very inexpensive binder is desired. Upon evaporation, these binders form a strong, glassy bond. Sodium silicate binders have poor refractoriness, which greatly limits their sphere of application. In addition, they are not resistant to the steam atmosphere of dewaxing autoclaves. Nevertheless, they have found some use, sometimes in conjunction with colloidal silica or ethyl silicate.

Other Binder Materials. The operation of directional solidification processes, which subject the mold to high temperatures for relatively long times, along with the introduction of even more reactive superalloys, has led to interest in more refractory binders. Colloidal alumina and colloidal zirconia binders have been made available for this purpose (Ref 51, 52). Both, however, are inferior to colloidal silica in room-temperature bonding properties.

Other Ingredients

Wetting Agents. In addition to the binder and refractory, slurries generally contain anionic or nonionic wetting agents, such as sodium alkyl aryl sulfonates, sodium alkyl sulfates, or octylphenoxy polyethoxyethanol, to promote wetting of the pattern or prior slurry coats. These are generally used in amounts of 0.03 to 0.3% by weight of the liquid. Wetting agents are sometimes omitted from ethyl silicate/alcohol slurries and from water-base backup slurries.

Antifoam Compounds. Where wetting agents are used, especially in prime coats, an antifoam compound may be included to suppress foam formation and to permit air bubbles to escape. Commonly used defoamers are aqueous silicone emulsions and liquid fatty alcohols such as *n*-octyl alcohol and 2-ethyl hexyl alcohol. Depending on type, these formulations are effective in very low concentrations of 0.002 to 0.10%, based on the liquid weight.

Miscellaneous Constituents. Organic film formers are sometimes used to improve the green strength and resilience of the dried coating or to enhance the coating ability of the slurry. Aqueous polyvinyl acetate emulsions, polyvinyl alcohol, and ammonium alginate have been used for this purpose. Small additions of clay have also been used to improve coating characteristics. Where close control of grain size is required, as for equiaxed superalloy casting, a nucleating agent (grain refiner) is added to the prime slurry in amounts ranging from about 0.5 to 10% by weight of the slurry refractory (Ref 53, 54, 55). Preferred nucleating agents are refractory cobalt compounds such as aluminates, silicates, titanates, and oxides.

Slurry Formulation

The actual percentage composition of ceramic shell slurries depends on the particular refractory powder, type and concentration of binder, liquid vehicle, and desired slurry viscosity. Composition generally falls in the following broad range by weight:

Ingredient	Composition, %
Binder solids	**5-10**
Liquid (from binder or added)	**15-30**
Refractory powder	**60-80**

Other optional ingredients, when present, are used in the amounts already given. Slurry compositions are usually proprietary, but three published formulas for zircon slurries are given in Table 2.

Table 2 Formulations and properties of three types of zircon slurries

Slurry	**Constituents**										Properties		
	Colloidal silica (30%)		**Water**		**Zircon powder**		**Wetting agent**		**Silica**		**Density**		Viscosity, s[a]

(a) No. 4 Zahn cup.

(b) A general-purpose slurry.

(c) A high-strength slurry used for ceramic shell molds for castings with heavy sections and for applications in which high wax pressure during meltout and high metal pressure are used.

(d) Modified with silica; used with castings with small cored holes from which cores are removed by leaching with molten alkali salts

Two extremely important properties of ceramic shell molds are green strength and fired strength. A fundamental study of the effects of composition and processing parameters on these properties is described in Ref 56 and 57, which also provide additional examples of slurry compositions. This work was further amplified by another researcher (Ref 58). The effects of the usual refractory powders and stuccos on hot strength were investigated, and it was found that strength after firing is not a good indication of hot strength (Ref 59). However, it is still an important property because it affects the shell removal operation.

Slurry Preparation and Control

Preparation. Slurries are prepared by adding the refractory powder to the binder liquid, using sufficient agitation to break up agglomerates and thoroughly wet and disperse the powder. Viscosity initially tests excessively high because of air entrainment and lack of particle wetting; therefore, mixing is continued until the viscosity falls to its final level before the slurry is put into use. Continued stirring is required in production to keep the powder from settling out of suspension. Either rotating tanks with baffles or propeller mixers are used for this purpose--but generally at a lower agitation level than that used for the initial dispersion.

Control procedures for slurries vary considerably among foundries, reflecting in part the wide range of specifications that different shops work to, depending on their product line. The most prevalent controls are the measurement of the initial ingredients and the viscosity of the slurry. The latter is measured by a flow cup, such as a No. 4 or 5 Zahn cup, or a rotating viscometer of the Brookfield type.

Other parameters that are often controlled include slurry temperature, density, and pH, all of which are easily determined. More involved and time consuming is the determination of the actual composition of the slurry in terms of water content, silica binder, and refractory powder. This type of analysis, therefore, is performed less often and is sometimes reserved for troubleshooting rather than control. In the ceramic retention test, which is used by relatively few foundries, the actual weight of slurry adhering to a standard test plate under controlled conditions is determined.

Some properties of the finished ceramic shells that can be monitored include weight, modulus of rupture (green and/or fired), and permeability. Equipment for determining the hot strength of shells is relatively rare in the industry and is largely used for research. Test procedures for raw materials, slurries, molds, and cores are described in Ref 48, and the problems involved in slurry control are discussed in Ref 60, 61, 62.

Cluster Preparation

Before dipping, pattern clusters are usually cleaned to remove injection lubricant, loose pieces of wax, or dirt. Cleaning is accomplished by rinsing the pattern clusters in an appropriate solution, such as a water solution of a wetting agent, a solvent that does not attack the wax, or a solvent mixture capable of attacking the wax in a controlled manner to produce a fine uniform etching action that promotes slurry adhesion without affecting the cast surface. An additional rinse can be used to remove the cleaning agent. Another procedure involves dipping the cluster into a liquid that deposits an ultrathin refractory oxide coating that renders the surface hydrophilic; thus, the cluster is readily wetted by the ceramic slurry (Ref 63). These different solutions can sometimes be used in combination.

The clusters are usually allowed to dry before dipping. Drying produces a chilling effect, which causes unwanted contraction in pattern dimensions; therefore, the clusters are generally allowed to stand until they return to room temperature.

Coating and Drying

Dipping, draining, and stuccoing of clusters are carried out manually, robotically, or mechanically. Companies are increasingly using robots in order to heighten productivity, to process larger parts and clusters, and to produce more uniform coatings. When robots are introduced, they are often programmed to reproduce the actions of skilled operators. Dedicated mechanical equipment can sometimes operate faster, especially with standardized clusters, and finds some application. Most dipping is done in air. Dipping under vacuum is very effective for coating narrow passageways and for eliminating air bubbles, but it is not widely practiced.

The cleaned and conditioned cluster is dipped into the prime slurry and rotated; it is then withdrawn and drained over the slurry tank with suitable manipulation to produce a uniform coating. Next the stucco particles are applied by placing the cluster in a stream of particles failing from an overhead screen in a rainfall sander or by plunging the cluster into a fluidized bed of the particles. In the fluidized bed, the particles behave as a boiling liquid because of the action of pressurized air passing through a porous plate in the bottom of the bed.

Generally, prime slurries contain finer refractory powder, are used at a higher viscosity, and are stuccoed with finer particles than backup coats. These characteristics provide a smooth-surfaced mold capable of resisting metal penetration.

Backup coats are formulated to coat readily over the prime coats (which may be somewhat porous and absorbent), to provide high strength, and to build up the required thickness with a minimum number of coats. One or two additional prime coats are sometimes used before starting the backup coats. The number of coats required is related to the size of the

clusters and the metal weight to be poured and may range from as few as 5 for small clusters to as many as 15 or more for large ones. For most applications, the number ranges from 6 to 9.

Between coats, the slurries are hardened by drying or gelling. Air drying at room temperature with circulating air of controlled temperature and humidity is the most common method. Drying is usually carried out on open racks or conveyors, but cabinets or tunnels are sometimes used.

Drying is complicated by the high thermal expansion/contraction characteristics of waxes. If drying is too rapid, the chilling effect causes the pattern to contract while the coating is wet and unbonded. Then, as the coating is developing strength and even shrinking somewhat, the wax begins to expand as the drying rate declines and it regains temperature. This can actually crack the coating. Therefore, relative humidity is generally kept above 40%. For normal conditions, a relative humidity of 50% has been recommended as ideal (Ref 64). The essential point is that the maximum temperature differential between the wax and the drying air should not be excessive. Shop experience indicates that 4 to 6 °C (7.2 to 10.8 °F) is a practical maximum (Ref 65).

The slurry does not have to be thoroughly dried between coats, but it must be dry enough so that the next coat can be applied without washing off the previous one. An alternative technique is to harden the slurry by chemical gelation, which can be accomplished without drying. This is most successful with ethyl silicate binders, which can be surface gelled by exposure to an ammonia atmosphere. Hardening by chemical gelation permits the minimum time between coats. Gelling can also be accomplished by adding gelling agents to the stucco or by alternating alkaline and acidic slurries or negatively charged and positively charged slurries in the dipping sequence. Shells that are gelled without drying are generally weaker even when subsequently dried. In addition, the weight of the unevaporated solvent can be excessive and can cause the wax cluster to yield or even break in some cases.

Manufacture of Ceramic Cores

Ceramic coring is widely used in investment casting to produce internal passage-ways in castings. Investment casting cores are either self-formed (produced in place during the mold building operation) or preformed (made separately by an appropriate ceramic forming process).

Self-Formed Cores

Self-forming requires that the wax patterns already have the openings corresponding to the passageways desired in the castings. For simple shapes, this is accomplished by the use of metal pull cores in the pattern tooling. For shapes in which a simple pull core cannot be extracted, soluble wax cores are made, placed in the pattern tooling, and the pattern injected around them. The soluble core is then dissolved out in a solution that does not affect the wax pattern, such as an aqueous acid. Soluble cores are generally made from a solid polyethylene glycol, with a powdered filler such as sodium bicarbonate or calcium carbonate. The fillers dissolve in the acid with vigorous gas evolution, which provides agitation to speed the dissolution process.

Where openings are large enough, self-formed cores are made in the normal course of shelling, but where openings are deep or narrow, the shelling process must be modified to accommodate the special requirements of the cores. This may require special attention to slurry viscosity, stucco particle size, and drying. Vacuum dipping is an excellent tool in this case. Ethyl silicate/alcohol slurries reduce drying problems. The self-forming of cores is extensively practiced for small hardware castings, for which the cost of a preformed core would be prohibitive.

Preformed Cores

Self-formed cores have severe limitations, which are overcome by using preformed cores. Preformed cores require separate tooling and can be produced by a number of ceramic forming processes. Simple tubes and rods are commonly extruded from silica glass. Many cores, especially larger ones, are produced from ethyl silicate slurries that are cast by gravity or injected under pressure into aluminum dies and then gelled. The technology is similar to ceramic molding processes (see the article "Ceramic Molding" in this Volume).

Many cores are made by injection molding; a smaller number, by transfer molding. Ceramic injection molding is similar to the plastics injection molding described earlier, except that a mixture of fine ceramic powder in an organic vehicle is injected, usually into hardened tool steel dies. The organic vehicle, which also functions as a green binder, employs such thermoplastic materials as polyethylene, ethyl cellulose, shellac, resins, waxes, and subliming organic compounds such as naphthalene and paradichlorobenzene. After forming, the cores are subjected to a two-stage heat treatment. In the first stage, the organics are removed without disrupting the core (which is sometimes a lengthy process), and in the second stage, the core is sintered to its final strength and dimensions.

Transfer molding is similar to injection molding. The primary difference is that a preform of thermosetting plastic and ceramic powder is softened and injected into a die, where it is cured (thermally set) under heat and pressure.

Although a considerable number of materials have been proposed for ceramic cores, they are usually made of fused silica, sometimes with additions of zircon. Fused silica cores provide satisfactory refractoriness and are readily leached from the castings in molten caustic baths, aqueous solutions of caustic in open pots or autoclaves, and hydrofluoric acid solutions.

Preformed cores are usually used by placing them in the pattern die and injecting wax around them. For some simple shapes, the cores are inserted into the patterns immediately after the patterns are injected. Cores expand differently from the shell molds in which they are used because of differences in composition and heating rates; therefore, cores of any size must be provided with slip joints in the mold (Ref 66). The factors to be considered in using ceramic cores are discussed in Ref 66.

Pattern Removal

Pattern removal is often the operation that subjects the shell mold to the most stresses, and it is a frequent source of problems. These arise from the fact that the thermal expansions of pattern waxes are many times those of the refractories used for molds (compare Fig. 2 and 3). When the mold is heated to liquify the pattern, this expansion differential leads to enormous pressure that is capable of cracking and even destroying the mold. In practice, this problem can be effectively circumvented by heating the mold extremely rapidly from the outside in. This causes the surface layer of wax to melt very quickly before the rest of the pattern can heat up appreciably. This molten layer either runs out of the mold or soaks into it, thus providing space to accommodate expansion as the remainder of the wax is heated. Melt-out tips open to the outside are sometimes provided or holes are drilled in the shell to relieve wax pressure.

Even with these techniques, the shell is still subjected to high stress; therefore, it should be as strong as possible. It should also be thoroughly dried before dewaxing. To achieve thorough drying, shells are subjected to 16 to 48 h of extended drying after the last coat; this drying is sometimes enhanced by the application of vacuum or extremely low humidity.

A number of methods have been developed to implement the surface melting concept (Ref 67), but only two have achieved widespread use: autoclave dewaxing and high temperature flash dewaxing. In addition, hot liquid dewaxing has found some use among smaller companies seeking to minimize capital investment.

Autoclave dewaxing is the most widely used method. Saturated steam is used in a jacketed vessel, which is generally equipped with a steam accumulator to ensure rapid pressurization, because rapid heating is the key to success. Autoclaves are equipped with a sliding tray to accommodate a number of molds, a fast-acting door with a safety lock, and an automatic wax drain valve. Operating pressures of approximately 550 to 620 kPa (80 to 90 psig) are reached in 4 to 7 s. Molds are dewaxed in about 15 min or less. Wax recovery is good. Polystyrene patterns cannot be melted out in the autoclave.

Flash dewaxing is carried out by inserting the shell into a hot furnace at 870 to 1095 °C (1600 to 2000 °F). The furnace is usually equipped with an open bottom so that wax can fall out of the furnace as soon as it melts. Some of the wax begins to burn as it falls, and even though it is quickly extinguished, there is greater potential for deterioration than with an autoclave. Nevertheless; wax from this operation can be reclaimed satisfactorily. Flash dewaxing furnaces must be equipped with an after-burner in the flue or some other means to prevent atmospheric pollution. Polystyrene patterns are readily burned out in flash dewaxing, but polystyrene often can cause extensive mold cracking unless it is embedded in wax in the pattern (as in integral nozzle patterns) or unless the polystyrene patterns are very small.

Liquid dewaxing requires the minimum investment in equipment. Hot wax at 177 °C (350 °F) is often used as the medium. Other liquids can also be used. Cycles are somewhat longer than for autoclave and flash dewaxing, and there is a potential fire hazard.

Mold Firing and Burnout

Ceramic shell molds are fired to remove moisture (free and chemically combined), to burn off residual pattern material and any organics used in the shell slurry, to sinter the ceramic, and to preheat the mold to the temperature required for casting. In some cases, these are accomplished in a single firing. Other times, preheating is performed in a second firing. This permits the mold to be cooled down, inspected, and repaired if necessary. Cracked molds can be repaired with

ceramic slurry or special cements. This will not heal cracks, but will seal them and reinforce the shell so that it can be successfully cast. Many molds are wrapped with ceramic-fiber blanket at this time to minimize the temperature drop that occurs between the preheat furnace and the casting operation or to provide better feeding by insulating selected areas of the mold.

Gas-fired furnaces are used for mold firing and preheating, except for molds for directional solidification processes, which are preheated in the casting furnace with induction or resistance heating. Batch and continuous pusher-type furnaces are most common, but some rotary furnaces are also in use. Most furnaces have conventional firebrick insulation, but furnaces with ceramic-fiber insulation and luminous wall furnaces (Ref 68) are also in use. The latter two provide very fast heat up and cool down as well as good fuel economy. Conventional and ceramic-fiber furnaces can be equipped with ceramic recuperators for greater fuel economy and reduced smoke emissions (Ref 69). Good circulation is essential, especially in preheat furnaces, to provide uniform temperatures. Approximately 10% excess air is provided in burnout furnaces to ensure the complete combustion of organic materials.

Burnout is commonly conducted between 870 and 1095 °C (1600 and 2000 °F). Many molds can be placed directly into the hot furnace, but others may have to be loaded at a low temperature and heated gradually. This includes molds made with crystalline silica and molds in which some parts are shielded from radiation. Preheat temperatures vary over a large range above and below burnout temperatures, depending on part configuration and the alloy to be cast. Common ranges are 150 to 540 °C (300 to 1000 °F) for aluminum alloys, 425 to 650 °C (800 to 1200 °F) for many copper-base alloys, and 870 to 1095 °C (1600 to 2000 °F) for steels and superalloys. Molds for the directional solidification process are preheated above the liquidus temperature of the alloy being cast.

Melting and Casting

Melting Equipment. In the past, the small carbon arc rollover furnace was the workhorse of the early investment casting industry (Ref 70), but this furnace has been gradually displaced by the induction furnace, which is more flexible and economical to operate. Induction furnaces are used in conjunction with various casting methods developed for the specific requirements of investment casting. Today most investment casting uses induction melting.

The furnaces used are of the coreless type and generally employ preformed crucibles for melting (or monolithic linings for large sizes). They consist of a water-cooled copper coil that surrounds the melting crucible, a power supply to energize the coil with alternating current, and the appropriate electrical controls. The alternating current flowing through the coil sets up an alternating magnetic field that induces eddy currents in the metal charge. The heating effect is self-generated within the charge as a result of its resistance to the current flow. Earlier models used spark gap converters or motor-generator sets as power supplies, but today solid-state power supplies are standard.

Most induction furnaces for investment casting have capacities ranging from 7.7 to 340 kg (17 to 750 lb). They are usually tilting models, although some small rollover models are used where very rapid mold filling is required. Melting rates of 1.36 kg/min (3 lb/min) are common, but this depends on the relative size of the power supply and the melt. Induction furnaces can be employed for melting in air, inert atmosphere, or vacuum. They are extensively used for melting steel, iron, cobalt and nickel alloys, and sometimes copper and aluminum alloys. The crucibles typically used are magnesia, alumina, and zirconia, which are made by slip casting, thixotropic casting, dry pressing, or isostatic pressing. For vacuum casting, there is some use of disposable liners, which are made by conventional ceramic shell techniques or by the slip casting of fused silica.

Gas-fired crucible furnaces and, more recently, electrical resistance furnaces are used for aluminum casting. Gas-fired furnaces using glazed clay-bonded graphite crucibles are satisfactory for aluminum and copper alloy castings, and these furnaces are inexpensive. Silicon carbide crucibles are sometimes used for copper-base alloys. Resistance furnaces eliminate combustion products and help reduce hydrogen porosity. Magnesium can be melted in gas-fired furnaces using low-carbon steel crucibles.

Consumable-electrode vacuum arc skull furnaces are used for melting and casting titanium in a process originally developed at the U.S. Bureau of Mines (Ref 71). A billet of the alloy to be cast serves as the consumable electrode and is are melted under vacuum into a water-cooled copper crucible. The crucible has a permanent, thin skull of solidified alloy on its inner face, and this skull prevents the crucible from contaminating the melt. Molten alloy accumulates in the crucible until there is a sufficient quantity to fill the mold, at which time it is poured. Furnaces of various sizes are available and are capable of melting up to 522 kg (1150 lb). The number of such installations is small because only a few companies make titanium investment castings, but this reflects the technical difficulties involved rather than any lack of a market.

Electron beam melting has been used in Europe as an alternative to vacuum arc melting for the casting of titanium (Ref 72). It is being used by an aircraft engine manufacturer in the United States for melting superalloys for directionally solidified and single-crystal casting (Ref 73). The arrangement is basically similar to that used for vacuum arc skull melting except that the electron beam is used in place of the vacuum arc.

Casting Methods. Both air and vacuum casting are important in investment casting. Most vacuum casting is investment casting, although there is some use of rammed graphite molds in vacuum arc furnaces for casting titanium. Most castings are gravity poured.

Air casting is used for such commonly investment cast alloys as aluminum, magnesium, copper, gold, silver, platinum, all types of steel, ductile iron, most cobalt alloys, and nickel-base alloys that do not contain reactive elements. Zinc alloys, gray iron, and malleable iron are usually not investment cast for economic reasons, but if they were, they would be air cast.

Vacuum casting provides cleaner metal and often superior properties, and sometimes this is an incentive to cast some of the normally air-melted alloys in vacuum. However, its major use is for alloys that cannot be satisfactorily cast in air, such as the γ'-strengthened nickel-base alloys, some cobalt alloys, titanium, and the refractory metals. Batch and semicontinuous interlock furnaces are satisfactory for vacuum casting, but the latter are clearly preferred.

A major advantage of investment casting is its ability to cast very thin walls. This results from the use of a hot mold, but is further enhanced by specific casting methods, such as vacuum-assist casting, pressurized casting, centrifugal casting, and counter-gravity casting.

In vacuum-assist casting, the mold is placed inside an open chamber, which is then sealed with a plate and gaskets, leaving only the mold opening exposed to the atmosphere. A partial vacuum is drawn within the chamber and around the mold. The metal is poured into the exposed mold opening, and the vacuum serves to evacuate air through the porous mold wall and to create a pressure differential on the molten metal, both of which help to fill delicate detail and thin sections.

Rollover furnaces are pressurized for the same purpose. The hot mold is clamped to the top with its opening in register with the furnace opening, and the furnace is quickly inverted to dump the metal into the mold while pressure is applied using compressed air or inert gas.

Centrifugal casting uses the centrifugal forces generated by rotating the mold to propel the metal and to facilitate filling. Vacuum arc skull furnaces discharge titanium alloy at a temperature just above its melting point, and centrifugal casting is usually needed to ensure good filling. Dental and jewelry casting use centrifugal casting to fill thin sections and fine detail. These three applications represent the major uses for centrifugal casting in investment casting.

Counter-gravity casting is discussed in the article "Counter-Gravity Low-Pressure Casting" in this Volume. Counter-gravity casting is also an excellent method of filling thin sections, and it is not limited to use with investment molds.

Postcasting Operations

Postcasting operations represent a significant portion (often 40 to 55%) of the cost of producing investment castings. A standard shop routing is provided for each part, and important savings can be realized by specifying the most cost-efficient routing. For example, it is often cost effective to detect and eliminate scrap early to avoid wasting finishing time, even if this means including an extra inspection operation. Alternative methods may be available for performing the same operation, and the most efficient one should be selected. The actual sequence in which operations are performed can be important. Some specifications require verification of alloy type, and this is done before parts are removed from the cluster.

Knockout. Some of the shell material may spall off during cooling, but a good portion usually remains on the casting and is knocked off with a vibrating pneumatic hammer or by hand. Brittle alloys require special attention. Part of the prime coat sometimes remains adhered to the casting surface, and bulk shell material may remain lodged in pockets or between parts. This is removed in a separate operation, usually shotblasting. Clusters are hung on a spinner hanger inside a blasting cabinet or are placed on a blasting table. If cores are to be removed in a molten caustic bath, the entire cluster can be hung in the bath at this point, and the remaining refractory can be removed along with the cores. High-pressure water blasting (69 MPa, or 10 ksi) is sometimes used instead of mechanical knockout.

Cut-Off. Aluminum, magnesium, and some copper alloys are cut off with band saws. Other copper alloys, steel, ductile iron, and superalloys are cut off with abrasive wheels operating at approximately 3500 rpm. Torch cutting is sometimes used for gates that are inaccessible to the cutting wheel. Some brittle alloys can be readily tapped off with a mallet if the gates are properly notched. Shear dies have also been used to remove castings from standardized clusters. Following cutoff, gate stubs are ground flush and smooth using abrasive wheels or belts. These are also used for other finishing operations, along with small hand grinders equipped with mounted stones.

Core Removal. Where the opening size permits, cores can be removed by abrasive or water blasting. If abrasive or water blasting cannot be used, the cores can be dissolved out. This can be accomplished in a molten caustic bath (sodium hydroxide) at 480 to 540 °C (900 to 1000 °F), in a boiling solution of 20 to 30% sodium hydroxide or potassium hydroxide in an open pot, or in the same solutions in a high-pressure autoclave. Hydrofluoric acid can also be used with alloys that are inert to it, such as platinum and many cobalt superalloys.

Heat Treatment. Both air and vacuum heat treatments are extensively performed as needed to meet property requirements. The vacuum heat treatment of stainless steels (instead of in air) is sometimes practiced to achieve a clean, bright surface and to avoid the need for any further cleaning. Before they are heat treated, single-crystal castings must be handled very carefully to avoid recrystallization during subsequent heat treatment. They must not be dropped, allowed to hit one another, or subjected to a blasting operation until heat treated.

Abrasive Cleaning. Blast cleaning is also used to remove scale resulting from core removal or heat treatment. Both pneumatic and airless (centrifugal) blasting machines are employed. Metallic abrasives (steel or iron grit or shot) and ceramic abrasives (silica sand, aluminum oxide, garnet, and staurolite) are all commonly used, depending on the application.

The hardness and angular shape of alumina produce rapid cleaning, which is especially cost effective when work is being blasted by hand. Alumina blasting is very effective at opening up and exposing surface defects, thus facilitating subsequent finishing or inspection operations. However, it is rather expensive, and less costly materials such as garnet, staurolite, or silica sand are often used instead. Metal shot and glass beads provide good peening action and produce shiny surfaces, both of which are sometimes desired. Equipment used for blasting includes hand cabinets as well as automatic units with rotating tables, spinner hangers, or rotating tumblers to hold the work.

Another type of abrasive finishing process is mass finishing. In this process, castings are treated with chemical finishing compounds and synthetic abrasives of specific geometric shapes, such as cones, triangles, and stars, to produce deburring, fine finishing, and radii blending in vibratory, tumbling, or centrifugal machines.

Miscellaneous Operations. Hot isostatic pressing is becoming increasingly important for the densification of castings to eliminate porosity, to improve fatigue, ductility, and other properties, and to reduce property scatter (see the article

"Hot Isostatic Pressing of Castings" in this Volume). Its most important application in investment casting is for titanium. Applications for steel, superalloys, and aluminum are more selective but still very important.

Machining is often performed on investment castings, although the amount may be minimal, and there are many applications in which no machining is required. Machining is generally confined to selected areas requiring closer dimensions than can be achieved by casting, and it is occasionally used to incorporate some detail that is less expensive to machine in than to cast. The machining and welding of investment castings are discussed in Ref 74. Welding can be used to repair and join castings--primarily large, structural castings. Other methods used to improve dimensional accuracy are broaching and coining, as well as abrasive grinding. Straightening operations are performed when required, either manually or using hydraulic presses, with suitable fixtures. Castings can be heated to facilitate straightening.

Chemical finishing treatments are also used. The various treatments include acid pickling to remove scale, passivation treatments for stainless steel, chemical milling to remove the α case on titanium, and chemical treatment to apply an attractive satin finish to aluminum or to polish stainless steel.

Inspection and Testing

Alloy Type Test. The first inspection operation performed is often an alloy verification test. This test is conducted on the cluster before cutoff. A spectrometer or x-ray analyzer is used to verify that the correct alloy has in fact been poured.

Visual Inspection. An early visual inspection is essential so that obvious scrap does not get passed on to expensive finishing or inspection operations. Some commercial parts require only visual inspection.

Liquid fluorescent penetrant inspection is extensively used for nonmagnetic alloys. It can also be used for magnetic alloys, but a magnetic penetrant is generally specified instead. The liquid fluorescent penetrant detects defects on, or open to, the surface, such as porosity, shrinkage, cold shuts, some inclusions, dross, and cracks of any origin (hot tears, knockout, grinding, heat treat, straightening).

In this technique, the surface is properly cleaned, and a liquid penetrant with low surface tension and low viscosity is applied and is drawn into the defects by capillary action. Excess liquid is wiped away, a developer is applied that functions as a blotter to draw the liquid out, and the area is examined visually in a dark enclosure under black (near ultraviolet) light, which reveals defects that cannot be detected visually.

Applicable specifications include ASTM E 165 and MIL-1-6866. Turbine blades, which represent one of the most demanding applications for investment casting, are often subjected to a thermal cycle before the final fluorescent penetrant inspection; this is done to open very small defects that might otherwise go undetected.

Because the defects detected are often only surface defects, they can sometimes be removed by various finishing operations, and such rework operations are commonly attempted. They are generally successful if the defect is not so deep that dimensional or surface finish requirements are violated in removing it.

Magnetic particle inspection is used to detect the same types of defects as fluorescent penetrant inspection, but is preferred for use on ferromagnetic alloys. The method involves surface preparation, magnetization of the casting, and application of either a liquid suspension of magnetic particles (wet method) or fine magnetic iron particles (dry method). The presence of a defect causes a leakage field that attracts the magnetic particles and causes them to cling to the defect and define its outline. Colored particles and fluorescent particles (for viewing under black light) are available. Applicable specifications include ASTM E 125 (Reference Photographs), ASTM E 109 (Dry Particle), ASTM E 138 (Wet Particle), and MIL-STD-1949.

X-ray radiography is used to detect differences in material density or thickness to reveal such internal defects as dross, shrinkage, gas holes, inclusions, broken cores, and core shift. Many parts receive 100% inspection; others are inspected according to an appropriate sampling plan. Even when x-ray inspection is not required, it can be used as a foundry control

tool to aid in establishing a satisfactory gating system, to determine the effect of process changes, to monitor process reliability, and to troubleshoot foundry problems. X-ray inspection is sometimes used to examine wax patterns containing delicate ceramic cores to ensure that the cores were not broken during the pattern injection operation. Applicable specifications for castings are ASTM E 192, MIL-C-2175, and MIL-STD-453. Real time x-ray inspection is beginning to be used in the larger investment foundries serving the aircraft industry.

Formerly, defects within the casting detected by x-ray radiography could be repaired only by grinding and welding the affected area, but this procedure was not always cost effective and could not be applied to all alloys or applications. Currently, many castings, including those that cannot be welded, are being repaired by hot isostatic pressing.

Miscellaneous Inspection Methods. Hardness testing is widely used to verify the response of castings to heat treatment. Chemical analysis is generally controlled through the use of certified master heats. Mechanical properties are determined on separately cast test bars or test specimens mounted on production clusters. Specimens machined from castings are used for process development and periodic audits.

Grain size is regularly checked on many equiaxed castings, following chemical or electrolytic etching. Even where grain inspection is not specified, it is often used as part of the process development effort. Electrolytic etching is also used for examining and detecting grain defects in directionally solidified and single-crystal castings. The orientation of single-crystal castings is determined by Laue back-reflection x-ray diffraction.

Pressure tightness tests are conducted for a variety of applications. Dimensional inspection ranges from manual checks with a micrometer or simple go/no-go gages to the use of coordinate-measuring machines and automatic three-dimensional inspection stations capable of checking a sculptured surface in a continuous sweep. Wall thickness on many cored turbine blade castings is determined ultrasonically. Nodularity is checked metallographically on the first and last cluster poured from heats of ductile iron. Metallography is an essential part of process development for high-performance castings.

Design Advantages of Investment Castings

The challenge in designing for investment casting is to make full use of the enormous capability and flexibility inherent in the process to produce parts that are truly functional and cost effective. Often such parts will also be more aesthetically pleasing. The principal advantages of investment casting that permit this challenge to be met will be discussed in this section.

Complexity. Almost any degree of external complexity, as well as a wide range of internal complexity, can be achieved, and in certain cases, the only limitation is the state of the art in ceramic core manufacturing. As a result, parts previously manufactured by assembling many individual components are currently being made as integral castings at much lower costs and often with improved functionality. This ability to produce complexity with ease can even benefit simple parts, which can be redesigned to save weight without loss of strength by providing I- or H-sections, or thin walls with ribs. Thus, many parts from competitive processes can be converted to investment casting.

Freedom of Alloy Selection. Any castable alloy can be used, including ones that are impossible to forge or are too difficult to machine. Further, the cost of the alloy is less important in the final price of an investment casting than it is in many other metal-forming processes; therefore, an upgraded alloy can often be specified (especially if the part is redesigned to save weight) at little or no increase in price.

Close Dimensional Tolerances. The absence of parting lines and the elimination of substantial amounts of machining by producing parts very close to final size give investment casting an enormous advantage over sand casting and conventional forging.

The availability of prototype and temporary tooling is a major advantage in the design and evaluation of parts. The direct machining of wax patterns or the use of any of the quick, inexpensive tooling methods described earlier facilitates timely collaboration between the designer and the foundry to produce parts that are functional and manufacturable. This capability is simply not found in such competitive processes as die casting, powder metallurgy, or forging. Further, temporary tooling used in the design phase can often serve for production while the market is tested or permanent tooling is constructed.

Reliability. The long-standing use of investment castings in aircraft engines for the most demanding applications has fully demonstrated their ability to be manufactured to the highest standards.

Wide Range of Applications. In addition to complex parts and parts that meet the most severe requirements, investment casting also produces many very simple parts competitively. This capability is often made possible by the low tooling costs associated with investment casting. Investment castings are competitively produced in sizes ranging from a few grams to more than 300 kg (660 lb), and the upper limits continue to increase.

Design Recommendations

The following recommendations provide a useful guide to the design of investment castings:

- Look for ways to implement the advantages mentioned above
- Focus on final component cost rather than casting cost
- Design parts to eliminate unnecessary hot spots through changes in section sizes, use of uniform sections, location of intersections, and judicious use of fillets, radii, and ribs
- Promote good communication between foundry and customer to resolve questions of functionality versus producibility
- Use prototype castings to resolve questions of functionality, producibility, and cost
- Do not overspecify; permit broader-than-usual tolerances wherever possible
- Use the data in Ref 75 as a guide to the dimensional tolerances attainable
- Indicate datum planes and tooling points on drawings; follow ANSI Y14.5M for dimensioning and tolerancing

More detailed information is available in Ref 75 and 76.

Applications

Applications for investment castings exist in most manufacturing industries. A partial list is given in Table 3. The largest applications are in the aircraft and aerospace industries, especially turbine blades and vanes cast in cobalt- and nickel-base superalloys as well as structural components cast in superalloys, titanium, and 17-4-PH stainless steel. Examples of current applications for investment castings are shown in Fig. 4, 5, and 6. All were cast in ceramic shell molds using wax patterns unless otherwise noted.

Table 3 Some applications of investment casting

Aircraft engines, air frames, fuel systems
Aerospace, missiles, ground support systems
Agricultural equipment
Automotive
Baling and strapping equipment
Bicycles and motorcycles
Cameras
Computers and data processing
Communications
Construction equipment
Dentistry and dental tools
Electrical equipment

Electronics, radar
Guns and small armaments
Hand tools
Jewelry
Machine tools
Materials handling equipment
Metalworking equipment
Oil well drilling and auxiliary equipment
Optical equipment
Packaging equipment
Pneumatic and hydraulic systems
Prosthetic appliances
Pumps
Sports gear and recreational equipment
Stationary turbines
Textile equipment
Transportation, diesel engines
Valves
Wire processing equipment

Special Investment Casting Processes

The investment casting process is highly flexible and can handle a great variety of parts with the same basic method. However, specialized versions of the process can be highly effective in reducing costs on particular types of parts. Two variations that are being increasingly applied are the Shellvest system and the Replicast CS process.

The Shellvest system provides a unique method of manufacturing small parts in high quantities at low cost. To provide large numbers of patterns at high production rates and low cost, automatic plastic injection machines are used, along with a special plastic/wax pattern material. Wax patterns are used when production requirements do not justify plastic tooling.

Pattern assemblies are made by attaching the patterns to large-diameter horizontal cardboard drums instead of conventional wax sprues. As shown in Fig. 7, the drum has a through handle for handling and for mounting in the moldmaking equipment. Each end of the drum is closed with an end plate, one of which is removable. The drum is wrapped with a thin layer of cardboard having corrugations on its inner surface and a smooth outer surface. The corrugated cardboard is attached with masking tape. Over the cardboard is a layer of thin, perforated paper called a gate master. As shown in Fig. 7, the gate master has markings printed on it that indicate the cross section of each pattern gate and exactly where it is to be mounted on the drum. This greatly facilitates the operation of mounting patterns on the drum and ensures proper spacing and orientation.

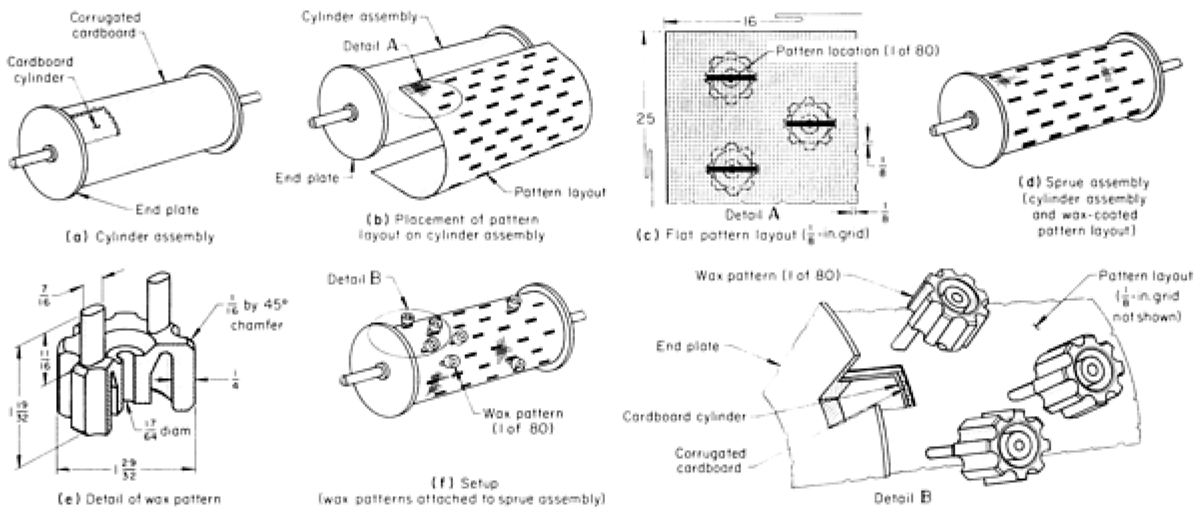

Fig. 7 Schematic showing the Shellvest system for investment casting of small parts. Dimensions given in inches.

The completed drum assembly is rotated through a bath of molten wax to apply a thin wax coating to which the patterns are attached. Individual patterns are attached by wax welding. Splitters can be used that divide the drum into several segments so that up to four molds can be formed simultaneously (Ref 77).

The completed pattern assembly is mounted horizontally in a vacuum slurry tank. The assembly is lowered into the tank so that its lower surface is immersed in the ceramic slurry. Here it rotates through the slurry while the chamber is under sufficiently high vacuum to boil the water in the slurry. The combination of rotation and vacuuming flushes air out of the system and enables the slurry to enter and coat the finest detail on the patterns, including core openings.

After the coating operation is complete, the assembly is raised out of the slurry and rotated in air to drain excess slurry back into the bath. It is then spun to provide a very uniform coating, after which it is immediately transferred to a fluidized bed for stuccoing. Here it is again mounted horizontally and rotated so that its bottom surface passes through the fluidized stucco particles. After stuccoing, the assembly is dried, and the sequence is then repeated four to six times to build up the required shell thickness.

When shelling is complete, one end plate is removed, and the cardboard tube is pulled out. Next the corrugated cardboard liner and the gate master paper are removed, and the setup readily separates into individual molds according to the number of splitters used. Each mold includes a cylinder with a large number of individual pattern cavities gated into its surface. The molds are dewaxed in a conventional steam autoclave. This operation is greatly facilitated by the fact that the gate of each pattern is immediately accessible to the steam. This provides very rapid melting and release of pressure, so that the plastic/wax material is readily removed without cracking the shell.

The ceramic shell mold is prepared for casting by firing it at the required preheat temperature, thus combining burnout and preheating. The mold is then placed over a ceramic-coated resin-bonded sand core in a vacuum-assist casting furnace (Ref 78). The diameter of the core is selected so that the annular space between the mold and the core will contain sufficient metal to feed all of the castings that are gated into this area. This is called a hollow-sprue gating system. It permits the use of large-diameter sprues carrying large numbers of parts, while still maintaining a very favorable ratio of gating metal to castings. Casting is carried out by the vacuum-assist method described previously.

After casting, the resin-bonded sand core disintegrates from the heat of the metal and falls out. The casting then proceeds through the conventional finishing and inspection operations.

The Replicast CS process uses conventional investment molding techniques to form a thin ceramic shell mold around a foamed polystyrene pattern of the type used in the lost foam casting process (see the discussion on the evaporative foam process in the article "Sand Molding" in this Volume). Information on the Replicast CS process is available in the article "Replicast Process" in this Volume.

Replicast Process*

R.E. Grote, Missouri Precision Castings; Thomas S. Piwonka, University of Alabama

---

Introduction

THE REPLICAST PROCESS was developed to overcome several shortcomings of the early evaporative pattern (lost foam) casting processes--primarily the formation of lustrous carbon defects in the castings and carbon pickup in steel castings. The process has two variations:

- Replicast FM (full mold), which is nearly identical to the lost foam process

- Replicast CS (ceramic shell), which is similar to investment casting in that it employs a ceramic shell to surround the pattern

The difference between the Replicast CS process and investment casting is that in the Replicast process the pattern is made from expanded polystyrene (EPS) and is surrounded by a much thinner shell than in investment casting. Figure 1 shows a flow chart of the Replicast CS process, and Table 1 compares the essential features of the Replicast CS and investment casting processes.

Table 1 Essential features of the Replicast CS and investment casting processes

Feature	Replicast CS	Investment casting
Pattern manufacture	Partially expanded EPS beads are blown into aluminum tooling and completely expanded. Finished patterns are lightweight, have high density, and provide good surface finish and excellent dimensional accuracy.	Softened wax is injected at high pressure into a metal tool. The wax is subject to shrinkage and deformation, and it is expensive and heavy. It is reclaimable to some degree.
Shell manufacture	Successive coats of refractory slurry and stucco are applied. Three or four coats are required, resulting in a relatively light and easy-to-handle shell. Firing at 925-1000 °C (1700-1830 °F) for 5 min removes the EPS pattern and hardens the shell.	Successive coats of refractory slurry and stucco are applied. Five to ten coats are required; completed shells are often heavy and difficult to handle. Firing at 1000 °C (1830 °F) for 20 min removes the residual wax and hardens the shell.
Pouring	Thin ceramic shell is surrounded by loose sand vibrated to maximum bulk density, and the vacuum is applied during pouring to prevent shell breakage.	Metal is frequently poured into hot, unsupported shells; breakage is possible.

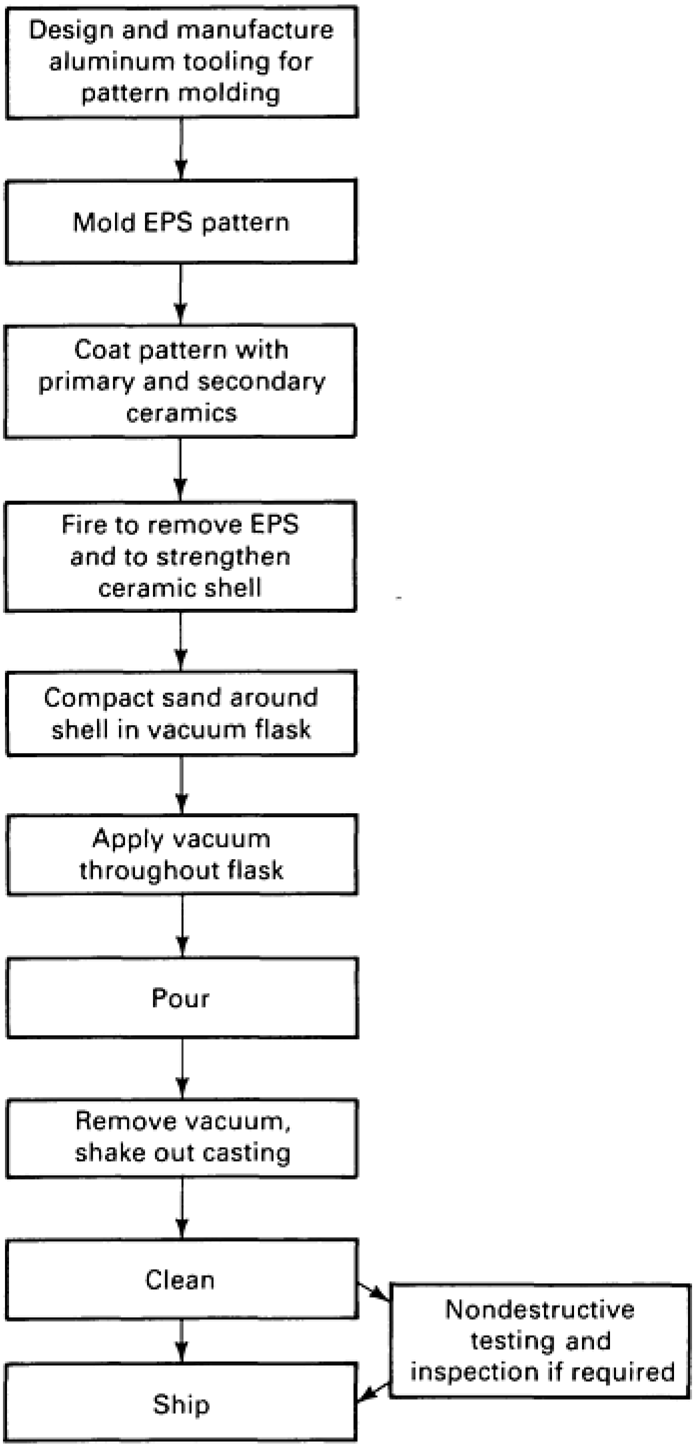

Fig. 1 Flow chart of the Replicast CS process. Source: Ref 1

The Replicast CS process is the one that is commonly referred to as Replicast. More information on lost foam casting is available in the article "Sand Molding" in this Volume (see the discussion of the evaporative foam process in the section "Unbonded Sand Molds").

Replicast Process*

R.E. Grote, Missouri Precision Castings; Thomas S. Piwonka, University of Alabama

Process Details

Pattern Production. Aluminum tooling must be developed in order to produce the EPS pattern. The tooling is made from cast aluminum and incorporates risers, cored passages, and so on, wherever possible. The necessity of incorporating styrofoam fill openings, vents, steam, air, and water lines makes the tooling complex and more expensive than metal green sand equipment. However, the use of insert-type tooling can significantly reduce tooling costs.

Patterns are produced from size "T" high-density polystyrene beads. The beads are preexpanded using steam or vacuum, passed into the aluminum tooling, and expanded again to fill the tool cavity and to bond with each other. The high-density EPS used in the Replicast process yields a better casting surface finish than the low-density material used for lost foam patterns.

The following steps are required for the production of EPS patterns:

- Close and hydraulically clamp molding box halves
- Blow in preexpanded styrofoam beads
- Close off styrofoam fill guns, then inject steam to expand and bond the beads
- Stop the steam and run water through cooling lines
- Open the mold box
- Eject pattern from cavity

The finished EPS pattern has a density of 10.75 to 12.90 g/cm^3 (2.5 to 3.0 lb/ft^3) and a smooth, hard surface. Minimal shrinkage of the EPS pattern occurs with age. Coating the EPS pattern with ceramic immediately after fabrication produces no detrimental effects.

Pattern Assembly. In some cases, the EPS pattern is complete as-molded and is sent to the ceramic coating area. More frequently, additional work is needed to produce a complete pattern assembly. Risers can be glued to the pattern, and ceramic pouring cones can be added. Gluing is done by spray, brush, or glue gun. A low ash content hot-melt glue is used for brush or gun application. A low-melting wax is used to fill and smooth the glue joints. Figure 2 shows completed pattern assemblies ready for the ceramic coating area.

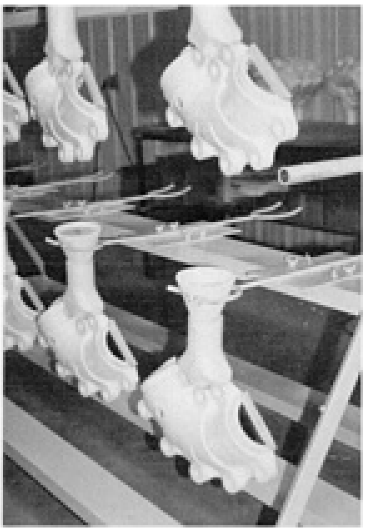

Fig. 2 Completed EPS pattern assemblies ready for ceramic coating. Courtesy of R.E. Grote, Missouri Precision Castings

Ceramic Coating and Firing. The next step in the Replicast process is the formation of a thin ceramic shell over the EPS pattern assembly. This is done by using techniques similar to those found in investment casting. The pattern assembly is first dipped into a ceramic slurry and then stuccoed using a granular refractory in a fluidized bed or rain sander. The shell is allowed to air dry for a minimum of 1 h. This process is repeated until the desired shell thickness is achieved. Thickness depends on product size, shape, and section thickness; shell thicknesses of 3.2 to 4.8 mm ($\frac{1}{8}$ to $\frac{3}{16}$ in.) are common.

Completed shells are then fired at 925 to 1000 °C (1700 to 1830 °F) to remove the EPS pattern material completely and to harden the ceramic. The shell is then embedded in an unbonded sand mold to support the thin ceramic shell and to prevent breakage. This allows the use of shells thinner than those employed for investment casting.

Pouring. The completed ceramic shells are transported to the foundry, where several shells are placed into a molding flask. The flask incorporates a plenum chamber through which air can be extracted to create a vacuum. The flasks are filled with unbonded loose sand, which is vibrated to achieve maximum bulk density. A vacuum is applied to the flask immediately before pouring. Pouring is then accomplished using conventional techniques. The vacuum can be switched off a few minutes after pouring.

Cleaning. After cooling, the castings are shaken out and moved to a cleaning area. The brittle ceramic shell fractures easily and tends to break off the casting surface. After initial abrasive blast cleaning, conventional cleaning techniques are implemented (see the article "Blast Cleaning of Castings" in this Volume).

Replicast Process*

R.E. Grote, Missouri Precision Castings; Thomas S. Piwonka, University of Alabama

Process Capabilities

Outstanding features of the Replicast process include:

- Surface finish comparable to that obtainable in conventional investment casting
- Elimination of cores through the use of core inserts in patternmaking tooling; patterns can often be produced in one piece, including risers
- Improved casting yields because of the elimination of downsprues, runners, and so on
- High as-cast quality levels with regard to casting integrity and dimensional accuracy

Replicast Process*

R.E. Grote, Missouri Precision Castings; Thomas S. Piwonka, University of Alabama

Dimensional Accuracy

The dimensional accuracy of Replicast parts is comparable to that of investment castings. Based on measurements of Replicast parts of various sizes, the following tolerances on linear dimensions are recommended:

Dimension, mm (in.)[a]	Tolerance, mm (in.)
2.5-102 (0.1-4)	±0.25 (±0.010) or 0.75% of dimension, whichever is greater
104-305 (4.1-12)	±0.76 (±0.030)
307-610 (12.1-24)	±1.52 (±0.060)

(a) Nonrisered surfaces

With no wear occurring on tooling, long-term dimensional reproducibility is readily obtainable.

The smooth surface finish of Replicast parts, combined with near zero draft molding capabilities, can result in the elimination of considerable machining. Cast bolt holes, virtually flat flange faces, and blind and through holes as small as 9.6 mm ($\frac{3}{8}$ in.) in diameter can be attained. For those surfaces requiring finish machining, an allowance of 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) is usually sufficient.

Replicast Process*

R.E. Grote, Missouri Precision Castings; Thomas S. Piwonka, University of Alabama

Applications

Because the EPS pattern material is completely removed from the ceramic shell during firing, the Replicast process is suitable for pouring any metal or alloy without fear of carbon pickup. The process is commonly used to produce carbon, low-alloy, and stainless steel castings. Figure 3 illustrates two typical applications.

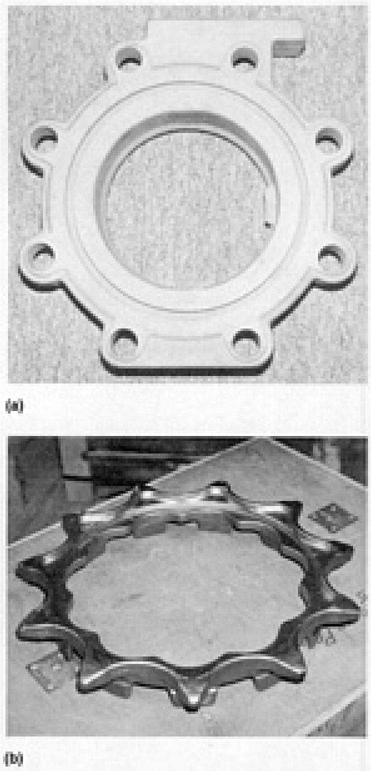

Fig. 3 Two applications of Replicast steel parts. (a) CF-8M stainless steel 150 mm (6 in.) butterfly valve body. The part is approximately 305 mm (12 in.) in outside diameter, 64 mm ($2\frac{1}{2}$ in.) thick, and weighs 11 kg (25 lb). Note as-cast bolt holes and O-ring groove. (b) 8640 steel drive sprocket for armored personnel carrier. The part is 510 mm (20 in.) in outside diameter, 114 mm ($4\frac{1}{2}$ in.) thick, and weighs 28 kg (62 lb). Sprocket teeth are used as-cast, resulting in a significant savings in machining costs. Courtesy of R.E. Grote, Missouri Precision Castings

Rammed Graphite Molds

Dan Kihlstadius, Oregon Metallurgical Corporation

Introduction

RAMMED GRAPHITE is used to produce molds for the casting of reactive metals and alloys such as titanium and zirconium (see the articles "Titanium and Titanium Alloys" and "Zirconium and Zirconium Alloys" in this Volume). Because such metals and alloys react vigorously with silica, conventional molding sands cannot be used.

Rammed Graphite Molds

Dan Kihlstadius, Oregon Metallurgical Corporation

Production of Rammed Graphite Molds

Mold Mixture. Rammed graphite molds are manufactured from a mixture consisting primarily of finely divided graphite having a closely controlled particle size and size distribution. To this mixture, nominally 10% water, 10% pitch, 7% baumé syrup, and 3% starch are added. These ingredients are required for good coating of the graphite grains and for the development of optimal mold properties. The mold mixture has the appearance of green sand (Fig. 1). The mold mixture is pneumatically tamped (rammed) around a pattern, stripped from the pattern, air dried, baked, and fired.

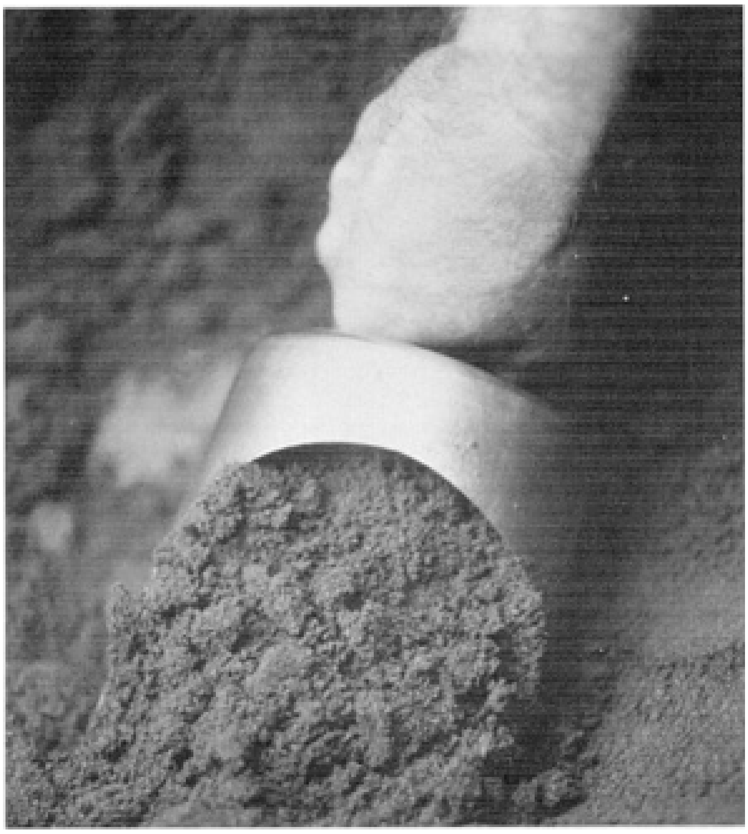

Fig. 1 Graphite mold mixture, which resembles green sand in appearance

Air drying influences both the green and baked strengths of the mold (Fig. 2). Molds are air dried on racks; after 24 h of air drying, the mold reaches about 13% of its maximum green strength. Maximum green strength is achieved after 94 h of air drying.

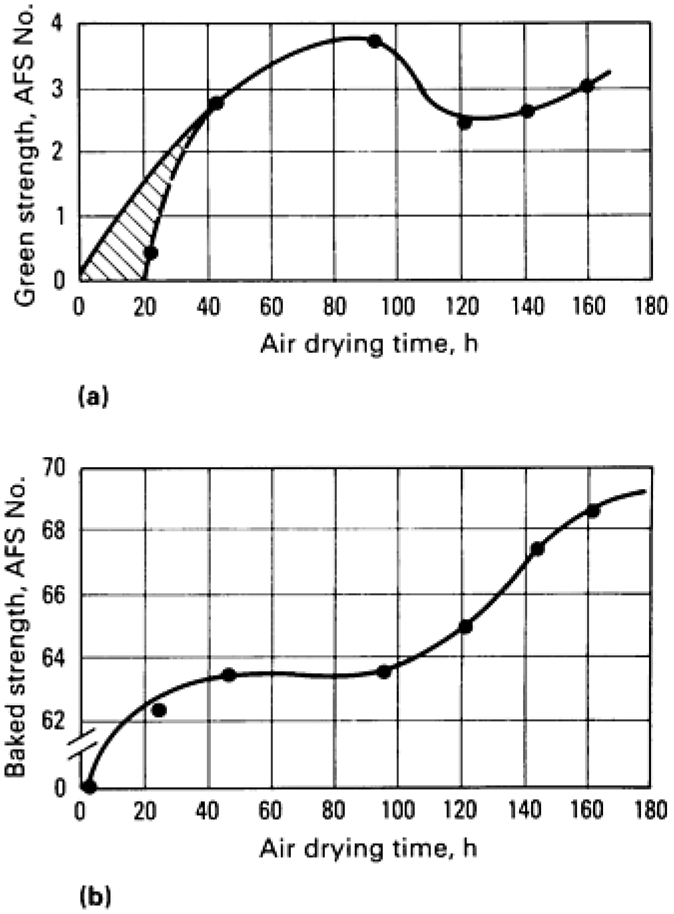

Fig. 2 Effect of air drying time on green strength (a) and baked strength (b) of graphite molds

Baking. After air drying, molds are baked at 175 °C (350 °F). Baking time depends on mold section thickness and geometry. All moisture must be removed during baking to prevent steam generation and potential mold cracking during firing.

Firing removes all of the remaining volatile carbonaceous materials from the mold and develops final bonds. The strength and hardness of the mold increase with firing temperature (Fig. 3); best results are obtained at minimum firing temperatures of 870 °C (1600 °F). Firing is performed in a reducing atmosphere to prevent oxidation of the graphite. The fired mold is rigid and is similar to ceramic in texture and hardness (see the article "Ceramic Molding" in this Volume).

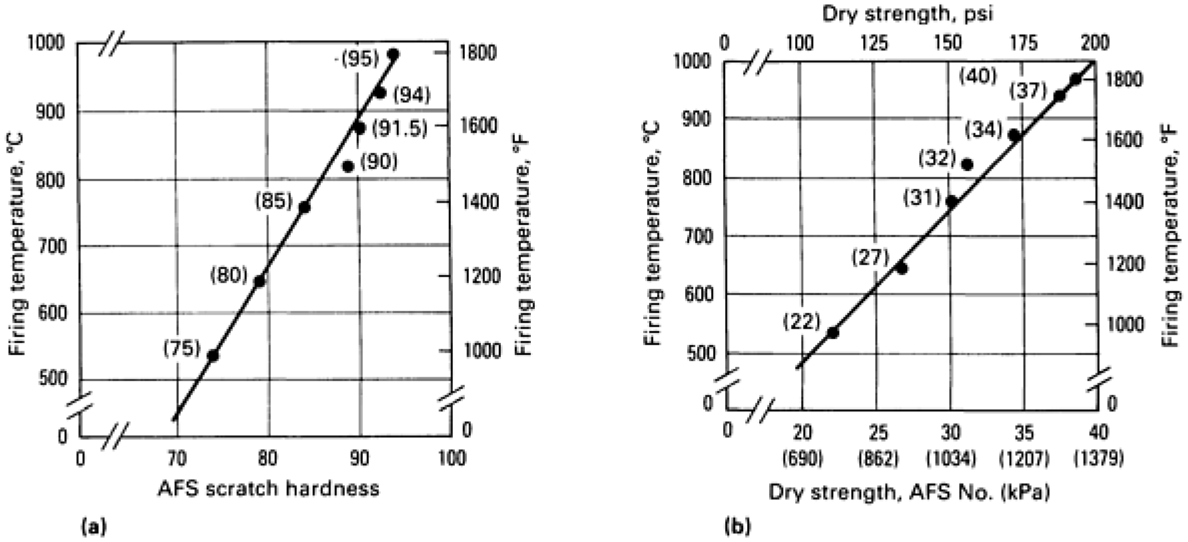

Fig. 3 Effect of firing temperature on the hardness (a) and strength (b) of graphite molds

Storage. After firing, molds should be stored in a controlled environment (minimum temperature of 25 °C, or 75 °F, and relative humidity below 40%) to prevent moisture absorption. Moisture absorption is particularly rapid at high relative humidities and low temperatures.

Rammed Graphite Molds

Dan Kihlstadius, Oregon Metallurgical Corporation

Molding Problems

Although a correct binder system can be developed for any graphite particle size distribution, mold permeability will vary with the type and amount of binder used. Mold shrinkage can be predicted and controlled if ramming pressure and binder composition are constant.

Graphite mixing problems may also be related to the pitch and syrup ingredients. Good mixing should result in uniform coating of the graphite grains with pitch and the water-syrup mixture. Pitch or syrup in excess of that required for coating of the graphite particles may cause balling of the mold mixture. Pitch balls are aggregates of excess graphite and graphite fines containing a greater-than-average amount of syrup. Mold mixtures become more susceptible to balling as the percentage of reclaimed graphite fines in the mixture increases. Therefore, control of graphite particle size distribution is crucial.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Introduction

IN PERMANENT MOLD CASTING, sometimes referred to as gravity die casting, a metal mold consisting of two or more parts is repeatedly used for the production of many castings of the same form. The liquid metal enters the mold by gravity. Simple removable cores are usually made of metal, but more complex cores are made of sand or plaster. When sand or plaster cores are used, the process is called semipermanent mold casting.

Permanent mold casting is particularly suitable for the high-volume production of castings with fairly uniform wall thickness and limited undercuts or intricate internal coring. The process can also be used to produce complex castings, but production quantities should be high enough to justify the cost of the molds. Compared to sand casting, permanent mold casting permits the production of more uniform castings, with closer dimensional tolerances, superior surface finish, and improved mechanical properties. Figure 1 shows castings made by the permanent mold process.

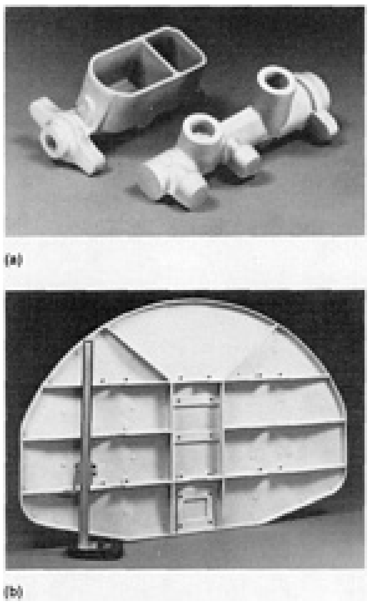

Fig. 1 Two examples of aluminum alloy castings made in permanent molds. (a) Alloy 356 brake master cylinder. (b) Alloy 356 basketball backboard. Courtesy of Stahl Specialty Company

Permanent mold casting has the following limitations:

- Not all alloys are suitable for permanent mold casting
- Because of relatively high tooling costs, the process can be prohibitively expensive for low production quantities
- Some shapes cannot be made using permanent mold casting, because of parting line location, undercuts, or difficulties in removing the casting from the mold
- Coatings are required to protect the mold from attack by the molten metal

Metals that can be cast in permanent molds include the aluminum, magnesium, zinc, and copper alloys and hypereutectic gray iron. Practical sizes of permanent mold castings differ according to materials cast, part configuration, and number of parts needed.

Aluminum Alloys. In high production, permanent mold castings weighing up to 70 kg (150 lb) have been made from aluminum alloys in casting devices. However, much larger castings can be produced. For example, aluminum alloy engine blocks with a trimmed weight of 354 kg (780 lb) have been produced in a four-section permanent mold having a vertical parting line.

Magnesium alloys, despite their comparatively low castability, have been cast in permanent or semipermanent molds to produce relatively large and complex castings. For example, an 8 kg (17.7 lb) housing for an emergency power unit was poured from Alloy AZ91C in a semipermanent mold. In another application, 24 kg (53 lb) spoolhead castings 760 mm (30 in.) in diameter were produced from Alloy AZ92A in a two-segment permanent mold with vertical parting.

Copper alloy permanent mold castings weighing more than 9 kg (20 lb) can rarely be justified.

Gray Iron. The production of gray iron castings in permanent molds is seldom practical when the castings weigh more than 13.6 kg (30 lb).

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Casting Methods

Manually operated permanent molds may consist of a simple book-type mold arrangement (Fig. 2a). For castings with high ribs or walls that require mold retraction without rotation, the manually operated device shown in Fig. 2(b) can be used. With either type of device, the mold halves are separated manually after releasing the eccentric mold clamps.

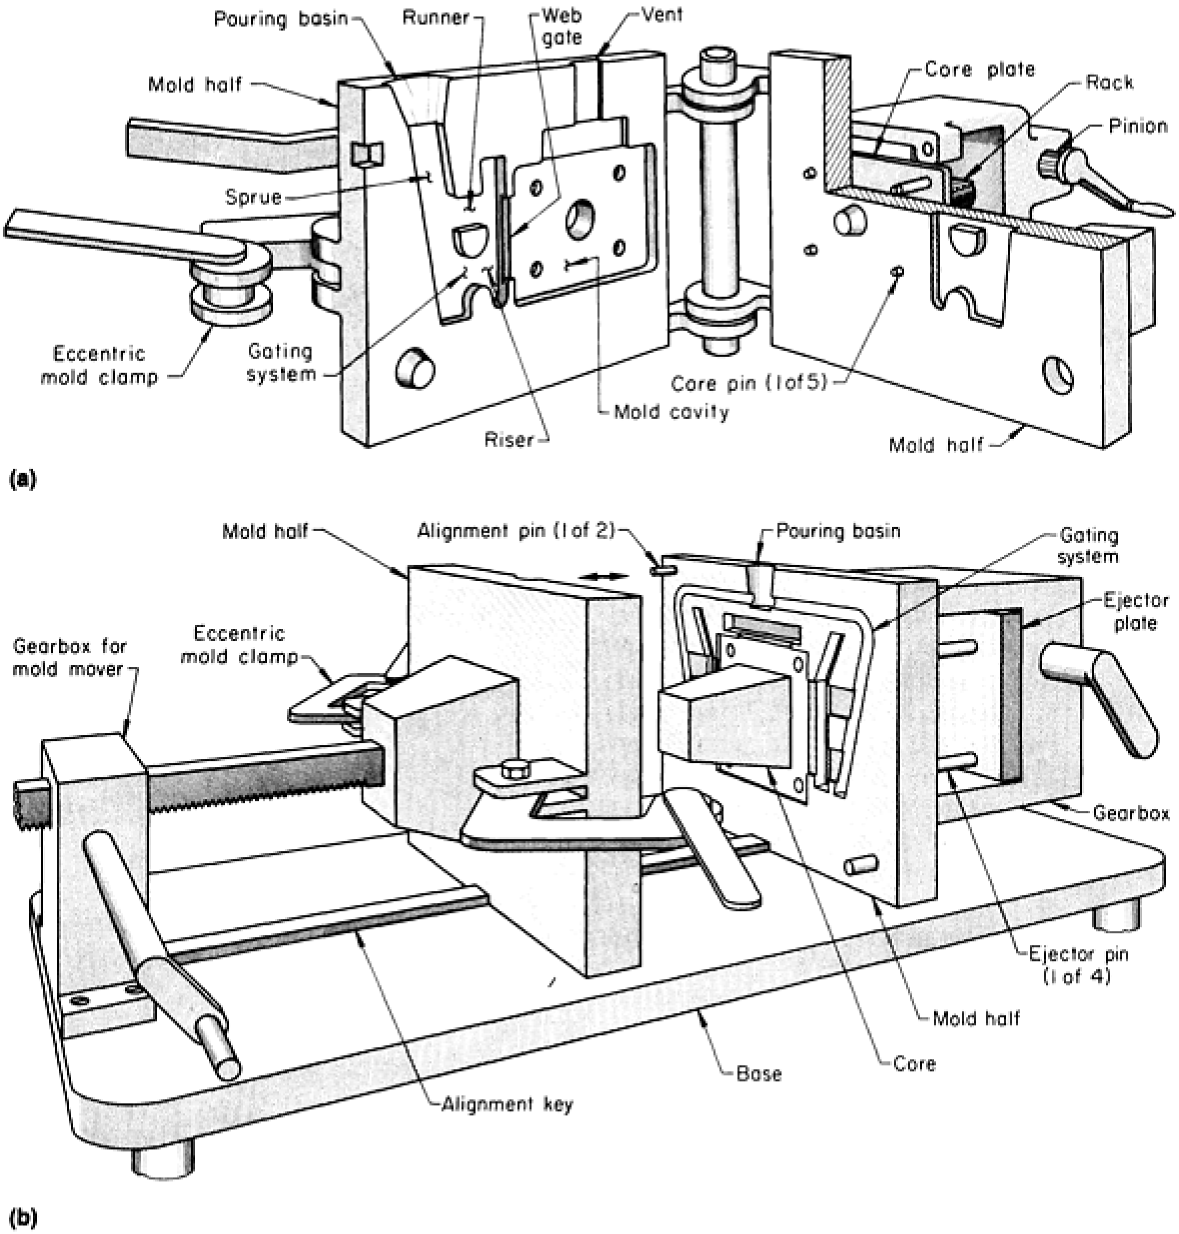

Fig. 2 Two types of manually operated permanent mold casting machines. (a) Simple book-type mold for shallow-cavity castings. (b) Device with straight-line retraction for deep-cavity molds

Semiautomatic Devices. For high-volume production, manual drives are replaced by two-way air or hydraulic mechanisms. These units can be programmed to open and close in a preset cycle. Therefore, the operation is automatic except for pouring of the metal and removal of the castings.

Figure 3 shows an automatic casting device equipped with automatic mold, core, and insert-setting components; the only manual operations are pouring of the metal and placing the inserts in the setter. For simple castings, this type of device can be fully automatic.

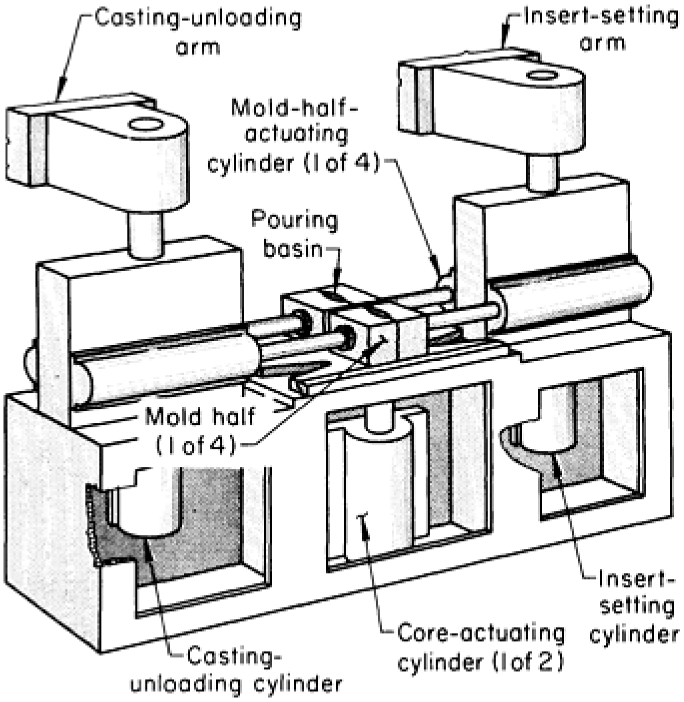

Fig. 3 Automatic permanent mold casting machine with a setter for cast-in inserts

Devices for Horizontal Parting and Tilt Casting. The mold parting for the casting devices shown in Fig. 2 and 3 is in a vertical plane, which is often the preferred position for mold opening and casting removal. Many castings, however, are best poured with the parting in a horizontal plane. Some castings with horizontal parting are poured using devices with a tilting mechanism; thus pouring is done with the parting in the horizontal plane, and the mold position is then changed to permit removal of the casting with parting in the vertical plane.

Some castings are partially poured with the parting in the horizontal plane and then slowly rotated while the pouring is completed. For example, in casting a frame for a duplicating machine, pouring with the parting in a vertical plane required a long drop of molten metal, which resulted in splashing and severe turbulence and produced unacceptable castings. To eliminate the long drop of molten metal, the mold was placed in a tilt device that allowed the metal to be introduced into the mold with the parting oriented horizontally. The main body of the casting was poured with the mold in this position. The lower offset segment of the casting was then gently filled as the mold was rotated 90° to place the parting in a vertical plane. At this position, the casting was allowed to solidify and was then removed from the mold.

Turntables. Small, lightweight castings can be poured and removed manually, but manual handling becomes increasingly difficult as pouring temperatures rise and casting weight increases. The casting process must then be automated. This is often done by using casting machines mounted on a turntable.

A commonly used turntable accommodates 12 casting devices, as shown in Fig. 4, and completes one revolution in 2 to 7 min. Steps in the casting process, which include pouring, mold coating, core setting, solidification, and ejection, are completed progressively as the casting devices pass through the various work stations. With this type of equipment, maximum production rates are achieved when all 12 devices have identical molds. However, different molds can be used in all 12 devices.

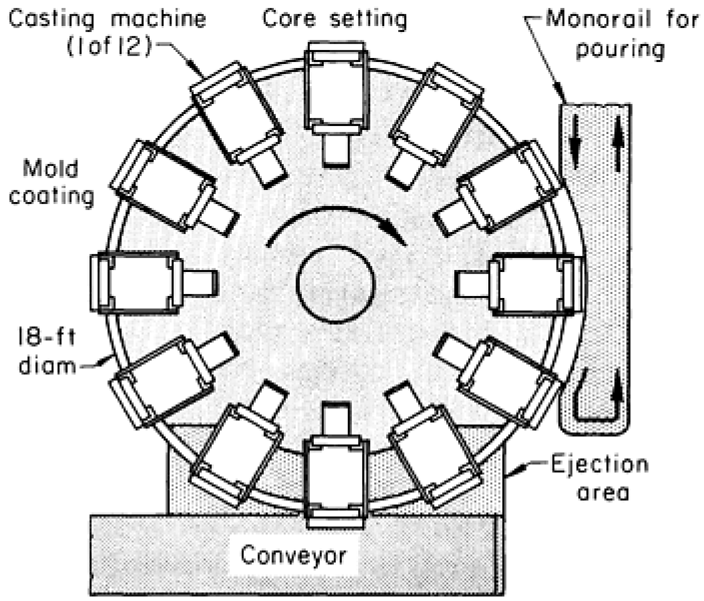

Fig. 4 Schematic of a 12-machine turntable for automatic permanent mold casting

In low-pressure die casting, the mold is placed in a casting device above a sealed airtight chamber that contains a crucible holding molten metal (Fig. 5a). A fill tube extends from the mold down into the molten metal bath. The casting is made by pressurizing the chamber and forcing the metal up into the mold. The metal in the fill tube acts as the riser; this gives low-pressure die casting very favorable casting yields. The low-pressure method lends itself to automation, and it usually runs at lower mold temperatures and with shorter cycle times than conventional gravity-poured permanent mold methods. The rapid solidification rates associated with low-pressure casting result in castings with finer grain size, smaller dendrite arm spacings, and enhanced mechanical properties.

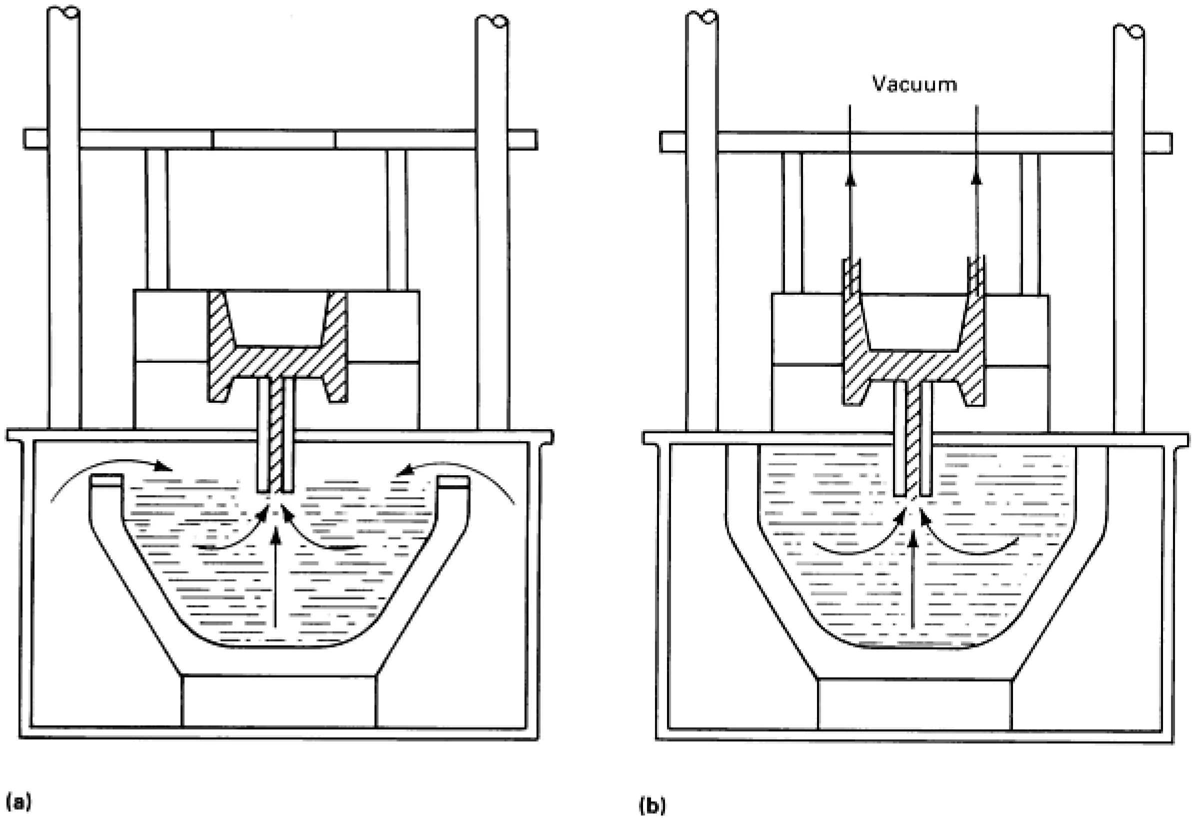

Fig. 5 Schematics of low-pressure (a) and vacuum casting (b) units used with permanent molds

Vacuum casting is similar to low-pressure casting, except a vacuum is created within the mold cavity and the metal is pulled rather than pushed into the mold (Fig. 5b). Excellent mechanical properties and high production rates are often realized in vacuum casting because of the low mold temperatures associated with the method. As with low-pressure die casting, the metal in the fill tube acts as a riser, and excellent metal yields are obtainable. The process lends itself to

automation, and the result is the ability to produce large quantities of high-quality castings at a competitive price. The process is usually associated with smaller castings and requires specialized, complex mold designs to induce the vacuum properly.

In constant-level pouring, the mold is placed in a device, and as the metal is poured into the mold, the mold is lowered at a rate consistent with the rate of fill, effectively pouring the metal at one constant level. If the metal source, rather than the mold, is in the device, the metal source is raised and the mold remains stationary. This method virtually ensures lamellar flow and greatly reduces oxide formation.

In centrifugal casting, cylindrical or symmetrically shaped castings are poured using the centrifugal force of a spinning mold to force the metal into the mold. The sprue is located at the center of rotation. The force generated by the spinning of the mold helps the metal fill thin casting sections and maintains good contact between the metal and the mold. This provides a higher rate of heat flow and a more rapid solidification rate, resulting in increased mechanical properties. Multiple molds can be used in centrifugal casting, and care should be taken to design gating systems that produce little or no turbulence. Segregation can be a problem with alloys containing immiscible or heavy elements, such as tin in the 850 aluminum alloys. These alloys require special casting practices. More information on centrifugal casting is available in the article "Centrifugal Casting" in this Volume.

Squeeze casting is another variation of the permanent mold process. It consists of pouring a specific amount of metal into the lower half of a mold, closing the mold, and then allowing the metal to solidify under pressure. One of the advantages of squeeze casting is the casting yield, because no gating system is required. More information on this process is available in the article "Squeeze Casting" in this Volume.

Continuous casting is usually considered an ingot-making process (see the article "Continuous Casting" in this Volume). However, it can also be used to make small, solid cylindrical castings. It is primarily used with the 850 series aluminum-tin alloys. Continuous casting can be done either horizontally or vertically, but vertical casting is the most common.

The process consists of a highly chilled mold with a movable base. The metal is poured into the mold as the base is lowered. As the solidified portion of the casting is lowered out of the mold, the water cooling the mold flows onto the casting, increasing the solidification rate of the casting. The molten metal flowing into the top of the mold acts as the casting riser. The lack of a gating and risering system provides for a good casting yield, and the rapid solidification rate gives continuous cast material good mechanical properties.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

---

Mold Design

A simple permanent mold is shown in the book-type casting device illustrated in Fig. 2. Here the two mold halves are hinged on a pin and aligned. The mold cavity with the mold halves closed determines the shape of the casting. The casting is poured by means of the sprue and runners to the riser, which is provided with a web gate to the mold cavity. The cavity is vented to allow air to escape. The plate-shape cavity shown in Fig. 2 required five core pins, which were moved by means of the manually driven gearbox mounted on the back of the right-hand mold half.

In operation, the mold halves are closed and locked. Metal is then poured to fill the gating system and the mold cavity. After the metal has solidified, the mold is opened, leaving the casting on the core pins. The core pins are withdrawn, and the casting is removed manually.

The mold shown in Fig. 2 is designed with the parting vertical and in a single plane. This mold could also be designed for horizontal parting or with parting in two or more planes, and instead of side gating, it could have bottom gating (Fig. 6a).

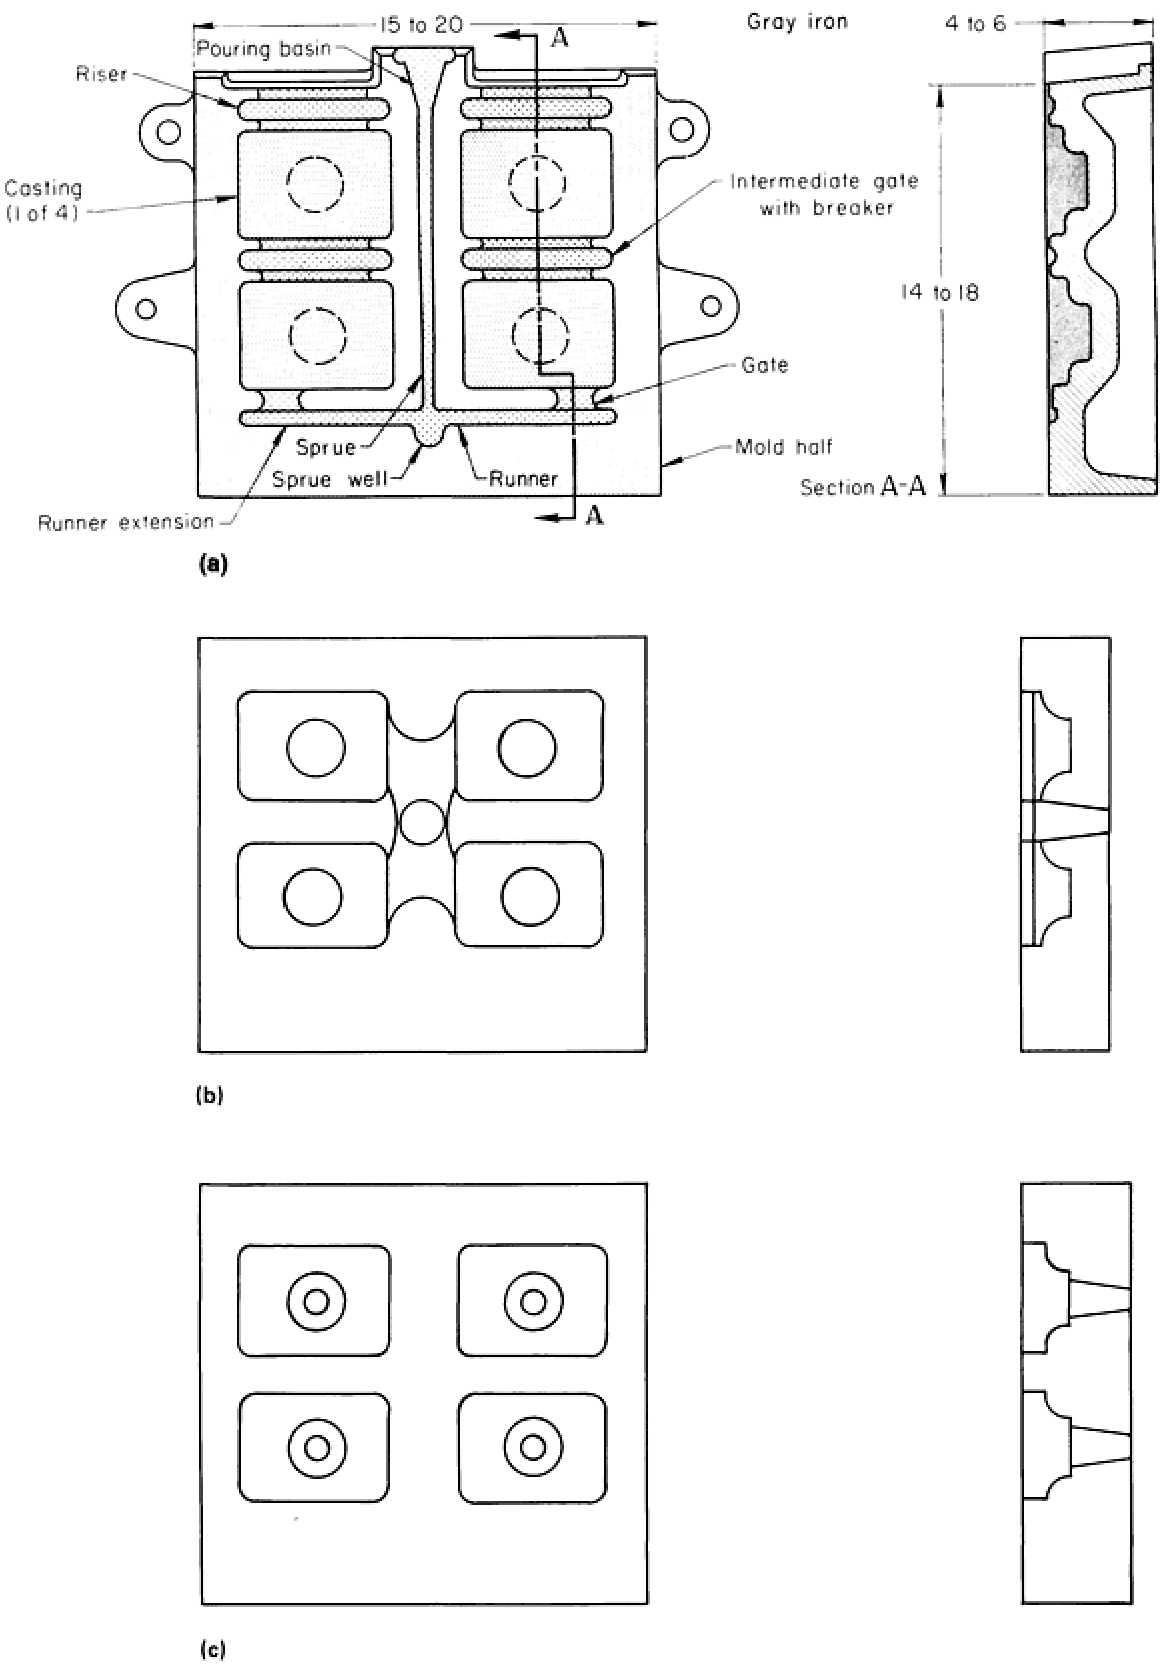

Fig. 6 Bottom-gated permanent mold (a) with stacked cavities for four castings. (b) Multicavity mold with low-pressure gating system. (c) Alternate gating system for low-pressure or vacuum casting

The mold shown in Fig. 2(b) is also designed for vertical parting and side gating. However, because of the deep cavity and correspondingly long core required, a hinged-type mold cannot be used. The mold shown is opened and closed by straight-line movement of one mold half to and away from the other mold half, which remains fixed.

Undercuts on the outside of a casting complicate mold design and increase casting cost because additional mold parts or expendable cores are needed. Complicated and undercut internal sections are usually made more easily with expendable cores than with metal cores, although collapsible steel cores or loose metal pieces can sometimes be used instead of expendable cores.

Isolated heavy sections completely surrounded by thin areas should be avoided. Thin deep ribs should also be avoided because they are likely to cause cold shuts and misruns. Adequate draft must be allowed in order to prevent ribs from sticking and breaking off in the mold.

Casting Ejection. Only the most simple permanent mold castings can be ejected from the mold with no mechanical help. Most castings are ejected by well-distributed ejector pins, or are confined in one mold half during opening of the mold and then ejected by the withdrawal of the retaining core or cores. It is important that the casting remain in the correct mold half until ready for ejection.

The number of castings per mold is a major consideration in designing the mold; the objective is to have the optimum number of cavities per mold that will yield acceptable castings at the lowest cost. Except for very small and thin castings, the machine cycle time increases as the weight of the metal being cast per mold increases. However, these increases are not directly proportional. A mold with the maximum number of cavities will often produce more castings per unit of time than a mold with a smaller number of cavities that was designed to operate on a shorter cycle. This is because there is a minimum solidification time for every casting, regardless of the number of cavities in the mold. The number of rejects sometimes increases as the number of cavities is increased, but this is usually offset by the greater productivity. For relatively simple castings, the cavities can be placed one above the other. This permits maximum use of the face area of the mold. However, for more complex castings, especially those for which there are significant projections in the cavities, it is usually necessary to gate each cavity individually.

For low-pressure casting, the mold parting plane will be horizontal, and the gating system shown in Fig. 6(a) will be replaced by the system shown in Fig. 6(b). In Fig. 6(b), the metal enters the mold through a centrally located fill tube and is distributed to the casting cavities by the gating system shown. The gating system also acts as a riser. An alternate system (Fig. 6c) is often used in low-pressure and vacuum casting. Here the metal enters the cavity directly, reducing the need for an additional gating system, decreasing feeding distances, and increasing casting yield.

Progressive Solidification. Alloys should be cast so that solidification takes place progressively toward the risers, which are generally to one side or on top of the casting. To achieve this solidification pattern, thinner sections of the casting should be away from the gating system, and heavy sections should be adjacent to it. Rib sections and thin walls vent and fill more easily when they are vertical, but filling a vertical mold cavity may promote turbulence in the molten metal, resulting in excessive dross; consequently, the mold should be tilted when being poured. To avoid oxide contamination, dross traps or filters are placed in the gating system as shown in Fig. 7. Steel or fiberglass can be used to filter the metal and reduce metal velocity. Tilt molding can be used for large, vertically gated castings.

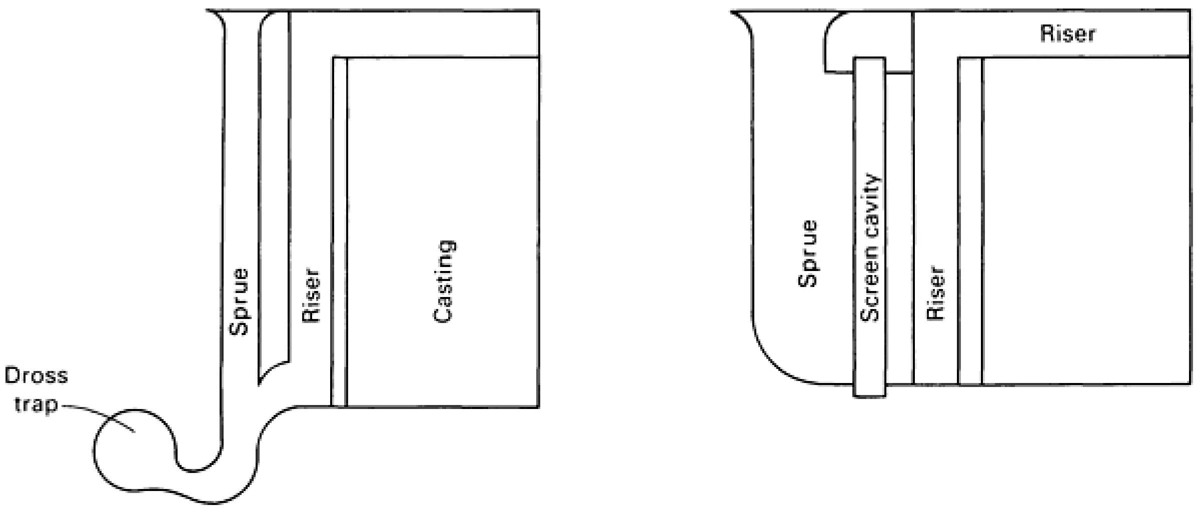

Fig. 7 Gating systems with dross traps or screens

In designing a permanent mold, the part is laid out in the desired orientation, and the mold is designed around it, allowing sufficient space for gating, for the seal needed to prevent metal leakage, and for coring and mold inserts. It is common practice to contour the back of the mold so that its exterior conforms roughly with the cavity. This permits a more even temperature distribution and heat dissipation. For castings with heavy sections, the adjacent mold sections are generally heavier. For aluminum castings, a ratio of three or four mold wall thicknesses to one casting wall thickness is often used, but a mold wall this thin cannot always be used in making thin-wall castings without jeopardizing mold stability. Ribbing is often used to stiffen the mold structure, but excessive ribbing can cause distortion by increasing the temperature differential between inner and outer mold surfaces.

Temperature stability must also be considered in the design of molds for thin-wall castings. Thin-wall castings are sensitive to temperature changes and will misrun readily. Consistent, relatively high mold temperatures are required; this necessitates the use of thicker, more massive molds.

Vents. The gap that exists between the mold halves after closing is sometimes large enough to permit air to escape and thus prevent misruns and cold shuts. Frequently, however, vents must be added to allow the air to escape as the mold is filled. Mold coatings can also be used for this purpose. Some form of venting also must be provided in die casting (see the article "Die Casting" in this Volume).

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Gating Systems

Permanent mold castings can be gated from the top, side, or bottom. Single or multiple gates can be used.

Top Gating. In this arrangement, the sprue and the riser are usually the same. Thin sections are placed farthest from the gate so that directional solidification is toward the gate. After pouring, the gate functions as a riser. The metal in the riser solidifies last, thus ensuring sound metal throughout the casting.

Side gating is frequently used, particularly for aluminum castings. In this gating system, the riser is at the top of the casting. The gate extends up the side of the casting to nearly 90% of its height, which ensures that the metal at the top of the casting and in the riser is hotter than the first metal to enter the mold. Thin sections should be placed remote from the gate and riser. The direction of solidification is from the mold cavity toward the gate and riser so that shrinkage porosity is minimized.

Gating systems for permanent molds are less flexible than those for sand molds and are nearly always located in parting planes. Gating must supply metal fast enough to fill all sections of the casting with minimal turbulence. Gating systems that permit minimal turbulence are especially important in the casting of aluminum and magnesium alloys because turbulence creates excessive amounts of oxide, which may cause defective castings. Molds for aluminum and magnesium alloys are poured in the vertical position or tilted from vertical. With this method, air is readily displaced and vented off at the mold parting.

Bottom Gating. If bottom-gating systems are not properly designed, the last metal into the casting (the hottest metal) will be at the bottom of the casting. This will interfere with gravity feeding and progressive solidification and will produce castings with shrinkage porosity. The same is true, even with proper gating, if the casting is too thick. Bottom gating in conventional permanent molds is usually used on castings with thinner sections.

With low-pressure or vacuum casting, bottom gating is the most widely used system. The difference is that in these methods the metal is moved into the mold by a pressure differential. This pressure differential allows the metal to feed into the casting during solidification.

In addition to supplying liquid metal to compensate for casting shrinkage, risers reduce the velocity of the metal before it enters the cavity and help sustain the mold temperature. The number of points at which metal is admitted to the mold cavity depends on the section thickness and the distance the metal must flow. Excessive flow through too few inlets may result in hot spots and consequent shrinkage. Sprues are usually restricted in area to choke off and prevent dross and air from entering the cavity. Because gating systems are often easier to enlarge than to reduce and because oversize gating can slow the cycle, it is common practice to start with small gates and then to enlarge them if necessary.

Misruns have several possible causes, including entrapped air, low mold temperature, or low pouring temperature. Misruns are often caused by a combination of two or more such conditions. Adequate venting is the simplest way to eliminate entrapped air. Increasing the mold temperature or the pouring temperature, or both, may eliminate misruns, but is likely to cause other defects, such as porosity. One common approach is to increase the mold temperature at critical locations by applying heat from an external source (antichill) or by using an insulating type of mold coating in the specific location of the mold to prevent the liquid metal from chilling in a specific area.

Shrinkage porosity associated with gating can be extremely difficult to eliminate because casting design sometimes precludes ideal metal feeding. This may necessitate complete redesign of the gating system and a change in the casting operation.

Dross. Gating systems often must be revised to eliminate excessive formation of dross. Fiberglass, metals, and ceramics are used in gating systems to remove dross, slow metal velocity, and help prevent further oxide generation.

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

---

Cores

The cores used in the permanent mold process can be of gray iron, steel, sand, or plaster. Metal cores can be movable or stationary. Stationary cores must be perpendicular to the parting line to permit removal of the casting from the mold, and they must be shaped such that the casting is readily freed. Metal cores not perpendicular to the parting line must be movable so that they can be withdrawn from the casting before it is removed from the mold.

When sand or plaster cores are used in a permanent mold, the process is referred to as semipermanent molding. With sand or plaster cores, which are expendable, more complex shapes can be produced than with metal cores.

The two cored passageways shown in Fig. 8 illustrate the limitations of cores in permanent mold castings. The cored passageway shown in Fig. 8(a) could be produced with metal cores. Sand or plaster cores would be needed to provide the radius of the passageway shown in Fig. 8(b), which would also be more expensive to produce.

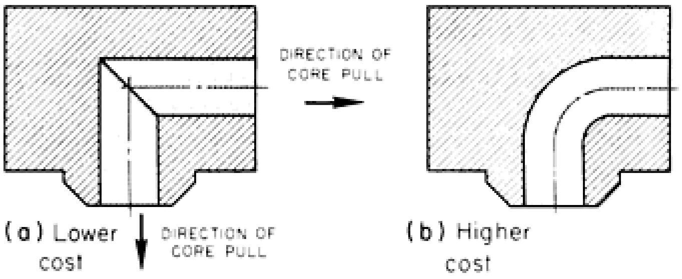

Fig. 8 Two types of cavities requiring different coring methods. (a) Corner radii must be sacrificed if metal cores are to be used. (b) Corner radii can be obtained with sand or plaster cores, but casting cost will be higher than in (a).

Cored holes in permanent mold castings can usually be held to closer tolerances, on both size and location, than in sand castings. Movable cores and stationary cores can both be machined to close dimensions and can be accurately located. Draft requirements for holes formed by steel cores are:

Hole dimensions, mm (in.)		Draft allowance per side, degrees
Depth	Diameter	
6.4 ($\frac{1}{4}$)	6.4 ($\frac{1}{4}$)	10
12.7 ($\frac{1}{2}$)	25.4 (1)	5
25.4 (1)	51 (2)	3
51 (2)	102 (4)	3

These drafts apply to all nonferrous metals cast in permanent molds.

Steel cores require the same coating as that applied to the mold; the dimensional accuracy of cavities made from coated steel cores is affected by the same factors that affect the accuracy of dimensions formed by coated metal molds. Unless a core is stationary, the clearance that must be provided to permit its withdrawal from the mold permits core movement, which may affect dimensions.

In terms of dimensional accuracy, sand cores have approximately the same limitations in permanent molds as in sand molds. However, when a sand core is located in a sand mold, some mold material may be disturbed or displaced. Because a permanent mold is more rigid, it provides a more accurate seat for locating a core.

Sand cores permit the casting of tortuous passages or of chambers or passages that are larger in section than the opening through the wall of the casting. Because sand cores are expendable, their removal presents no major problem.

Plaster cores are used in semipermanent molds to provide a surface finish better than that obtainable with sand or coated metal cores. For example, in a wave-guide casting requiring a smooth inside surface, the use of permeable plaster cores provides a surface finish better than that which could be obtained with coated metal cores. Plaster also has excellent insulating qualities and does not prematurely chill the metal in thin sections. With regard to dimensional accuracy, plaster cores offer no superiority over sand cores.

Collapsible Cores. It is preferable to avoid designs that require the use of collapsible metal cores (multiple-piece cores) in permanent molds. These cores add to the cost of the castings, and their assembly and removal increase production time. Furthermore, dimensional variations can result from the use of collapsible cores because they cannot be positioned as securely in the mold as single-piece cores or because of movement of core segments when the casting metal is poured. When castings must be designed to be made with collapsible cores, the designer should allow the loosest tolerances possible.

Despite the disadvantages of collapsible cores, they are extensively used in making certain castings. For example, nearly all of the aluminum pistons made for the automobile industry in the United States are cast in permanent molds using five-piece collapsible metal cores.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Selection of Mold and Core Materials

Four principal factors affect the selection of materials for permanent molds and cores:

- The pouring temperature of the metal to be cast
- The size of the casting
- The number of castings per mold
- Cost of the mold material

These variables form the basis for the recommendations given in Tables 1, 2, and 3.

Table 1 Recommended permanent mold materials

Casting alloy	Number of pours		
	1000	10,000	100,000
For small castings (25 mm, or 1 in., maximum dimension)			
Zinc	Gray iron; 1020 steel	Gray iron; 1020 steel	Gray iron; 1020 steel
Aluminum, magnesium	Gray iron; 1020 steel	Gray iron; 1020 steel	Gray iron with AISI H14 inserts; 1020 steel
Copper	Gray iron	Gray iron	Alloy cast iron

Gray iron	Gray iron[a]	Gray iron[a]	Quantity not poured
For medium and large-size castings (up to 915 mm, or 36 in., maximum dimension)			
Zinc	Gray iron; AISI H11[b]	Gray iron; AISI H11[b]	Gray iron; AISI H11[b]
Aluminum, magnesium	Gray iron	Gray iron	Gray iron; AISI H11 or H14[c]
Copper	Alloy cast iron	Alloy cast iron	Alloy cast iron[d]
Gray iron	Gray iron[a]	Gray iron[a]	Quantity not poured

(a) Same composition as being poured.

(b) AISI H11 is used when polish is required on medium-size castings.

(c) For medium-size parts; recommended materials for large parts are gray iron with H11 inserts or solid H11 die steel.

(d) For medium-size parts; large parts are not poured in this quantity.

Table 2 Recommended materials for small cores (<76 mm, or 3 in., in diameter and 255 mm, or 10 in., long) for permanent molds

Casting alloy	Recommended core materials[a]
Zinc	**Sand, plaster, gray iron, 1020 steel**
Aluminum, magnesium	**1010 or 1020 steel, sand, plaster, H11 die steel or equivalent[b], carbon[c]**
Copper	**Sand, 1020 steel, gray iron, plaster[d], graphite[c]**
Gray iron	**Sand, graphite, carbon, gray iron**

(a) Materials are listed in descending order of preference.

(b) Hardened to 42-45 HRC.

(c) For use with relatively few pours.

(d) For casting of aluminum bronzes

Table 3 Recommended materials for large cores (>76 mm, or 3 in., in diameter and 255 mm, or 10 in., long) for permanent molds

Casting alloy	Material for indicated number of pours[(a)]		
	1000	**10,000**	**100,000**
Zinc	Gray iron, 1020 steel	Gray iron, 1020 steel	Gray iron, 1020 steel
Aluminum, magnesium	Gray iron, gray iron with 1020 steel inserts[(b)], sand, plaster[(b)]	Gray iron[(b)], gray iron with 1020 or H11 inserts[(b)], sand, plaster[(b)]	Gray iron[(b)], gray iron with H11 inserts[(b)], H11 die steel
Copper	Sand	Sand	Quantity not poured

(a) Materials are listed in descending order of preference.

(b) Except for openings with complex shapes, which require expendable sand cores

As indicated in Table 1, gray iron is the most commonly used mold material. Aluminum or graphite molds are sometimes used for the small-quantity production of aluminum and magnesium castings, and graphite or carbon liners on steel are sometimes used for molds for casting copper alloys (see the section "Solid Graphite Molds" in this article).

With aluminum or magnesium casting alloys, it is not unusual to obtain 100,000 castings, or more, per mold; however, molds for copper or gray iron casting alloys have a shorter life because of the higher pouring temperatures required. Gray iron molds without tool steel inserts are satisfactory for long production runs of aluminum and magnesium castings that will be machined extensively and for which surface finish is not a major consideration. In the casting of zinc, well over 100,000 pours are possible in a gray iron mold (die casting is usually selected to produce zinc castings in such large quantities).

Mold Inserts. Full or partial mold cavity inserts of the same material as the mold, or of a different material, are sometimes used to obtain longer mold life, or to simplify machining, handling, or replacement. Inserts can also be used for venting, cooling thin walls, and heating portions of the mold or the full cavity area. Inserts made of cast-to-shape gray iron are used for casting complex aluminum and magnesium parts that range in surface area from 320 to 2900 cm^2 (50 to 450 $in.^2$). Tolerances on these parts range from ±0.76 to ±1.5 mm (±0.030 to ±0.060 in.). Inserts last for 5000 to 20,000 pours, depending on casting complexity.

Core materials are recommended in Tables 2 and 3 on the basis of performance over a wide range of coring requirements for small and large cores. An expendable core is used when the location or shape of the core does not permit its removal from the casting or when an intricate design can be obtained at less cost with materials for such cores. These materials are listed below in order of increasing preference:

- Sand (oil-bonded or resin-bonded, shell, carbon dioxide-silicate)
- Plaster
- Graphite and carbon

Mold parts can be cast to shape when the castings to be made are not complicated. Cast molds are suitable for applications for which gray iron or AISI H11 die steel is recommended in Table 3. Such cast molds are most often used when production requirements are large and when mold replacement or shipping schedules require several of the same molds.

Machining of the mold cavity is often a more significant factor in the cost of a mold than the cost of the mold material. The relative machining costs of identical molds fabricated from different materials increase as shown below. In this listing, machining costs for a gray-iron mold are taken as 1.0, and the costs include heat treatment when required:

Gray iron	1.0
Cast low-alloy steel	1.44
Gray iron with tool steel inserts	1.73
Cast tool steel	2.16

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Mold Life

Mold life can vary from as few as 100 pours to as many as 250,000 pours (or even more), depending on the variables discussed later in this section. A mold for an aluminum piston, for example, can be expected to produce 250,000 castings before requiring repair. After the production of 250,000 more castings, the repaired mold will require a major overhaul. With repeated repairs and overhauls, the mold can produce as many as 3.5 million castings before being discarded. However, a piston mold, with its relatively simple design, will have a much longer life than a mold that requires elaborate internal coring and external inserts, such as a cylinder-head mold.

Mold life is likely to be longer in the casting of magnesium alloys than in the casting of aluminum alloys of similar size and shape; this is because molten magnesium does not attack ferrous metal molds. However, the difference in mold life for magnesium alloys depends to a great extent on the effectiveness of the mold coating used. In the casting of gray iron, mold life is expected to be short compared to the casting of similar shapes from aluminum alloys.

Molds are often fabricated from cast iron because casting the mold close to the finished shape can decrease machining costs. In addition, cast iron is much more resistant to attack by molten aluminum than steel. Steel, however, is weldable and easier to repair than cast iron. Therefore, steel molds are often used for high-production castings.

Major variables that affect the life of permanent molds are:

- *Pouring temperature:* The hotter the casting metal is poured, the hotter the mold is operated, which leads to rapid weakening of the mold metal
- *Weight of casting:* Mold life decreases as casting weight increases
- *Casting shape:* Mold walls are required to dissipate more heat from castings having thick sections than from those having thin sections. When there is a significant variation in the section thickness of a casting, a temperature differential is set up among different portions of the mold. As the temperature

differential increases, mold life decreases

- *Cooling methods:* Water cooling is more effective than air cooling, but it substantially decreases mold life
- *Heating cycles:* Generally, a continuous run, in which the mold is maintained at a uniform temperature, provides maximum mold life. Repeated heating and cooling over a wide temperature range will shorten mold life
- *Preheating the mold:* This is done to operating temperature with a gas flame or electric heaters, and it greatly increases mold life. Thermal shock is one of the principal causes of mold failure
- *Mold coating:* This protects the mold from erosion and soldering by preventing the metal from contacting mold surfaces, thus increasing mold life
- *Mold materials:* See Table 1
- *Storage:* Improper storage can lead to excessive rusting and pitting of mold surfaces, which will reduce mold life
- *Cleaning:* The common practices for cleaning molds are abrasive blasting, dipping in caustic solution, and wire brushing. Dipping in caustic can be hazardous to the operator. Wire brushing and abrasive blasting can cause excessive mold wear if not carefully controlled. Glass beads are the safest abrasive blast material; their use minimizes dimensional changes due to erosion from the abrasive blast
- *Gating:* A poor gating system can greatly reduce mold life by causing excessive turbulence and washout at the gate areas
- *Method of mold operation:* Although the same materials are used to make molds and cores for both automatically operated equipment and hand-operated equipment, the life of the tool materials on hand-operated equipment is shorter because of the abuse the tooling must withstand. Tools for automatic equipment may last up to twice as long as for hand-operated equipment
- *End use of casting:* If the structural function of a casting is more important than its appearance, a mold can be used for more pourings before being discarded

Influence of Mold Design. In addition to the above factors, mold design has a marked effect on mold life. Variation in mold wall thickness causes excessive stress to develop during heating and cooling, which in turn causes premature mold failure from cracking. Abrupt changes in thickness without generous fillets also cause premature mold failure. Small fillets and radii lead to reduced mold life because checking and cracking, as well as ultimate failure, often start at these points.

Usually, less draft is required on external mold surfaces than on internal mold surfaces because of the shrinkage in the casting. A 5° draft is desirable, but 2° on external and 3° on internal mold surfaces can be used. Lower draft angles, however, decrease the number of castings that can be made between mold repairs. The effect of draft angle on the life of cores and molds used for producing aluminum alloy castings is shown in Fig. 9.

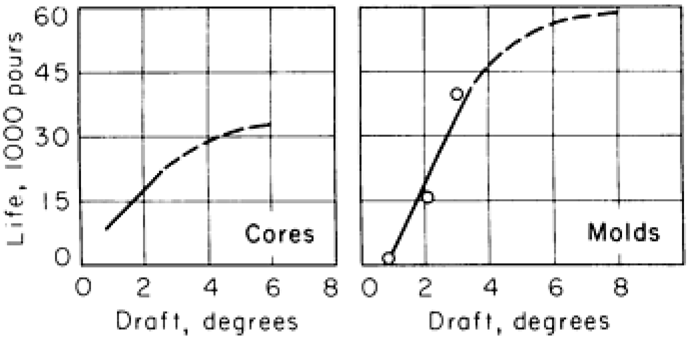

Fig. 9 Effect of draft angle on core and mold life in the permanent mold casting of aluminum alloys

Projections in the mold cavities contribute greatly to reduced mold life. These projections become extremely hot, which increases the possibility of extrusion, deformation, and mutilation when the casting is removed. It is sometimes possible to extend mold life by using inserts to replace worn or broken projections.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Mold Coatings

A mold coating is applied to mold and core surfaces to serve as a barrier between the molten metal and the surfaces of the mold while a skin of solidified metal is formed. Mold coatings are used for five purposes:

- To prevent premature freezing of the molten metal
- To control the rate and direction of solidification of the casting and therefore its soundness and structure
- To minimize thermal shock to the mold material
- To prevent soldering of molten metal to the mold
- To vent air trapped in the mold cavity

Types. Mold coatings are of two general types: insulating and lubricating. Some coatings perform both functions. A good insulating coating can be made from (by weight) one part sodium silicate to two parts colloidal kaolin in sufficient water to permit spraying. The lubricating coatings usually include graphite in a suitable carrier. Typical compositions of 15 mold coatings are listed in Table 4. Coatings are available as proprietary materials.

Table 4 Typical compositions of coatings for permanent molds

Coating No.	Composition, % by weight (remainder, water)									
	Sodium silicate	Insulators				Lubricants				Boric acid

(a) Serves also as an insulator.

(b) Plus silicon carbide, 2% by weight, for wear resistance

The various requirements of a mold coating are not always obtained with one coating formulation. These requirements are often met by applying different coatings to various locations in the mold cavity.

Coating Requirements. To prolong mold life, a coating must be noncorrosive. It must adhere well to the mold and yet be easy to remove. It must also keep the molten metal from direct contact with the mold surfaces.

A mold coating must be inert to the cast metal and free of reactive or gas-producing materials. If insulation is needed to prevent thin sections, gates, and risers from solidifying too quickly, fireclay, metal oxides, diatomaceous earth, whiting (chalk), soapstone, mica, vermiculite, or talc can be added to the mold coating. Graphite is added if accelerated cooling is needed. Lubricants, which facilitate removal of castings from molds, include soapstone, talc, mica, and graphite (Table 4).

Coating Procedure. The mold surface must be clean and free of oil and grease. The portions to be coated should be lightly sand blasted. If the coating is being applied with a spray, the mold should be sufficiently hot (205 °C, or 400 °F) to evaporate the water immediately.

For optimum coating retention, a primer coat of water wash should be applied before spraying the mold coating. Water wash is a very dilute solution of a mold coating. Dilute kaolin makes an excellent primer. An acceptable alternative is a 20 to 1 dilution of the coating to be sprayed. The high water content of the water wash very lightly oxidizes the mold surface and provides a substrate strate for subsequent layers to stick to. The water wash should be sprayed until the dark color of the mold starts to disappear. Lubricating materials or coatings are not acceptable as primers. Lubricants can be sprayed over insulating coatings, but insulating coatings will not adhere to lubricants.

The coating can be applied by spraying or brushing. It must be thick enough to fill minor surface imperfections, such as scratches. It should also be able to dry with a smooth texture on mold areas of light draft that form ribs and walls in the casting, and it must dry with a rough texture on large, flat areas of the mold to permit entrapped air to escape. The most pleasing cast surfaces are obtained when the coating has a matte or textured finish, which is most often obtained by spraying. Extremely smooth coatings should be avoided because they increase the formation of oxide skins. Thin successive layers are applied until the coating reaches the desired thickness, up to a maximum of 0.8 mm ($\frac{1}{32}$ in.).

Thick coatings are especially useful on the surfaces of sprues, runners, and risers because they provide more insulation than thinner coatings and result in slower metal freezing. However, they are more likely to flake off and should not be used on the surfaces of casting cavities. Thick coatings are applied by dabbing with a paint brush and adhere better if applied over an initial thin spray coat. It is mandatory that the coating be thoroughly dry before a casting is made, or an explosion will result.

Coating life varies considerably with the temperature of the metal being cast, the size and complexity of the mold cavity, and the rate of pouring. Some molds require recoating at the beginning of each shift; others may run for several shifts with only spot repairs or touchups before recoating is needed. Light abrasive blasting is used to prepare the coating for touchup or to remove old coats. To maintain maximum feeding with the mold, risers, runners, and gates should be recoated about every second time the casting cavity is recoated.

Mold Coatings for Specific Casting Alloys. The metal being cast has a major influence on the type of coating selected. Lubricating coatings are usually used for the casting of aluminum and magnesium. Relatively complex mixtures are sometimes used. For the casting of copper alloys, because of their high pouring temperatures and their solidification characteristics, an insulating type of mold coating is generally required.

The mold coatings used in the production of gray iron castings are divided into two categories: an initial coating, which is applied before the mold is placed in production, and a subsequent coating of soot (carbon), which is applied prior to each pouring. The initial coating consists of sodium silicate (water glass) and finely divided pipe clay, mixed in a ratio of about 1 to 4 by volume with enough water (usually about 15 parts by volume) to allow spraying or brushing. This mixture is applied to molds heated to 245 to 260 °C (475 to 500 °F).

The secondary coating is a layer of soot (carbon) deposited on the mold face and cavities each time the mold is to be poured. The soot is formed by burning acetylene gas delivered at low pressure (3.5 to 5.2 kPa, or 0.5 to 0.75 psig) so that a maximum amount of soot is produced and a minimum of heat is generated. It can be applied either manually or by automatic burners. This soot layer provides insulation between the mold and the casting, permitting easy removal of the castings from the mold, and it prevents chilling of the castings. It also provides a seal between the mold faces to minimize leakage. The thickness of the soot deposit is 0.10 to 0.25 mm (0.004 to 0.010 in.).

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

---

Mold Temperature

If the mold temperature is too high, excess flash develops, castings are too weak to be extracted undamaged, and mechanical properties and casting finish are impaired. When mold temperature is too low, cold shuts and misruns are likely to occur, and feeding is inhibited, which generally results in shrinkage, hot tears, and sticking of the casting to molds and cores.

The variables that determine mold temperature include:

- *Pouring temperature:* The higher the pouring temperature, the higher the temperature of the mold
- *Cycle frequency:* The faster the operating cycle, the hotter the mold
- *Casting weight:* Mold temperature increases as the weight of molten metal increases
- *Casting shape:* Isolated heavy sections, cored pockets, and sharp corners not only increase overall mold

temperature but also set up undesirable thermal gradients

- *Casting wall thickness:* Mold temperature increases as the wall thickness of the casting increases
- *Mold wall thickness:* Mold temperature decreases as the thickness of the mold wall increases
- *Thickness of mold Coating:* Mold temperature decreases as the thickness of the mold coating increases

After the processing procedure has been established for a given casting operation, mold coating, cycle frequency, chills, and antichills have significant effects on mold temperature. Mold coating is difficult to maintain at an optimum thickness, primarily because the coating wears during each casting cycle and because it is difficult to measure coating thickness during production. The most widely used method for controlling coating thickness is periodic inspection of the castings. Improper coating thickness is reflected by objectionable surface finish and loss of dimensional accuracy.

Preheating of Molds

In many casting operations, molds are preheated to their approximate operating temperature before the operation begins. This practice minimizes the number of unacceptable castings produced during establishment of the operating temperature.

Molds can be preheated by exposure to direct flame, although this method can be detrimental to the molds because of the severity and nonuniformity of heat distribution. Customized heaters are often built for molds. Preheating of the mold face in an oven is the best method because the thermal gradients are of smaller magnitude. Unfortunately, this is usually impractical for larger molds. Final mold operating temperatures are achieved after the first few production cycles.

Control of Mold Temperature

Optimum mold temperature is the temperature that will produce a sound casting in the shortest time. For an established process cycle, temperature control is largely achieved through the use of auxiliary cooling or heating and through control of coating thickness.

Auxiliary cooling is often achieved by forcing air or water through passages in mold sections adjacent to the heavy sections of the casting. Water is more effective, but over a period of time scale can coat the passages, thus necessitating frequent adjustments in water flow rates. Without cleaning, the flow of water eventually stops. Water passages should be checked and cleaned each time a mold is put into use.

The problem of scale formation has been solved in some plants by the use of recirculating systems containing either demineralized water or another fluid such as ethylene glycol. However, such systems are rarely used.

Water flow is regulated manually to each mold section with the aid of a flowmeter. A main shutoff valve is used to stop the water flow when the casting process is interrupted. Adjusting the rate of water flow to control the solidification rate of a heavy section permits some leeway in the variation of wall thickness that can be designed into a single casting. In addition to the control of water flow, the temperature of the inlet water (or any other coolant that might be used) affects the performance of the mold cooling system.

If water or another liquid coolant is used, it must never be allowed to contact the metal being poured, or a steam explosion will result. The intensity of a steam explosion increases as metal temperature increases. In addition, water will react chemically with molten magnesium.

A mold coating of controlled thickness can equalize solidification rates between thin and heavy sections. Chills and antichills can be used to adjust solidification rates further, so that freezing proceeds rapidly from thin to intermediate sections and then into heavy sections, and finally into the feeding system.

Chills are used to accelerate solidification in a segment of a mold. This can be done by directing cooling air jets against a chill inserted in the mold (Fig. 10) or, more simply, by using a metal insert without auxiliary cooling. Chilling can also be achieved by removing some or all of the mold coating in a specific area to increase thermal conductivity. Chills can be used to increase production rate, to improve metal soundness, and to increase mechanical properties.

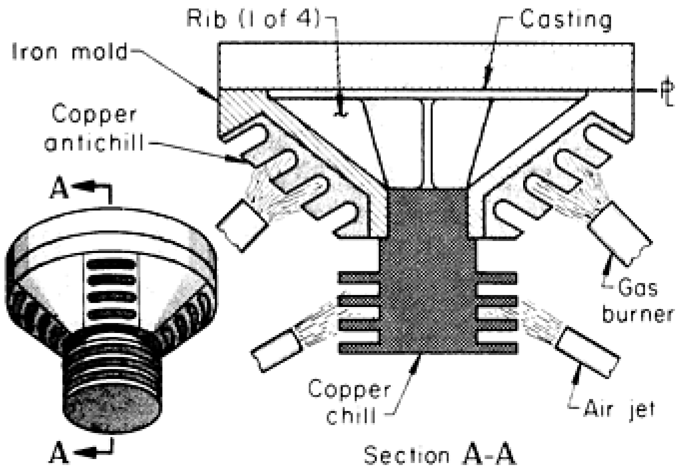

Fig. 10 Use of air-cooled chills and flame-heated antichills to equalize cooling rates in casting sections of varying thickness

Antichills. An antichill serves to slow the cooling in a specific area. Heat loss in a segment of a permanent mold can be reduced by directing an external heating device, such as a gas burner, against an antichill inserted in the mold (Fig. 10). The same effect can be produced by the use of insulating mold coatings.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Pouring Temperature

Permanent mold castings are generally poured with metal that is maintained within a relatively narrow temperature range. This range is established by the composition of the metal being poured, casting wall thickness, casting size and weight, mold cooling practice, mold coating, and gating systems used.

Low Pouring Temperature. If pouring temperature is lower than optimum, the mold cavity will not fill, inserts (if used) will not be bonded, the gate or riser will solidify before the last part of the casting, and thin sections will solidify too rapidly and interrupt directional solidification. Low pouring temperature consequently results in misruns, porosity, poor casting detail, and cold shuts. Sometimes only a small increase in pouring temperature is needed to prevent cold shuts.

High pouring temperature causes casting shrinkage and mold warpage. Warpage leads to loss of dimensional accuracy. In addition, variations in metal composition may develop if the casting metal has components that become volatile at a high pouring temperature. High pouring temperature also decreases solidification time (thus decreasing production rate) and almost always shortens mold life.

Pouring Temperatures for Specific Metals. The pouring temperature for aluminum alloys usually ranges from 675 to 790 °C (1250 to 1450 °F), although thin-wall castings can be poured at temperatures as high as 845 °C (1550 °F). Once established for a given casting, pouring temperature should be maintained within ±8 °C (±15 °F). If this control of pouring temperature cannot be maintained, the cooling cycle must be adjusted for the maximum temperature used. Internal mold cooling can be controlled by means of solenoid valves actuated by thermocouples inserted in the mold walls.

For magnesium alloys, the normal temperature range for pouring is 705 to 790 °C (1300 to 1450 °F). Thin-wall castings are poured near the high side of the range; thick-wall castings, near the low side. However, as for any permanent mold casting, pouring temperature is governed by the process variables listed in the section "Mold Temperature" in this article,

and some experimentation is often required to establish the optimum pouring temperature for a specific casting. Once established, the pouring temperature should be controlled within ±8 °C (±15 °F).

Copper alloys are poured at 980 to 1230 °C (1800 to 2250 °F), depending on the alloy as well as the process variables discussed in the section "Mold Temperature" in this article. Once the temperature is established for a specific set of conditions, it should be controlled within ±15 °C (±25 °F).

The fluidity of gray iron is excellent, and little difficulty is experienced at pouring temperatures of 1275 to 1355 °C (2325 to 2475 °F). Excessive pouring temperatures can cause flashing and leaking due to mold distortion. As the pouring temperature increases, there is a rapid increase in defects caused by local hot spots on the cavity surface and insufficient soot coverage.

Because the temperature of the molten iron decreases considerably between the time that the first and last machines are serviced, it is usually necessary to deliver the metal to the casting area in a transfer ladle. The metal in this transfer ladle is delivered at a higher temperature than that suitable for pouring. To obtain the desired pouring temperature, small amounts of chill (foundry scrap of the same metal) are added to the pouring ladle as needed. If several machines are being serviced, the metal may have cooled sufficiently so that no chilling is required by the time the last machine is serviced.

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Removal of Castings From Molds

After a casting has solidified, the mold is opened and the casting is removed. To facilitate release of the casting from the mold, a lubricant is often added to or sprayed over the mold coating. The use of as much draft as permissible on all portions of the casting facilitates ejection. For many castings, ejector pins or pry bars must be used. Core pins and cores should be designed so that they do not interfere with the removal of castings from the mold.

Aluminum alloy castings require at least a 1° draft for mechanical ejection from the mold prior to manual removal (the more draft, the easier the ejection). For castings with low draft angles, the mold coating usually contains a lubricating agent (usually graphite) to prevent sticking.

Magnesium alloy castings are subject to cracking when removed from the mold because the metal is hot short. Therefore, the use of adequate draft is mandatory. On ribs, a draft of 5° is an absolute minimum. However, 10° is recommended and will result in fewer ejection difficulties. In addition, because of the danger of cracking, extreme care should be taken to avoid side thrust when removing cores that must be retracted before the mold is opened.

Copper alloy castings will stick in the molds for any of several reasons, but insufficient draft is usually the primary reason. Draft requirements vary from less than $\frac{1}{2}$ to as much as 5°, depending on alloy, depth of cavity, dimensional and tolerance requirements, and general mold layout (location and number of parting planes). Normally, if draft angles of 4 to 5° are acceptable, castings do not stick in the mold. If tighter dimensional control is required (necessitating smaller draft angles), castings may stick. Sticking can be prevented by providing for mechanical ejection or by increasing draft on noncritical areas.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Casting Design

The design of permanent mold castings for production to acceptable quality at the lowest cost involves many considerations that apply to any method of casting (see the article "Casting Design" in this Volume). For example, casting sections should be as uniform as possible, without abrupt changes in thickness. Heavy sections should not be isolated and should be fed by risers. Tolerances should be no closer than necessary. In addition to these general considerations, the following aspects of design are particularly applicable to the low-cost production of sound permanent mold castings:

- Insofar as possible, all locating points should be in the same half of the mold cavity; in addition, locating points should be kept away from gates, risers, parting lines, and ejector pins
- The use of cored holes less than 6.4 mm ($\frac{1}{4}$ in.) in diameter should be avoided, even though cored holes 3.2 mm ($\frac{1}{8}$ in.) in diameter or smaller are sometimes possible
- Draft angles in the direction of metal flow on outside surfaces may vary from 1 to more than 10°, and internal draft from slightly less than 2 to 20°. However, using minimum draft increases casting difficulty and cost. Internal walls can be cast without draft if collapsible metal cores are used, but this practice increases cost
- Nuts, bushings, studs, and other types of inserts can often be cast in place. The bond between inserts and casting can be essentially mechanical, metallurgical, or both
- Under conditions of best control, in small molds, allowance for machining stock can be less than 0.8 mm ($\frac{1}{32}$ in.). However, maintaining machining allowance this low usually increases cost. Generally, it is more practical to allow 0.8 to 1.6 mm ($\frac{1}{32}$ to $\frac{1}{16}$ in.) of machining stock for castings up to 250 mm (10 in.) in major dimension and to allow up to 3.2 mm ($\frac{1}{8}$ in.) for larger castings
- The designer should not expect castings to have a surface finish of better than 2.5 μm (100 μin.) under optimum conditions. Ordinarily, casting finish ranges from 3 to 7.5 μm (125 to 300 μin.), depending on the metal being cast

The producibility of a casting can often be improved by avoiding abrupt changes in section thickness. Heavy flanges adjacent to a thin wall are especially likely to cause nonuniform freezing and hot tears; in such cases, redesign of the casting may be necessary. The minimum section thickness producible at reasonable cost varies considerably with the size of the casting and the uniformity of wall thicknesses in the casting.

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Dimensional Accuracy

The dimensional accuracy of permanent mold castings is affected by short-term and long-term variables. Short-term variables are those that prevail regardless of the length of run:

- Cycle-to-cycle variation in mold closure or in the position of other moving elements of the mold
- Variations in mold closure caused by foreign material on mold faces or by distortion of the mold elements
- Variations in thickness of the mold coating
- Variations in temperature distribution in the mold
- Variations in casting removal temperature

Long-term variables that occur over the life of the mold are caused by:

- Gradual and progressive mold distortion resulting from stress relief, growth, and creep
- Progressive wear of mold surfaces primarily due to cleaning

Dimensional variations can be minimized by keeping heating and cooling rates constant, by operating on a fixed cycle, and by maintaining clean parting faces. It is particularly important to select mold cleaning procedures that remove a minimum of mold material.

Mold Design. The mold thickness and the design of the supporting ribs both affect the degree of mold warpage at operating temperatures. Supporting ribs on the back of a thin mold will warp the mold face into a concave form. This mold design error can alter casting dimensions across the parting line by as much as 1.6 mm ($\frac{1}{16}$ in.). Adequate mold lockup will contribute to the control of otherwise severe warpage problems.

Mold erosion resulting from metal impingement and cavitation due to improper gating design both contribute to rapid weakening of the mold metal and to heat checking. These mold design errors contribute to rapid dimensional variation during a long run. Mechanical abrasion due to insufficient draft or to improperly designed ejection systems also contributes to the rapid variation of casting dimensions.

Sliding mold segments require clearance of up to 0.38 mm (0.015 in.) to function under varying mold temperatures. This clearance and other mechanical problems associated with sliding mold segments contribute to variations in casting dimensions. Sand cores further aggravate the problem.

Mold Operation. Metal buildup from flash can prevent the mold halves from coming together and can cause wide variations in dimensions across the parting line, even in a short run. Mold coatings on the cavity face are normally applied in thicknesses from 0.076 to 0.15 mm (0.003 to 0.006 in.). Poor mold maintenance can allow these coatings to build to more than 1.5 mm (0.060 in.) thick, causing extreme variation in casting dimensions. Inadequate lubrication of sliding mold segments and ejector mechanisms will contribute to improper mold lockup and consequent variation in casting dimensions. Variation in the casting cycle and in metal temperature will contribute to dimensional variations.

Wear Rates. The dimensions of many mold and core components change at a relatively uniform rate; therefore, it is possible to estimate when rework or replacement will be required. To maintain castings within tolerances, it is sometimes necessary to select mold component materials on the basis of their wear resistance.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

---

Surface Finish

The surface finish on permanent mold castings depends mainly on:

- *Surface of the mold cavities:* The surface finish of the casting will be no better than that of the mold cavity. Heat checks and other imperfections will be reproduced on the casting surface
- *Mold coating:* Excessively thick coatings, uneven coatings, or flaked coatings will degrade casting finish
- *Mold design:* Enough draft must be provided to prevent the galling or cracking of casting surfaces. The location of the parting line can also affect the surface finish of the casting
- *Gating design and size:* These factors have a marked effect on casting finish because of the influence on the rate and smoothness of molten metal flow
- *Venting:* The removal of air trapped in mold cavities is important to ensure smooth and complete filling
- *Mold temperature:* For optimum casting surface finish, mold temperatures must be correct for the job and must be reasonably uniform
- *Casting design:* Surface finish is adversely affected by severe changes of section, complexity,

requirements for change in direction of metal flow, and large flat areas

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Casting Defects

The defects that can occur in permanent mold castings are porosity, dross, nonmetallic inclusions, misruns, cold shuts, distortion, and cracking. Aluminum alloy castings are subject to all of these defects.

Magnesium alloy castings can have the same defects as aluminum alloy castings. In addition, magnesium alloys are more likely to be hot short.

Copper alloy castings are also susceptible to most of the defects common to aluminum and magnesium. Because of the high pouring temperatures, heat checking of the mold cavities is an added problem. Copper alloy castings often stick in the molds; this can sometimes be prevented by redesigning the mold cavity.

Permanent Mold Casting

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Cost

The total cost of a permanent mold casting includes the cost of metal, labor, fuel, supplies, maintenance of molds and other equipment, and inspection.

Manual Versus Automated Methods. Manually operated equipment is generally more economical for low production quantities, but automated molding invariably costs less for medium-to-high production quantities.

Cost Versus Quantity. Permanent mold casting is primarily used for medium and high production, although the process is sometimes used advantageously for low production. Cost per casting or per pound invariably decreases as quantity increases.

Permanent Mold Versus Sand Casting. The permanent mold process is often selected in preference to sand casting or another alternative process primarily because of the lower cost per casting, but there are often added benefits. For some castings, a minor design change can permit a change from sand casting to permanent mold casting that results in a considerable cost savings.

When castings must be machined, the significant cost is often not that of the casting itself but of the final machined product. Permanent mold casting is often economical because it permits a reduction in the number of machining operations required or in the amount of metal removed.

Revised by Charles E. West and Thomas E. Grubach, Aluminum Company of America

Solid Graphite Molds*

Permanent molds can be machined from solid blocks of graphite instead of steel. The low coefficient of thermal expansion and superior resistance to distortion of graphite make it attractive for the reproducible production of successive castings made in the same mold.

Because graphite oxidizes at temperatures above 400 °C (750 °F), molds would wear out quickly even if used for nonferrous casting. To protect the molds and to extend their service lives, they are usually coated with a wash, which is normally made of ethyl silicate or colloidal silica. Molds typically show wear by checking or by forming minute cracks in their surface.

Graphite permanent molds are used for a variety of products (notably bronze bushings and sleeves), and graphite chills are often inserted in molds to promote progressive or directional solidification. The use of graphite as a permanent mold material is perhaps best demonstrated in the casting of chilled iron railroad car wheels (the Griffin wheel casting process), as shown in Fig. 11. Graphite is a particularly suitable mold material for this process. It produces castings with closer tolerances than can be achieved with sand molding, and the high thermal conductivity of graphite chills the metal next to the mold face very efficiently, giving it a wear-resistant white iron structure.

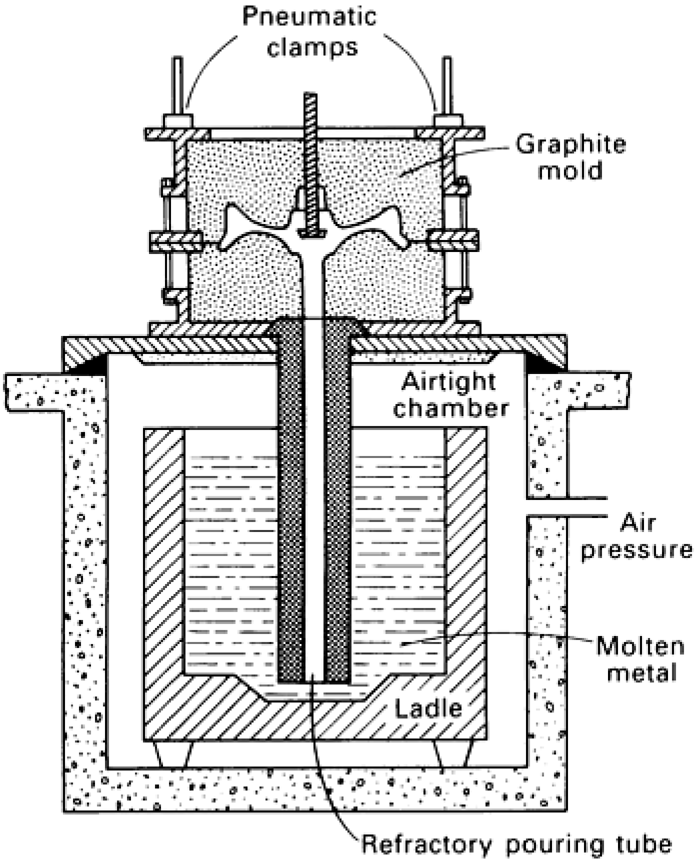

Fig. 11 Schematic of the Griffin wheel casting process. See text for details.

However, because graphite erodes easily, pouring the metal into molds from the top under the influence of gravity causes unacceptable mold wear. As a result, the process was developed so that the mold is positioned over a ladle of molten

metal placed in an airtight chamber. A refractory pouring tube extends from deep in the ladle up to the bottom of the graphite mold. Pouring is carried out by pressurizing the metal in the ladle by means of increasing the pressure in the chamber. This forces metal up the pouring tube into the mold. When the casting is filled, a plunger blocks the pouring tube, the air pressure is released, and the metal that remains in the pouring tube drains back into the ladle. The mold and casting are then transferred to a cooling conveyor, and another mold is placed in position over the ladle.

The process is highly automated, and it has a high casting yield with little gate removal required. Because metal is drawn from the bottom of the ladle, there is little chance for slag to be entrained in the castings, which are clean and have excellent surfaces. Casting quality is further controlled by the ease of regulating the flow of metal into the mold. The technique has been used to make ferrous castings weighing up to 410 kg (900 lb).

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Introduction

DIE CASTING is characterized by a source of hydraulic energy that imparts high velocity to molten metal to provide rapid filling of a metal die. The die absorbs the stresses of injection, dissipates the heat contained in the metal, and facilitates the removal of the shaped part in preparation for the next cycle. The hydraulic energy is provided by a system that permits control of actuator position, velocity, and acceleration to optimize flow and force functions on the metal as it fills the cavity and solidifies.

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Die Casting Processes

The variety in die casting systems results from trade-offs in metal fluid flow, elimination of gas from the cavity, reactivity between the molten metal and the hydraulic system, and heat loss during injection. The process varieties have many features in common with regard to die mechanical design, thermal control, and actuation. Four principal alloy families are commonly die cast: aluminum, zinc, magnesium, and copper-base alloys (Table 1). Lead, tin, and, to a lesser extent, ferrous alloys can also be die cast. The three primary variations of the die casting process are the hot chamber process, the cold chamber process, and direct injection.

(a) Maximum, unless range is given or otherwise indicated.

The hot chamber process is the original process invented by H.H. Doehler. It continues to be used for lower-melting materials (zinc, lead, tin, and, more recently, magnesium alloys). Hot chamber die casting places the hydraulic actuator in intimate contact with the molten metal (Fig. 1). The hot chamber process minimizes exposure of the molten alloy to turbulence, oxidizing air, and heat loss during the transfer of the hydraulic energy. The prolonged intimate contact between molten metal and system components presents severe materials problems in the production process.

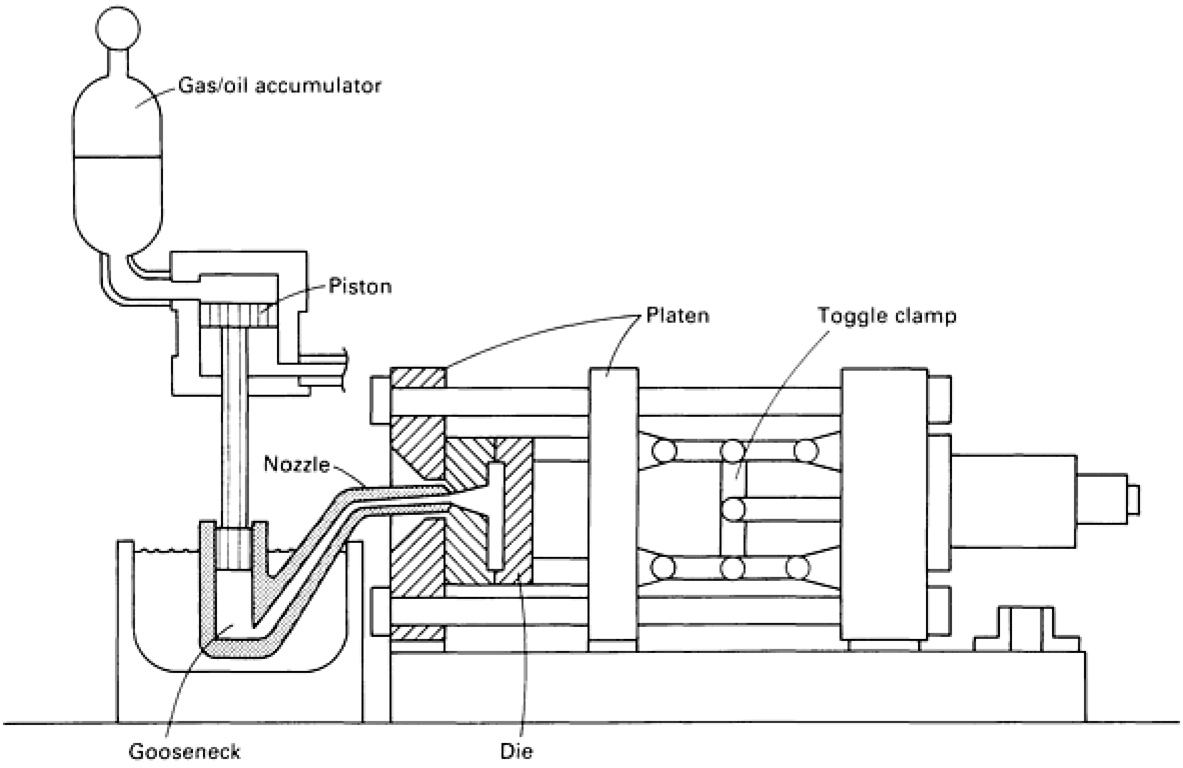

Fig. 1 Schematic showing the principal components of a hot chamber die casting machine

The cold chamber process solves the materials problem by separating the molten metal reservoir from the actuator for most of the process cycle. Cold chamber die casting requires independent metering of the metal (Fig. 2) and immediate injection into the die, exposing the hydraulic actuator for only a few seconds. This minimal exposure allows the casting of higher-temperature alloys such as aluminum, copper, and even some ferrous alloys.

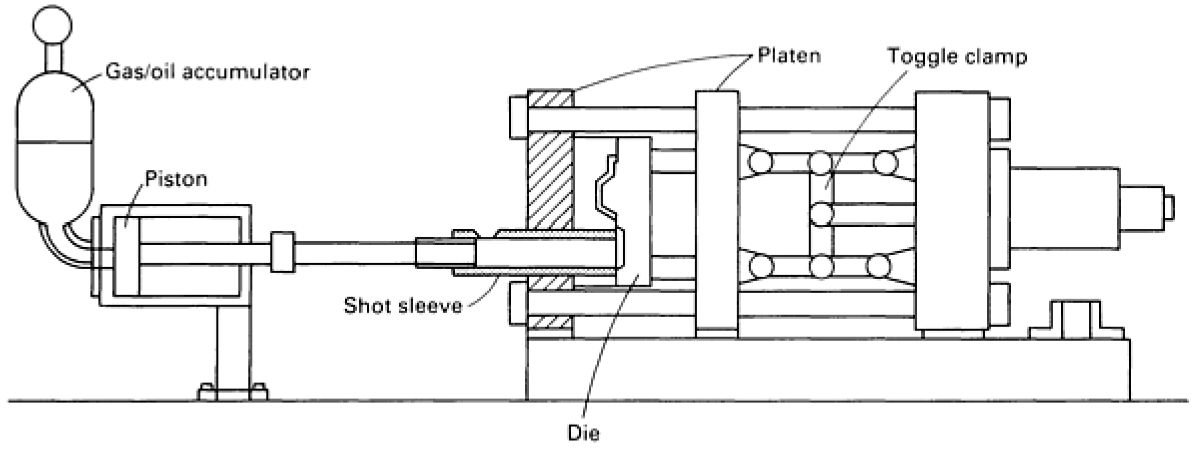

Fig. 2 Schematic showing the principal components of a cold chamber die casting machine

Direct injection extends the technology used for lower-melting polymers to metals by taking the hot chamber intimacy to the die cavity with small nozzles connected to a manifold, thus eliminating the gating and runner system. This process, however, is still under development.

Process control in die casting to achieve consistent high quality relates to timing, fluid flow, heat flow, and dimensional stability. Some features are chosen in die and part geometry decisions and are therefore fixed; others are defined by the process at the machine and can be adjusted in real time. All are related and therefore must be dealt with in parallel; the best die castings result from an intimate interrelationship between product design and process design.

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Product Design for the Process

Product design and die design are intimately related. The principal features of a die casting die are illustrated in Fig. 3. The high-speed nature of the process allows the filling of thin-wall complex shapes at high rates (of the order of 100 parts per hour per cavity). This capability places additional demands on the casting designer because traditional feeding of solidification shrinkage is almost impossible. The inability to feed in the traditional sense demands that machining stock be kept to a minimum; high-integrity surfaces should be preserved.

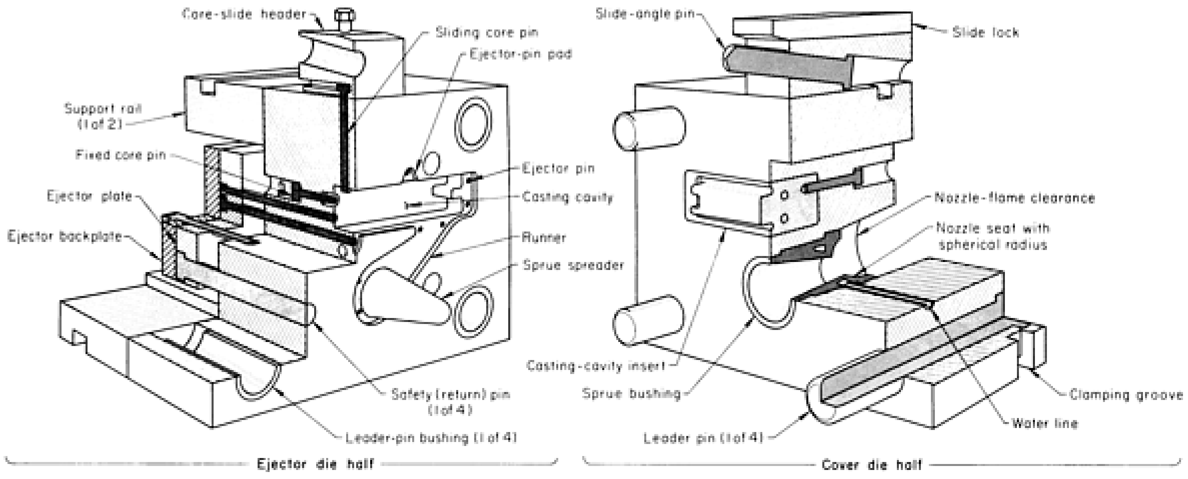

Fig. 3 Components of a single-cavity die casting die for use in a hot chamber machine

A factor in cost is the parting line topology. The parting line is the line on the casting generated by the separation between one die member and another. The simplest and lowest-cost die has a parting line in one plane. Casting design should be adjusted if possible to provide flat parting lines. Draft is required on the die casting walls perpendicular to the parting line or in the direction of die motion (Fig. 4). An important characteristic of good design is uniform wall thickness, which is necessary for obtaining equal solidification times throughout the casting. Die castings have wall thicknesses of about 0.64 to 3.81 mm (0.025 to 0.150 in.), depending on casting shape and size (Table 2). Bosses, ribs, and filleted corners always cause local increases in section size. In particular, bosses that must be machined require consideration of the entire product-manufacturing cycle. The machinist will find it easier to drill into a solid boss; cored bosses may require floating drill heads in order to align the drill with the cast tapered hole that preserves the high-integrity skin of the casting.

Table 2 Minimum section thicknesses for die castings

Surface area of casting[(a)]		Minimum section thickness for:					
		Tin, lead, and zinc alloys		Aluminum and magnesium alloys		Copper alloys	
cm^2	$in.^2$	mm	in.	mm	in.	mm	in.
Up to 25	Up to 3.875	0.635	0.025	0.81	0.032	1.52	0.060
25-100	3.875-15.5	1.02	0.040	1.27	0.050	2.03	0.080
100-500	15.5-77.5	1.52	0.060	1.78	0.070	2.54	0.100

(a) Area of a single main plane

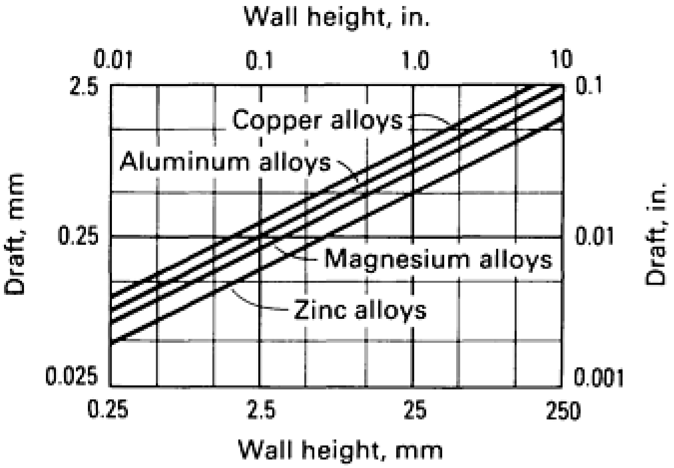

Fig. 4 Minimum drafts required for inside walls of die castings made from four different types of casting alloys

Cores and slides provide side motions for undercuts. A core body is generally round and buried within the cover or ejector die. A slide body has a rectangular or trapezoidal shape and crosses the parting line of the die. As with the cover and ejector dies, the impression steel is often separate from the holder steel. Cores and slides are actuated by various methods, including hydraulic cylinders, rack and pinion, and angle pins. Innovative die design permits radial die motion at a price of die expense. There are die casting processes that use complex-shaped disposable cores similar to those in other gravity casting processes. Cores and slides provide the casting designer with tremendous flexibility at the expense of an increase in die complexity. A standard set of cores--fixed core pins for small holes that are screwed in, or bolted-in inserts--can be used to reduce die construction cost and to permit rapid replacement.

Loose Pieces and Inserts. In certain cases, a reentrant shape needs to be cast into the part where there is no space for core/slide mechanisms. In such a case, the die designer can use a loose piece. A loose piece is placed in the die before each shot is made. It is then ejected from the die with the casting and separated manually or by fixture. Although it provides design flexibility, the load/unload sequence required for loose pieces slows the process, thus increasing cost.

Similarly, the die casting process can allow the part designer great flexibility in local material properties by the use of cast-in inserts of other materials, such as steel, iron, brass, and ceramics. The bond between insert and casting is physical, not chemical, in nature. Therefore, the insert should be clean and preheated. The insert should be designed to prevent pullout or rotation under working loads; knurling, grooves, hexagons, or flats are commonly used for this purpose. Proper support of hollow inserts will prevent crushing of the insert under the high metal injection pressure. The wall thickness of the casting surrounding an insert should be no less than 2.0 mm (0.080 in.) to prevent cracking by shrinkage, hot tearing, and excessive residual stresses.

Trimming. The die cast part is ejected from the die with a variety of appendages (gates, overflows, vents, flash, and robot grasping lugs) that must then be removed. This secondary process is called trimming. Although trimming can be done manually, the high production rates characteristic of die casting demand automation. Trim presses are used to remove the excess material. Castings are often trimmed immediately after the casting process because their higher temperature reduces the strength of the metal.

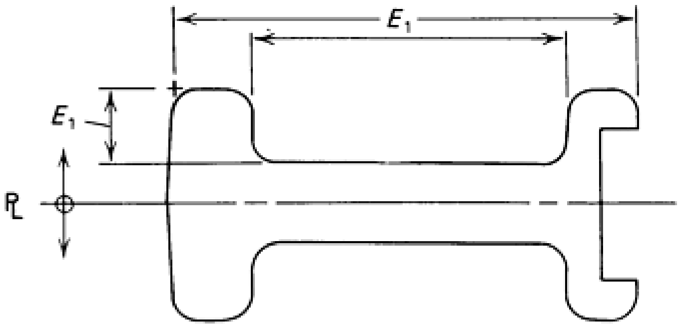
Trimming conditions directly influence the design of the part and the die casting process, especially gating and parting line definition. Trimming is facilitated by flat parting lines. The relatively rough edge that results from trimming may be acceptable and is often left as is. In some cases, this rough edge is not acceptable and must be removed by machining or grinding. The direction of flash must be such that the edge is machinable.

Dimensional variation is determined by die design, the accuracy of die construction, and process variation. The most accurate dies are those machined using computer numerical control methods. Close control of alloy composition, temperature casting, time, and injection pressure will lead to more consistent casting dimensions. The minimum variation in dimensions is required for those features contained entirely within one die half. Table 3 lists the tolerances on linear dimensions recommended by the American Die Casting Institute (ADCI); Tables 4 and 5 list additional tolerances recommended by ADCI. Therefore, machining locators should ideally be placed in the same die half. Tolerances are a

function of casting size and projected area. Features across parting lines have added variation because of the accuracy of repeated die closing. Die temperature, machine hydraulic pressures, and die cleanliness are the principal factors to be controlled. Finally, further dimensional variation occurs if the feature is in a moving die member such as a slide or core.

Table 3 Recommended tolerances on as-cast linear dimensions of die castings

Additional tolerances are listed in Tables 4 and 5.



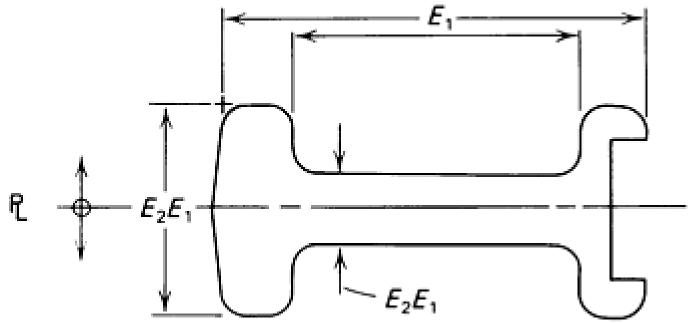
The tolerance on a dimension E_1 will be the value shown in the tables for dimensions between features formed in the same die part. The tolerance must be increased for dimensions of features formed between moving die parts (see Tables 4 and 5).

Length of dimension E_1, in.	Basic tolerance (in.) for:			Additional tolerance[(a)] (in.) for each additional inch of dimension E_1 for:		
	Zinc alloy castings	Aluminum and magnesium alloy castings	Copper alloy castings	Zinc alloy castings	Aluminum and magnesium alloy castings	Copper alloy castings
Noncritical dimensions						
Up to 1	±0.010	±0.010	±0.014	. . .	. . .	. . .
1-12	. . .	. . .	. . .	±0.0015	±0.002	±0.003
Above 12	. . .	. . .	. . .	±0.001	10.001	. . .
Critical dimensions						
Up to 1	±0.003	±0.004	±0.007	. . .	. . .	. . .
1-12	. . .	. . .	. . .	±0.001	±0.0015	±0.002
Above 12	. . .	. . .	. . .	±0.001	±0.0015	. . .

(a) Example: an aluminum alloy casting would have a tolerance of ±0.010 in. on a critical 5.000 in. dimension E_1 (that is, the basic tolerance of ±0.004 in. + 4 (0.0015) = ±0.010 in.).

Table 4 Recommended parting line tolerances for die castings

Tolerances given in this table are to be added to the basic tolerances given in Table 3. See also Table 5.



The tolerance on dimensions such as E_2E_1, which are perpendicular to the parting plane, will be the value shown in the table plus the linear tolerance from Table 3. The value chosen from the table depends on the projected area of the part. Additional tolerances in the case of other moving die parts are shown in Table 5.

Projected area of casting[(a)], in.^{2}	**Additional tolerance[(b)] (in.) for:**		
	Zinc alloy castings	**Aluminum and magnesium alloy castings**	**Copper alloy castings**
Up to 50	±0.004	±0.005	±0.005
50-100	±0.006	±0.008	. . .
100-200	±0.008	±0.012	. . .
200-300	±0.012	±0.015	. . .
300-500	10.016	±0.020	
500-800	±0.020	±0.025	. . .
800-1200	±0.025	±0.030	. . .

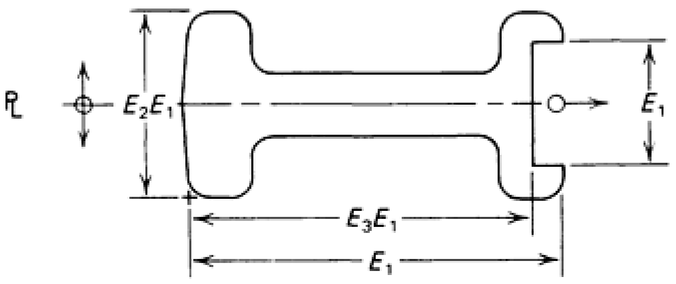
Source: Ref 2

(a) Projected area is the area of the part in the parting plane.

(b) Example: an aluminum die casting with a projected area of 75 in.^{2} would have a tolerance of ±0.018 in. on a critical 5.000 in. dimension E_2E_1 (that is, ±0.008 in. for 75 in.^{2} plus the basic linear tolerance of 0.010 in.). See Table 3.

Table 5 Recommended additional tolerances for die castings produced in dies with moving parts

Tolerances in this table should be used in conjunction with those listed in Table 3. See also Table 4.



The tolerance on dimensions such as E_3E_1 will be the value shown in the table plus the linear tolerance from Table 3. The value chosen from the table depends on the projected area of the portion of the die casting formed by the moving die part perpendicular to the direction of movement.

Projected area of die casting, in.^{2}	**Additional tolerance[(a)] (in.) for:**		
	Zinc alloy castings	**Aluminum and magnesium alloy castings**	**Copper alloy castings**
Up to 10	±0.004	±0.005	±0.010
10-20	±0.006	±0.008	. . .
20-50	±0.008	±0.012	. . .
50-100	±0.012	±0.015	. . .
100-200	±0.016	±0.020	. . .
200-350	±0.020	±0.025	. . .
350-600	±0.025	±0.030	. . .
600-1000	±0.030	±0.035	. . .

(a) Example: An aluminum alloy casting formed using a moving die part and having a projected area of 75 in.^{2} would have a tolerance of ±0.025 in. on a critical 5.000 in. dimension E_3E_1 (that is, ±0.015 in. for 75 in.^{2} plus ±0.010 in. on linear dimensions). See Table 3.

In summary, a cost-effective die casting demands proper attention to the dimensional variation of the process. Inattention to dimensional factors will lead to an inability to provide consistent products within economic process conditions. The product designer signer and the die caster must therefore initiate a dialog early in the product cycle.

Gating

The first step in the process sequence is the supply of the molten alloy to the casting machine and its injection into the die. The fluid flow is divided into three considerations: metal injection, air venting, and feeding of shrinkage.

Metal Injection

The distinguishing characteristic of the die casting process is the use of high-velocity injection. The short fill time (of the order of milliseconds) allows the liquid metal to move a great distance despite a high rate of heat loss. The elements of a typical metal gating system are illustrated in Fig. 5.

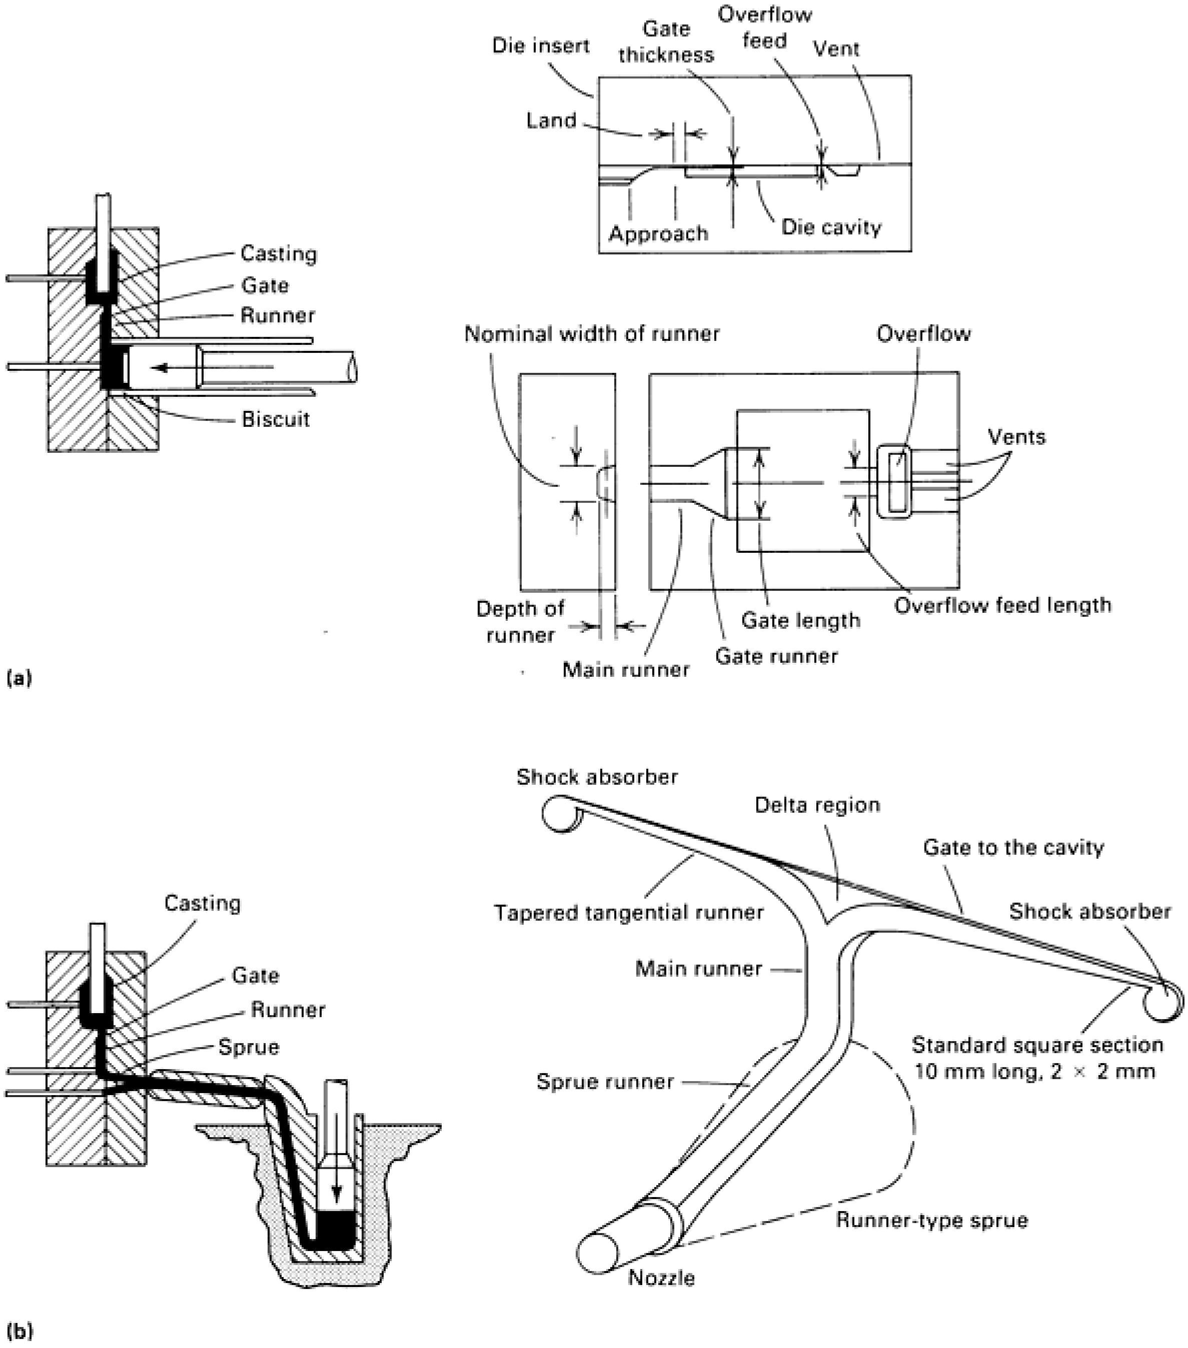

Fig. 5 Schematics showing gating systems for cold chamber (a) and hot chamber (b) die casting machines

Proper process performance depends on the delivery of molten metal with high quality as defined by temperature, composition, and cleanliness (gas content and suspended solids). The molten alloy is prepared from either primary ingot or secondary alloys. A melting furnace is used to provide the proper temperature and to allow time for chemistry adjustment and degassing. The alloy is often filtered during transfer to a holding furnace at the casting machine.

The Injection Chamber. Three components make up the injection chambers used for the three types of die casting: the shot sleeve, the gooseneck, and the nozzle (Fig. 1, 2). The cold chamber shot sleeve (Fig. 2) is unique. Initially, it is only partially filled to prevent splashing and to allow for metering error, and it must be filled by slow piston movement to avoid wave formation and air entrainment. Then, for all three chambers, the hydraulic piston rapidly accelerates the molten metal to the desired velocity for injection (Fig. 6). Most die casting machines provide the ability to control the piston acceleration in a linear fashion. Parabolic velocity curves are also available on some controls. This phase of injection can be accomplished in several steps. The third phase of injection is activated as the cavity is close to being filled. This intensification phase draws on an accumulator of high-pressure hydraulic fluid or multiplies pressure using

conventional piston intensifiers. This increases the pressure on the metal to force the rapidly freezing alloy into incipient shrinkage cavities.

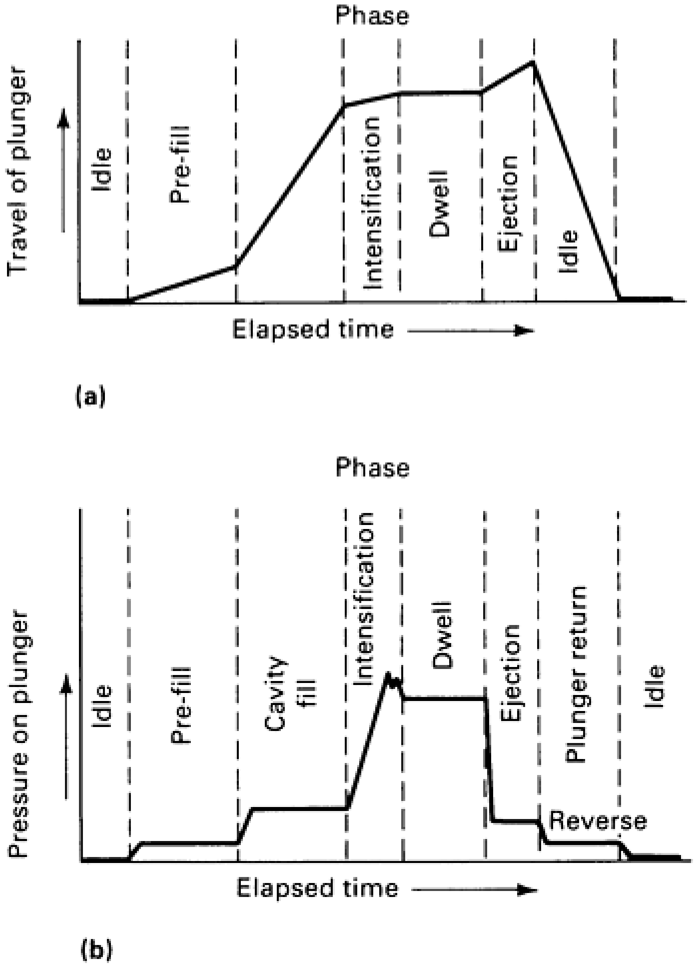

Fig. 6 Curves for plunger travel versus time (a) and plunger pressure versus time (b) indicating the various phases of a shot

Sprues and Runners. The sprue provides a smooth transition from the shot sleeve or nozzle and promotes high cooling heat flow after injection is complete. The runner carries the flowing metal from the injection chamber to the desired location(s) on the casting periphery. Runners are not used in direct injection. Heat loss, unnecessary turbulence, and die erosion can be minimized by proper attention to basic hydraulic principles when designing runners. Typical runners are therefore round or nearly square trapezoidal in section to minimize surface area and heat loss. There is a distinct change in section from the thick runner to the thin gate. A change in flow direction also often occurs. The approach section is the means for achieving these two needs. The shape of this section of the flow channel often provides the name of the gate, for example, chisel gate or fan gate. The use of tapered tangential runners eliminates this approach feature.

The gate is the controlling entry point into the casting. The gate serves a fluid flow need, but it must later be removed from the casting by trimming. Therefore, the gate cross section should be the smallest in the gating system. The cross section is determined by the desired fill time and flow rate that the casting machine can provide. A number of methods are available for calculating gate area; these are discussed below.

The shape of the part is primarily governed by the end use, not by fluid flow considerations. Indeed, the die casting process excels in very complex near-net shape configurations. The high-velocity inertia-driven flow, combined with rapid heat loss and partial freezing during fill, eliminates the possibility of a rigorous fluid mechanics solution. However, the die caster must always attempt to understand the flow in the part cavity.

The overflow is the final component in the fluid flow system. Although they add to the weight of remelt, overflows do serve a variety of purposes. They can act as a reservoir for metal to be removed from the cavity, and they can provide an off-casting location for ejection pins, robot holds, or instrumentation points.

Gating System Design. Several methods are available for designing gating systems. Design of the gating system is always a compromise. Unlike the flow of polymers or metal flow in forging, the high-velocity metal flow of die casting, combined with heat loss and simultaneous solidification, cannot be rigorously solved with computational methods. Therefore, various methods have been developed to provide the die caster with tools to address the problem on a sound, consistent basis. All of these methods attempt to take into account the influence of the following key variables:

- Part shape
- Internal quality
- Surface quality
- Mechanical properties
- Die temperature
- Die erosion
- Die material
- Die venting
- Metal temperature
- Metal fluidity
- Metal heat content
- Metal microstructure

Since the invention of the die casting process, many die castings have been successfully made with gating systems designed by experience only. Each company has a reservoir of this closely guarded experience. Trial-and-error adjustments at the casting machine are frequently part of the learning. However, the decline of the presence of the artisan in the foundry is forcing a move toward analytically based gating design, but the analysis base is still tempered with the fine tuning of experience. This is especially true in gate location and local angle of entry, which are directly affected by part shape and secondary operations.

One of the first analysis methods was the ADCI/DCRF Nomograph (Fig. 7), which solves geometric relationships for the bulk flow design. The selection of a fill time for the casting is based on experience and experiment. The limited selection of plunger diameters for a given machine restricts the design. The cold chamber process links the volume of metal to plunger diameter by filling the shot sleeve about two-thirds full. The nomograph is used to develop a required volume fill rate Q.

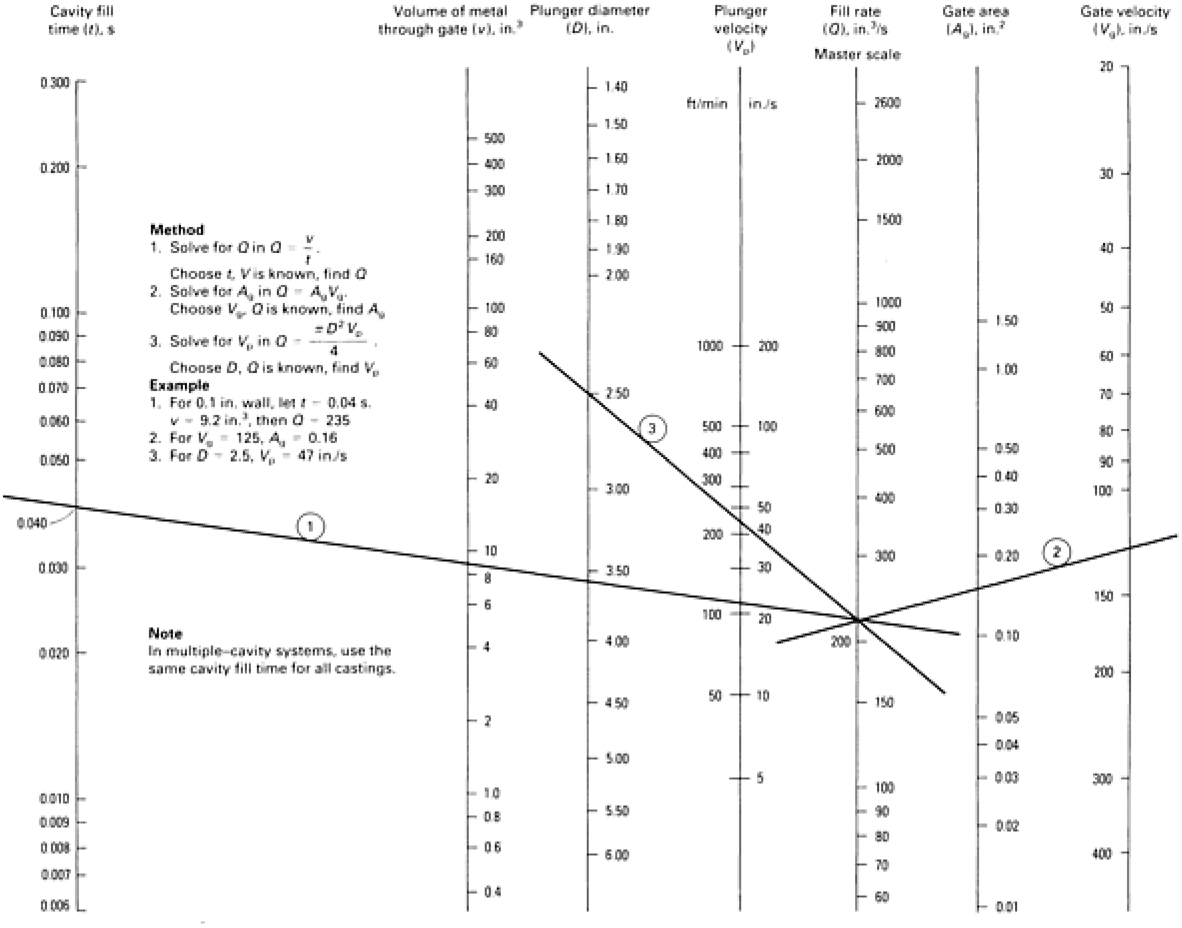

Fig. 7 Nomograph used to determine the volume fill rate *Q* required for different casting process parameters

It has recently been recognized that the ability of the casting machine to provide this metal volume flow, while keeping the dies closed during injection, must be considered. The tool that has been developed for this purpose is called the P-Q^2 diagram (Fig. 8). It can be shown that the pressure *P* on the metal and hydraulic system is proportional to the square of the injection velocity and therefore the volume flow rate *Q*. The line with the negative slope is the machine characteristic line. The characteristic line moves as shown with changes in hydraulic pressure, shot valve throttling, and plunger diameter. The line that starts at the origin of the graph is a measured relationship of pressure to flow rate for the particular casting and gate being cast. The effect of adjusting the gate area is shown.

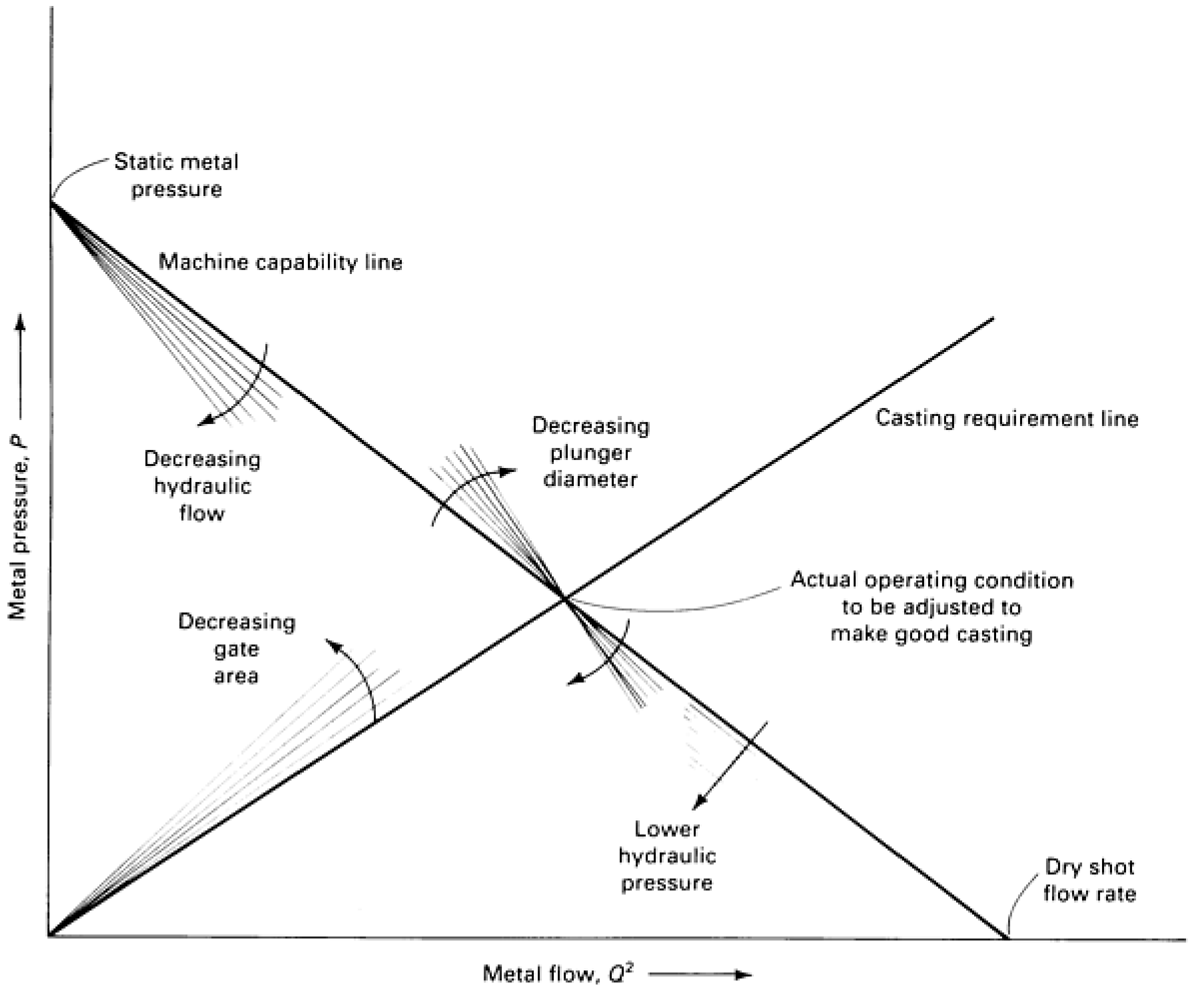

Fig. 8 Metal pressure versus metal flow (P-Q^2) diagram used to determine or optimize process parameters in die casting

Optimization of these various parameters for the casting and machine provides the process engineer with a powerful tool for process definition and debugging. A number of microcomputer programs are available to base gate design on this hydraulic approach (see the Selected References at the end of this article).

Air Venting

The subject of air venting is often neglected in die casting texts, but it can have a profound effect on product quality. Back pressure directly affects fluid flow. The molten metal injected into the die must displace the gas initially within the die cavity or absorb it as compressed bubbles. The common belief that die castings cannot be heat treated is an indication that they often contain entrained high-pressure gas pockets. Effective air removal eliminates entrained gas, resulting in optimum metal properties and even heat-treatable castings.

Gas Displacement. The most common method of gas displacement is the use of thin channels called vents that are open to the outside of the die. The total area of vents should be approximately 20% of the gate area. The machined channels are no more than 0.18 to 0.38 mm (0.007 to 0.015 in.) thick to ensure that the metal will freeze off before the edge of the impression block is reached. The turbulence of flow makes complete removal of cavity gases difficult by displacement venting. Vent placement is a matter of experience, with final design often done by trial and error on the casting machine.

An alternative to displacement venting is the extraction of the air ahead of the metal by a vacuum system using an accumulator. Once the die is closed and the shot hole sealed, the vacuum valve is opened and the air in the cavity is drawn

into the accumulator. The vacuum valve is either closed after a preset time or by metal impingement, which shuts the valve to prevent metal from filling the vacuum system. The accumulator is then pumped down for the next cycle.

Another method of eliminating entrained gas bubbles is to rely on the reactivity of the molten alloy with oxygen. The normal air in the cavity can be displaced by a pure oxygen purge. When the molten metal is injected, the gaseous oxygen combines with the metal to form a finely distributed solid oxide. This is known as the pore-free process.

The overflow can also act as a reservoir for molten alloy that has flowed through the cavity. One method of removing entrained gas from the cavity relies on the transfer of some of the gas into the overflow. However, for this method to be effective, the proportion of overflow volume to casting volume must be relatively large.

Feeding of Shrinkage

Practically all casting processes except die casting and squeeze casting rely on a massive reservoir or riser of molten metal to feed incipient shrinkage. There is no such riser in a die casting die. Metal pressure intensification at the end of the injection cycle is the only force used to feed shrinkage. The largest thermal section in cold chamber die casting is the biscuit and the runner adjacent to the shot sleeve and up to the gate (see Fig. 5a). Given the very thin walls of many die castings, the effective feeding distance from the gate is very short. Therefore, the die caster must rely on other techniques to assist in minimizing shrinkage.

For example, near-eutectic alloys with short freezing ranges are preferred. Inoculation (grain refinement) ensures a small eutectic cell size for well-dispersed micro-shrinkage that is not interconnected. The remnant shrinkage might also be moved to an uncritical area. This is accomplished by manipulating metal flow and die temperatures. A mechanical solution is the use of pressure pins, which are small, hydraulically actuated cores that are driven into the freezing casting. Timing and pressure are critical to the proper use of pressure pins. This approach adds to the complexity of the die.

Interaction of Fluid Flow with Dies and Machines

The forces generated by injection of the molten metal are a key factor in die design. Although the forces are highly dynamic in nature, most dies are designed for peak static loads. The geometric factor that usually determines the size of the casting machine that must be used is the combined projected area of the casting, runner, and gating system. The force that must be contained by the machine is this area multiplied by the peak metal pressure during the injection cycle. This is the peak of the intensification pressure (Fig. 6b). Because metal pressures under intensification can exceed 69 MPa (10 ksi), the force pushing the die open can be more than 450,000 kg (over 1 million lbf) for a large casting, based on projected area. This force determines the locking capacity needed to keep the die closed. Die casting machines are available with locking forces ranging from 450 kN to 35 MN (50 to 4000 tonf). The tooling cost and process cost increase with projected area and machine size. The distribution of forces within the tie bars is also important; the objective is to load each tie bar equally.

If the die uses slides and cores, these must also resist the force of the metal. This is usually accomplished by a mechanical lock. The closing actuator should not be expected to perform this function.

The thermal effects of molten metal flow in the die are a major factor in determining die life, casting surface quality, and many internal quality parameters. Impingement of metal upon the die, excessive turbulence, and cavitation in the flow increase the local heat load on the die. The result can be premature die failure from thermal fatigue.

In summary, the fluid flow aspects of die casting are a major determinant in product quality and die life. Therefore, fluid flow, or gating, can control the economic success of a particular die casting product. The flow is complex, and success depends on experience to aid an evolving analysis technology.

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Heat Removal

Once the molten alloy is in the die cavity, the heat in the alloy must be removed to allow solidification and subsequent cooling to occur; the die acts as a heat exchanger. A number of heat flow paths are available for this transfer, as shown in Fig. 9. As with any heat flow problem, the geometry of the heat exchanger is critical; in this case, heat exchanger geometry is dictated by the part geometry. Longer cooling times are achieved by utilizing heavy sections, distance from cooling lines, and shapes with large volume-to-surface-area ratios (or large section modulus). Another critical result of shape is the possibility of large differences in cooling times creating stresses within the die casting. If cooling stresses become too high under the rigid constraint of the die, hot tears and cracks can result.

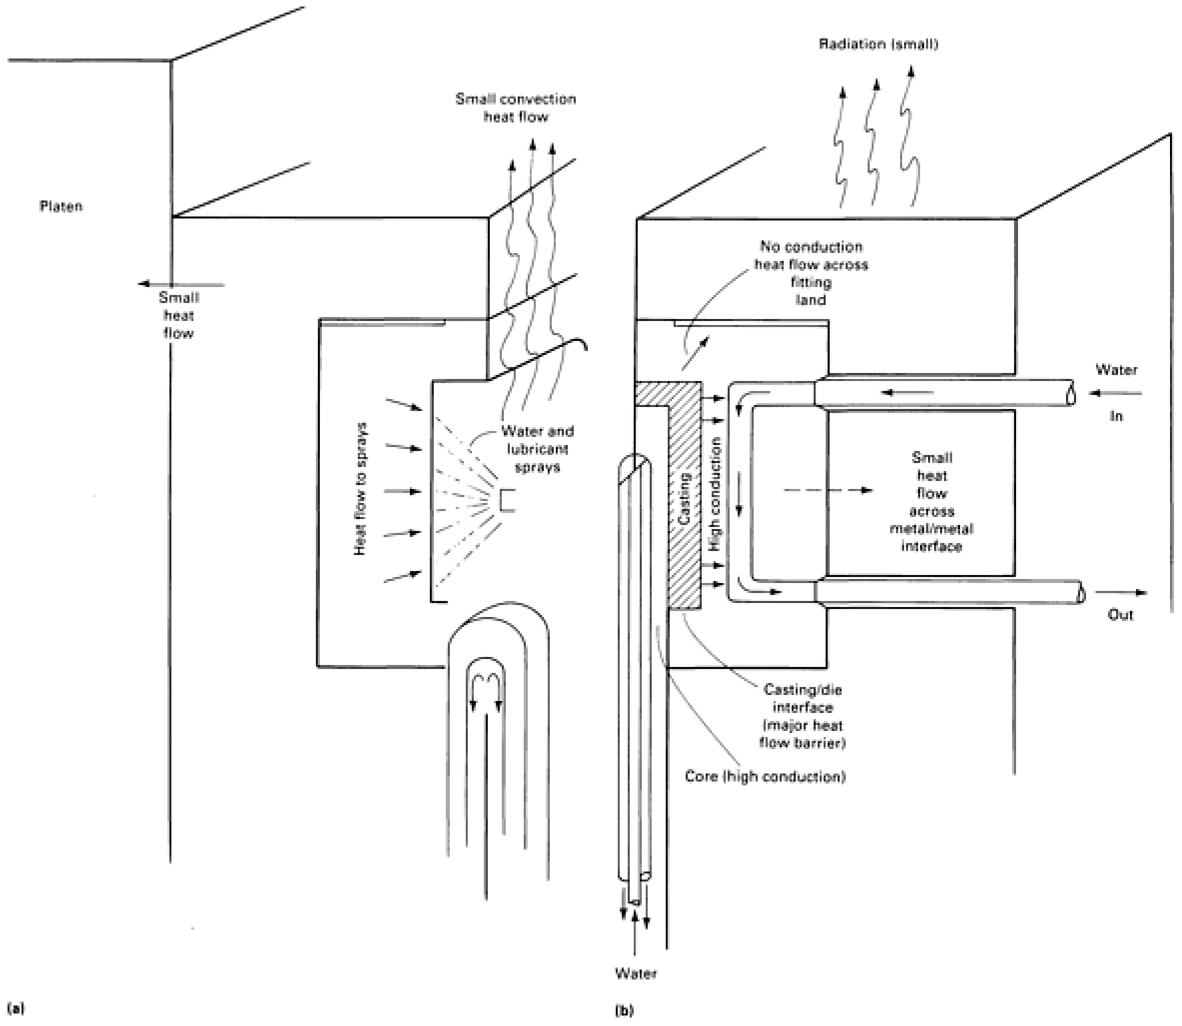

Fig. 9 Various heat flow paths available in die casting. (a) Die open for service. (b) Die closed after shot

The rate of heat removal is such that cooling is significant even during the filling process. Therefore, superheat and latent heat are transferred to the die before the alloy is stationary. The metal remote from the gate will be partially solid before the end of die filling. This transient heat flow results in more heat being transferred to the die near the gate.

Control of Heat Flow. The most important factor in controlling heat flow is the die/casting interface. The interface heat transfer coefficient is affected by a number of factors, such as shape, surface finish, lubrication, and steel oxide state. However, die material can also be used to influence heat flow. Conductive materials such as tungsten-base alloys and beryllium copper are used as inserts to promote high heat flow rates in local areas.

The location of waterlines is a key control of heat flow. The complex shapes of many die castings restrict the die designer in the placement of cooling lines. The basic factors controlling waterline effectiveness are location, coolant flow rate, temperature and pressure, and scale buildup. Placement of waterlines must be done in design. Coolant flow is a process control tool; scale buildup in waterlines is routinely controlled as part of preventive maintenance.

Cooling water can be replaced by hot oil to provide a source of heat in a die. Heat is often needed in configurations that suffer from excess temperature loss in filling. Hot oil and hot water systems can be effectively used to preheat a die before casting begins. This will promote longer die life.

In contrast, external die sprays between shots are one method of obtaining rapid heat flow where internal cooling is insufficient. As in the case of preheating by making shots, external sprays are very detrimental to die life. The trade-off in this case is between the cost required to maintain the die steel (including downtime) and the reduced cycle time for each part.

Analysis of Cooling Requirements. Several analytical methods are available for analyzing the cooling requirements of a die for a particular part. These tools vary widely in the detail and the time required for analysis. There are very simple methods that can be done quickly, and these are used for preliminary analysis. There are also methods that require more time and effort but provide the die designer with the detail necessary to obtain effective process definition.

A simple overall heat balance is the most basic tool that is used. In this technique, the heat content is calculated for one molten alloy shot between the injection temperature and the ejection temperature. This is the heat that must be removed within one cycle from the casting and the die. The proportion of the heat removed by cooling lines can then be determined. The size of preheating units required can also be found by using this simple method and taking into account the die properties.

There are also methods that use purely geometric considerations. In this case, the geometric shapes of part and die segments are considered in the conduction equation for the die. Computer-aided design (CAD) software is available to make this method simple to use once a surface model is created.

Analysis of cooling channel placement, along with hydraulic considerations for circuiting, is in general use for plastic injection molds. This method can also be adapted for die casting cooling design, and again, software is available in conjunction with a number of CAD packages.

Diffusion solutions, such as finite-element and finite-difference methods, represent the most detailed solution to the heat transfer design problem in die casting die design. The use of these tools will become more common as the cost of computation decreases. The sophistication of automated mesh generation must also improve if models are to be created and run within the short lead times often required for die design. The increased use of CAD for product design, where three-dimensional geometry is available to the die designer from the beginning, will also promote the use of these tools for initial design and for process improvement and optimization.

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Ejecting the Casting

After the casting has solidified and cooled, it must be removed from the die. Slides and cores generally must be withdrawn first, followed by opening of the die by ejector die motion. As the die opens, the casting is ejected from the die by the ejector pin. This is done by stopping the ejector plate while the die continues to retract or by using an actuator driven by hydraulic cylinder or rack and pinion. The casting is then taken from the pins manually, by dropping through the base of the machine under gravity, or by a robot or extractor.

Ejector pin size and location are governed by part geometry, especially depth of draw, draft, and surface contact area. The function of the casting can have considerable bearing on the allowable ejector pin location, and this is a subject for negotiation between the caster and the product designer. Bosses are often provided to ensure that there is a flat surface upon which the ejector pin can push. The mechanical design aspects of the ejection system must address stability and guidance during travel. Similarly, the die base in which the ejection system is contained must be strong enough to withstand the locking forces of the casting machine and metal flexure without undue deflection. Support pillars under the cavity may be required.

Lionel J.D. Sully, Edison Industrial Systems Center

Preparation for the Next Cycle

With the casting removed from the die, external water sprays can be used to cool the die. Compressed air blow off is used to blow residual water and any other loose flash from the internal die surfaces. This is followed by a lubricant spray to provide an insulating release agent between metal and die. A lubricant is also applied to the shot cylinder. The die can then be closed in preparation for the next cycle. The combined ejection and preparation phases can be up to 40 to 50% of the process cycle, as compared to 20% for plastic injection molding. The time required for ejection and preparation depends on casting size and die complexity.

Die Casting

Lionel J.D. Sully, Edison Industrial Systems Center

Die Casting Defects

Effective die design (fluid flow, heat flow, and mechanical design) and a well-defined process capability will combine to produce quality die castings. Proper attention to die casting process control will result in consistently high quality parts. The establishment of a stable process is the combined result of a partnership in casting design, die design, and process engineering.

Defects will occur if process variation is too broad. Defects are caused by three basic sources:

- Mechanical problems in the die
- Metallurgical problems in the molten alloy
- The interaction of heat flow and flaid flow

Care is necessary in order to identify the cause of a specific defect because several outward appearances can have different sources.

Mechanically induced defects such as galling or drag marks on the casting surface occur during ejection of the casting and are usually caused by insufficient draft in the die. Galling will be aligned with the direction of relative motion of the casting and its adjacent die segment. Lack of draft can be an error in die building, but it is readily corrected. Die design can cause lack of draft by inadequate specification, poor ejector system alignment, and inadequate slide or core alignment. Improper machine setup with uneven tie bar loading can cause the die to shift upon closing and opening and therefore create galling. Distorted or cracked castings are the result of extreme cases of poor mechanical design. Although a new die may be free of such mechanical defects, the normal wear and tear of the process may eventually lead to these defects. Proper attention to preventive maintenance will minimize such behavior.

Another class of mechanically induced defects can result from improper injection system performance. Machine-monitoring systems are available to measure and control critical timing, pressures, and velocities. These can be monitored on a shot-by-shot basis or on a periodic audit plan. In the event of loss of process control, these injection parameters should be the first to be checked. Changes to the die should be the last to be checked because they are the most difficult to diagnose and the most costly to implement.

Metallurgical Defects. Proper control of the quality of the molten metal is of primary importance with regard to metallurgical defects. The four principal factors are alloy composition, dissolved gas content, entrained solids (such as oxides and intermetallic compounds), and improper temperatures. The results can be poor fluidity, die soldering, shrinkage porosity, hot cracking, and gas porosity. Metallurgical factors interact directly with the primary causes of

casting defects: heat flow and fluid flow. A die casting process that experiences unexplained variations over time in the quantity of defects may be receiving poor-quality metal. As with a deterioration in the mechanical behavior of the die, metal quality is one of the first process parameters to be checked.

Interaction of Heat Flow and Fluid Flow. The die casting die is primarily a means of shaping a molten volume of metal and removing enough heat to permit ejection. Improper interaction of fluid and heat flow can lead to poor casting quality. The rapid fill time, the complex part geometries, and the high heat transfer rates of die casting combine to form a complex set of potential causes of defects. Flow/heat defects can be built into the die by poor design of the gating, venting, and thermal die layout. However, once the process is proven and the die is properly maintained, these parameters should not produce variations in the process.

Cold shuts are seams in the casting where two streams of metal have come together but have not fused. Cold shuts occur when solidification progresses too far in the flow streams, resulting in insufficient fluidity at the seam for mixing. The fixed causes of cold shuts are poor flow patterns due to inappropriate gating, excessive back pressure due to inadequate venting, and excessively thin walls in the part design. Process variables that cause the appearance of cold shuts are low die or metal temperatures, inadequate injection pressures, and excessive fill times.

Accurate volume measurement is important for precise process control. Insufficient volume can result in a very short biscuit (the cylinder left in the shot sleeve), premature freezing, and loss of effectiveness in injection pressure intensification. Excess volume can prolong cold chamber casting cycles because the biscuit is the last section of the casting to solidify.

Gas porosity consists of discrete, separate holes that have two sources: entrained air and, less frequently, dissolved gas. The latter source is entirely a metallurgical control problem, while the former has a variety of process causes. Built-in causes of excessive entrained gas are:

- Too empty a shot sleeve (excessive diameter or length)
- Inadequate venting
- Excessive use of lubricant
- Residual moisture from sprays
- Poor metal flow patterns that prevent venting

If the gas porosity is adjacent to the surface, a blister may form immediately following ejection as the high-pressure gas deforms the weak metal. The secondary factor is excessive die temperature on the blister side.

Shrinkage porosity is a series of interconnected holes created by a lack of feed metal at the end of solidification. Shrinkage is confined to the thermal center of a section, which can extend to the casting surface if local die temperatures are excessive. Shrinkage porosity can be built in by poor casting design that contains large sections, excessive die heating from poor metal flow distribution, and inadequate internal die cooling. Process variations in metal temperature, die temperature, inadequate injection pressures, and poor cooling from clogged cooling lines can result in shrinkage porosity.

Soldering is the adherence of the molten metal to the die surface; this results in tearing of the casting surface upon ejection. The condition appears where impingement of the flowing metal causes local overheating of the die. If the overheating is extreme, the molten metal stream will erode the die surface. This is most often seen at or near the gate. Poor gate design is the primary cause of soldering, combined with inadequate die cooling; poor die surface polishing can aggravate the problem. Process variations in lubricant application, die surface maintenance, or temperature control can lead to soldering and die erosion.

Molten aluminum is very aggressive toward unprotected die steels. If the iron content of the aluminum alloy is too low, the molten material tends to dissolve the die steel during injection. This tendency is especially pronounced under conditions that promote soldering and die erosion. This special soldering problem can be avoided by maintaining the iron content of aluminum die casting alloys between 0.8 and 1.1%.

Heat check fins are replica die cracks created by thermal fatigue. Thermal fatigue cracking (heat checking) is the result of the temperature cycles experienced at the die surface. High stresses may be built into the die by the design of the casting. Sharp corners and other stress raisers should be removed if at all possible. Excessive temperatures, combined

with local plastic deformation, creep, and phase changes in the steel, eventually lead to crack formation. Improper heat treatment will aggravate phase-induced failure. Dies for the low-melting metals rarely fail by thermal fatigue. Copper-base and ferrous castings rapidly cause checking of the die surface. Two process abuses are the most frequent irritants: making shots in a cold die, and excessive use of external water sprays.

Lionel J.D. Sully, Edison Industrial Systems Center

Postcasting Operations

Die Trimming. There are two postcasting operations that are unique to die casting. Die castings are taken from the die with flash, gates, and overflows attached to them. Trimming of these extraneous elements can be done by hand for low production volumes but is usually done with a hydraulic trim press for high-production parts. The press is set up with two handswitch interlocks to ensure that the operator's hands are out of the press after loading/unloading. Robot operation is also possible. Two types of trim dies are used: push-through and reverse-trim. Commercially available die sets are often used. The trim knives are hardened to greater than 50 HRC, and provision is made for self-cleaning or blow-off of flash to keep the trim dies clean.

Impregnation. Porosity in a die casting can lead to a lack of pressure tightness. Although porosity can be minimized by proper process design or control, it is sometimes necessary or cost effective to fill voids by using an impregnation process. Sodium silicate and anaerobic organic compounds are among the impregnants available. The typical procedure is as follows:

- Clean the casting
- Place in an autoclave and draw a vacuum of 710 mm (28 in.) of mercury for 15 min
- Introduce the sealant and apply hydrostatic pressure for 15 min
- Pump out and remove the castings
- Wash and dry

Horizontal Centrifugal Casting

Alain Royer and Stella Vasseur, Pont-á-Mousson S.A., France

HORIZONTAL CENTRIFUGAL CASTING is used to cast pieces having an axis of revolution. The technique uses the centrifugal force generated by a rotating cylindrical mold to throw the molten metal against the mold wall and form the desired shape.

The first patent on a centrifugal casting process was obtained in England in 1809. The first industrial use of the process was in 1848 in Baltimore, when centrifugal casting was used to produce cast iron pipes. In the 1890s, the principles already known and proved for liquids in rotation about an axis were extended to liquid metals, and the mathematical theory of centrifugal casting was developed in the early 1920s.

Horizontal centrifugal casting was first used mainly to manufacture thin-wall gray iron, ductile iron, and brass tubes. Improvements in equipment and casting alloys made possible the development of a flexible and reliable process that is both economical and capable of meeting stringent metallurgical and dimensional requirements. Cylindrical pieces produced by horizontal centrifugal casting are now used in many industries. Of particular importance are large-diameter thick-wall bimetallic and specialty steel tubes used in the chemical processing, pulp and paper, steel, and offshore petroleum production industries.

Equipment

A horizontal centrifugal casting machine must be able to perform four operations accurately and with repeatability:

- The mold must rotate at a predetermined speed
- There must be a means to pour the molten metal into the rotating mold
- Once the metal is poured, the proper solidification rate must be established in the mold
- There must be a means of extracting the solidified casting from the mold

Figure 1 shows a common design for a horizontal centrifugal casting machine. Many variations of this basic design are in use. Details may vary; for example, there are different types of drive systems, carrying rollers, and so on.

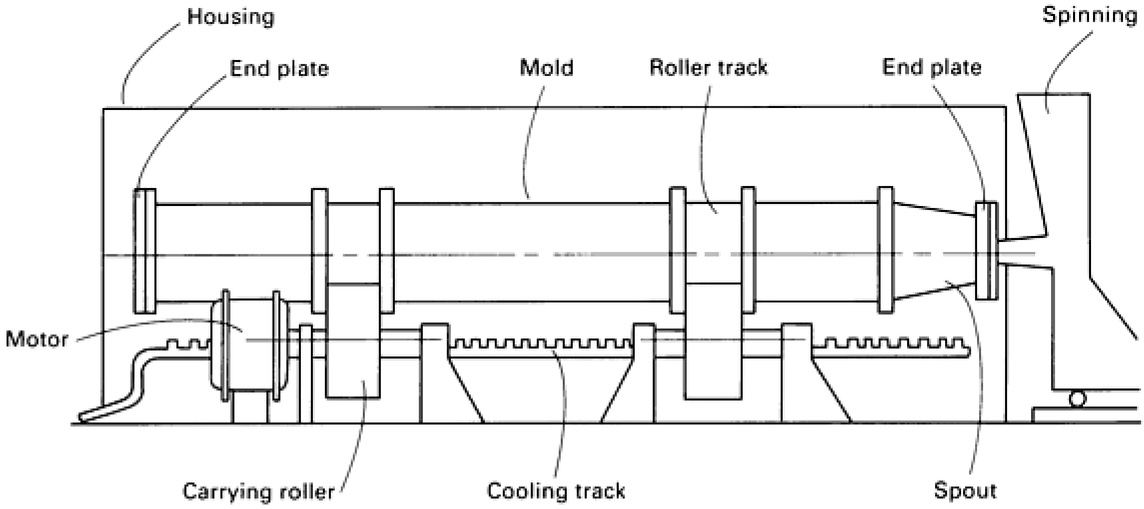

Fig. 1 Schematic of a common design for a horizontal centrifugal casting machine.

Molds

Molds consist of four parts: the shell, the casting spout, roller tracks, and end heads. The mold assembly is placed on interchangeable carrying rollers that enable the use of different mold diameters and fine adjustments. Molds are cooled by a water spray, which can be divided into several streams for selective cooling.

Different types of molds are generally used according to the geometry and quantity of castings needed and the characteristics of the metal or alloy being cast. Molds can be either expendable (a relatively thin case lined with sand) or permanent.

Expendable molds lined with sand are widely used in centrifugal casting, especially for producing relatively few castings. A single mold case can be used with different thicknesses of sand linings to produce tubes of various diameters within a limited range.

Green sand is commonly used as the liner in expendable molds. Various mixtures and binders are used--for example, a mixture of 60% silica sand and 40% calcined and crushed asbestos or sand bound with resin. Phenolic binders are also used with silica sand. One proprietary process uses a mixture of sand, silica flour, bentonite, and water.

Dry sand molds can also be employed; in this case, the sand is pressed down around a pattern having the same dimensions as the casting. Hardening is sometimes accomplished with carbon dioxide.

Mold washes of various compositions are used with sand molds. The wash hardens the mold surface and minimizes erosion of the mold by molten metal.

Permanent Molds. The most common materials for permanent molds are steel, copper, and graphite.

Steel molds are used to cast large quantities and for some casting alloys that require specific solidification conditions. Steel molds are sensitive to thermal shock; alumina- or zirconia-base mold sprays are used to lessen thermal shocks to the mold and to improve the mold surface. Mold coatings are also important in regulating the solidification rates of some casting materials. Other ceramic coating materials are beginning to be employed.

Copper molds are sometimes used for their high thermal conductivity. Their relatively high cost and the difficulty of calculating the correct dimensions of these molds limit their field of application.

Graphite Molds. Because of their relatively low cost, graphite molds can be an economical alternative to sand in the production of small quantities of parts. Graphite is the mold material of choice in the casting of 80% Cu bronzes, high-phosphorus brasses, and other copper alloys. Graphite has excellent thermal conductivity and resistance to thermal shock,

and it is easily machined. Care must be taken, however, to maintain the mold well below the oxidation temperature of graphite.

Casting Techniques

Pouring. Molten metal can be introduced into the mold at one end, at both ends, or through a channel of variable length. Pouring rates vary widely according to the size of the casting being produced and the metal being poured. For example, a pouring rate of 1 to 2 Mg/min (1.1 to 2.2 tons/min) has been used to cast low-alloy steel tubes 5 m (200 in.) long and 500 mm (20 in.) in outside diameter with 50 mm (2 in.) thick walls. Pouring rates that are too slow can result in the formation of laps and gas porosity, while excessively high rates slow solidification and are one of the main causes of longitudinal cracking.

Casting Temperatures. The degree of superheat required to produce a casting is a function of the metal or alloy being poured, mold size, and physical properties of the mold material. The following empirical formula has been suggested as a general guideline to determine the degree of superheat needed:

$$L = 2.4\Delta T + 110 \qquad \textbf{(Eq 1)}$$

where L is the length of spiral fluidity (in millimeters) and ΔT is the degree of superheat (in degrees centigrade). The use of Eq 1 for ferrous alloys results in casting temperatures that are 50 to 100 °C (120 to 212 °F) above the liquidus temperature. In practice, casting temperatures are kept as low as possible without the formation of defects resulting from too low a temperature.

A high casting temperature requires higher speeds of rotation to avoid sliding; low casting temperatures can cause laps and gas porosity. Casting temperature also influences solidification rates and therefore affects the amount of segregation that takes place.

Mold Temperature. Numerous investigators have studied the relationship between initial mold temperature and the structure of the resultant casting. Initial mold temperatures vary over a wide range according to the metal being cast, the mold thickness, and the wall thickness of the tube being cast. Initial mold temperature does not affect the structure of the resultant casting as greatly as the process parameters discussed above do.

Speed of Rotation. Generally, the mold is rotated at a speed that creates a centrifugal force ranging from 75 to 120 *g* (75 to 120 times the force of gravity). Speed of rotation is varied during the casting process; Fig. 2 illustrates a typical cycle of rotation. The cycle can be divided into three parts:

- At the time of pouring, the mold is rotating at a speed sufficient to throw the molten metal against the mold wall
- As the metal reaches the opposite end of the mold, the speed of rotation is increased
- Speed of rotation is held constant for a time after pouring; the time at constant speed varies with mold type, metal being cast, and required wall thickness

The ideal speed of rotation causes rapid adhesion of the molten metal to the mold wall with minimal vibration. Such conditions tend to result in a casting with a uniform structure.

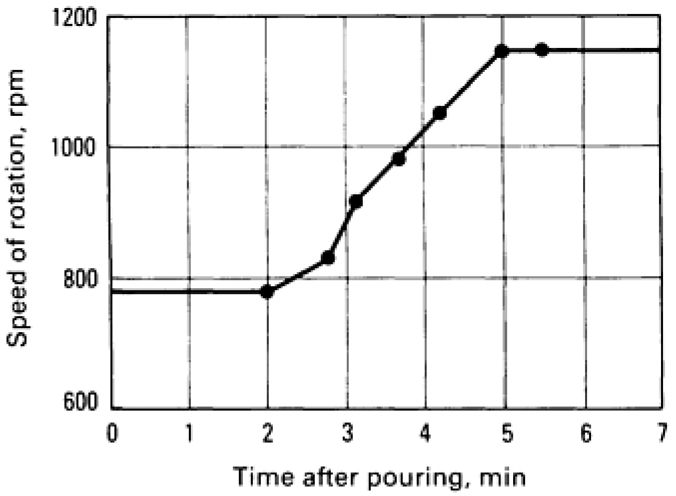

Fig. 2 Typical cycle of rotation in horizontal centrifugal casting.

As the molten metal enters the mold, a pressure gradient is established across the tube thickness by centrifugal acceleration. This causes alloy constituents of various densities to separate, with lighter particles such as slags and nonmetallic impurities gathering at the inner diameter. The thickness of these impurity bands is usually limited to a few millimeters, and they are easily removable by machining.

Too low a speed of rotation can cause sliding and result in poor surface finish. Too high a speed of rotation can generate vibrations, which can result in circumferential segregation. Very high speeds of rotation may give rise to circumferential stresses high enough to cause radial cleavage or circular cracks when the metal shrinks during solidification.

Solidification

In horizontal centrifugal casting, heat is removed from the solidifying casting only through the water-cooled mold wall. Solidification begins at the outside diameter of the casting, which is in contact with the mold, and continues inward toward the casting inside diameter. Several parameters influence solidification:

- The mold, including the mold material, its thickness, and initial mold temperature
- The thickness and thermal conductivity of the mold wash used
- Casting conditions, including degree of superheat, pouring rate, and speed of rotation
- Any vibrations present in the casting system

Thermal Aspects of Solidification. It appears that the mold-related parameters listed above have relatively little influence on solidification. Large variations in mold thickness, however, could become significant.

The parameters with the greatest effect are the degree of superheat in the molten metal and the thickness of the mold wash employed. Both of these process variables affect local solidification conditions and therefore modify the structure of the casting. Figure 3 illustrates the general effects of mold wash thickness and degree of superheat on solidification rates. Charts such as Fig. 3 can be used to predict total solidification time. They are especially useful in determining the optimal casting conditions for bimetallic tubes based on the type of bond required.

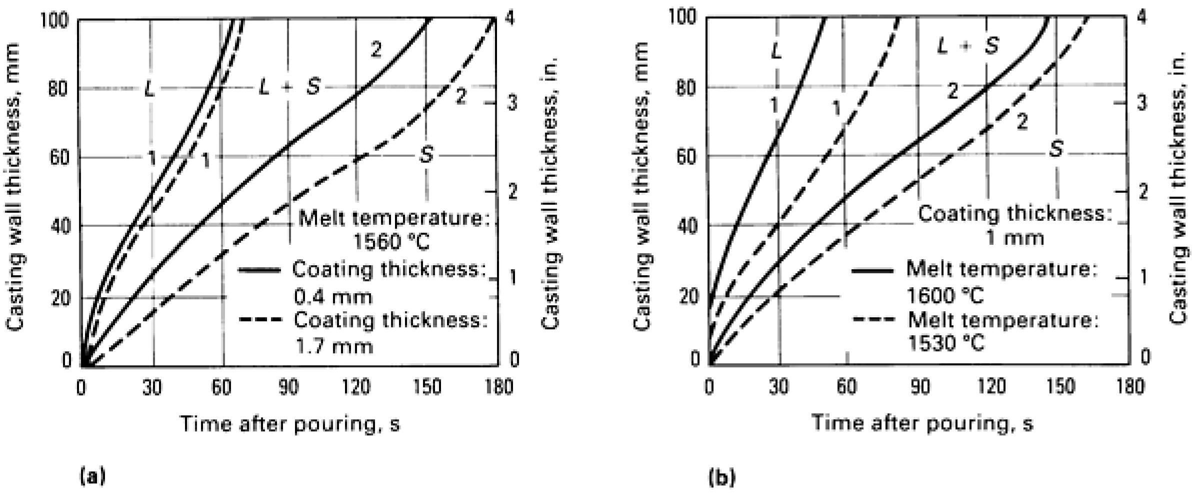

Fig. 3 Effect of mold coating thickness (a) and molten metal temperature (b) on solidification in horizontal centrifugal casting. Numbers 1 and 2 indicate liquidus and solidus curves, respectively.

Metallurgical Aspects of Solidification. The as-cast structures obtained in the horizontal centrifugal casting of steels vary according to composition. Regardless of the phase or phases that solidify first, certain features are common to the structures of centrifugally cast ferrous alloys (Fig. 4a):

- Very thin, fine columnar skin
- Well-oriented columnar structure adjacent to the skin
- More or less fine equiaxed structure

In the case of steels that solidify as ferrite, the columnar areas may be nonexistent if superheat and mold wash thickness are low (Fig. 4b). In steels that solidify as austenite, it is relatively easy to obtain well-oriented 100% columnar structures.

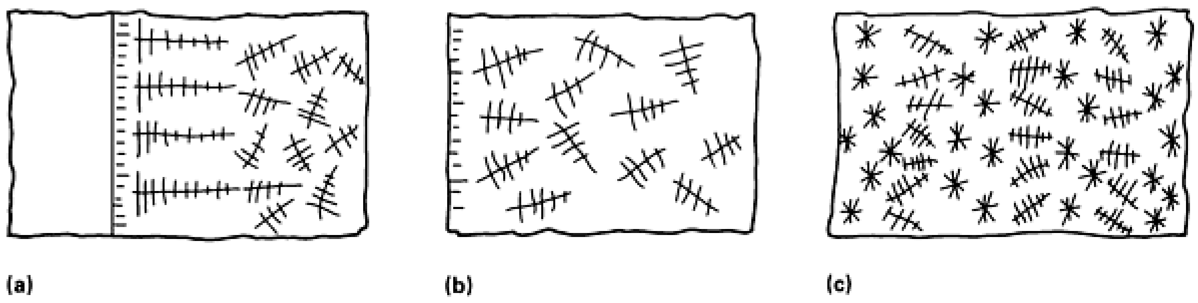

Fig. 4 Three types of as-cast structures seen in centrifugally cast ferrous alloys. (a) Fine columnar skin, large well-oriented columnar grains, and equiaxed area. (b) Completely equiaxed structure sometimes observed in ferritic steels. (c) Equiaxed bands of varying grain size. This type of structure is thought to be caused by machine vibrations.

A phenomenon specific to horizontal centrifugal casting is the formation of equiaxed bands through the entire thickness of the casting (Fig. 4c). A plausible explanation for this phenomenon is linked to machine vibrations, which may cause recirculation of the molten metal during solidification.

As in static casting, the rejection of solute ahead of the solidification front leads to microsegregation and to a progressive enrichment of the remaining liquid. Carbon steels are particularly sensitive to this effect; carbon, sulfur, and phosphorus contents must be limited to avoid local precipitation of carbides and sulfides.

Process Advantages

Flexibility in Casting Composition. Horizontal centrifugal casting is applicable to nearly all compositions with the exception of high-carbon steels (0.40 to 0.85% C). Carbon segregation can be a problem in this composition range.

Wide Range of Available Product Characteristics. The metallurgical characteristics of a tubular product are mainly characterized by its soundness, texture, structure, and mechanical properties. Centrifugal castings can be manufactured with a wide range of microstructures tailored to meet the demands of specific applications.

The high degree of microstructural control possible with horizontal centrifugal casting results in great flexibility in selecting properties for specific applications. Tubes can be manufactured with resistance to elevated temperatures, corrosion resistance, thermal fatigue resistance, low-temperature ductility, and so on. Centrifugally cast parts have a high degree of metallurgical cleanliness and homogeneous microstructures, and they do not exhibit the anisotropy of mechanical properties evident in rolled/welded or forged tubes.

Dimensional Flexibility. Horizontal centrifugal casting allows the manufacture of pipes with maximum outside diameters close to 1.6 m (63 in.) and wall thicknesses to 200 mm (8 in.). Tolerances depend on part size and on the type of mold used.

Materials

As mentioned at the beginning of this article, any material that can be statically cast can also be centrifugally cast. Materials that are currently being processed by horizontal centrifugal casting include high-strength low-alloy steels, duplex stainless steels, and chromium-molybdenum alloy steels. Also of importance are bimetallic tubes. These materials will be discussed briefly in this section. Specific applications for centrifugally cast tubes are discussed in the section "Applications" in this article.

High-strength low-alloy steels are important in offshore structures that must withstand extreme climatic conditions, for example, offshore drilling equipment in the North Sea. These materials must be weldable, with ductile-to-brittle transition temperatures below -40 °C (-40 °F). Likely candidate materials for use under such conditions are manganese-molybdenum steels with microalloying additions of vanadium, nickel, or niobium. Heavy-wall weldable pipes with good mechanical properties can be produced from such materials by horizontal centrifugal casting. Several proprietary alloys have been approved for use in offshore oil applications in the North Sea.

Duplex stainless steel tubes can be readily produced by horizontal centrifugal casting in any section size. Castings retain strength at temperatures to 600 °C (1110 °F), have good ductility, and are weldable without special precautions.

Chromium-molybdenum alloy steel tubes produced by horizontal centrifugal casting have homogeneous structures and are metallurgically sound. They are resistant to thermal fatigue and wear and have good toughness.

Bimetallic tubes with metallurgical (rather than mechanical) bonds can be readily produced by horizontal centrifugal casting. They are most commonly produced by successively casting one alloy inside the other. Bimetallic tubes are used for two primary reasons: to reduce cost by using an exotic material bonded to a less expensive backing material, and to obtain combinations of properties that could not be achieved by other methods.

There are no general rules regarding what materials can be combined in centrifugally cast bimetallic tubes, although it may be beneficial to cast the inner layer of such tubes from a material that is more fusible than the outer material. In addition, relatively thin inner layers should be manufactured from alloys with coefficients of thermal expansion smaller

than that of the outer alloy. In this way, the thin inner layer is put into compression, making it more resistant to cracking. Table 1 lists materials that are commonly combined in bimetallic tubes, as well as their applications.

Table 1 Common material combinations used in bimetallic centrifugally cast tubes

Outer material	**Inner material**	Typical applications
Chilled iron	Gray iron	**Bearing rollers**
27% Cr cast iron	Ni-Resist cast iron	**Mill rollers**
Low-alloy steel	Manganese-molybdenum steel	**Continuous casting rollers**
Low-alloy steel	Ni-Hard cast iron, martensitic or 27% Cr white iron	**Wear-resistant applications**
Chromium-nickel white iron	Gray ductile iron	**Mill rollers**
Chromium white iron	Gray iron	**Mill rollers**
Stainless steel	Gray iron	**Rollers for pulp and paper industry**
Low-alloy steel	**Pearlitic gray iron, stainless steel, or superalloy**	**Liners, pipelines for corrosives**

Applications

The flexibility of the horizontal centrifugal casting process, in terms of both materials and the wide range of part sizes that can be produced, has led to the application of centrifugally cast parts in many industries. Some of the most common applications are outlined briefly in this section.

Iron and Steel Industry. Centrifugally cast parts are used in the production of iron and steel for continuous casting rollers, rolling mill rolls, furnace rollers, special pipelines, winding spools, and other applications. Some of these uses are shown in Fig. 5.

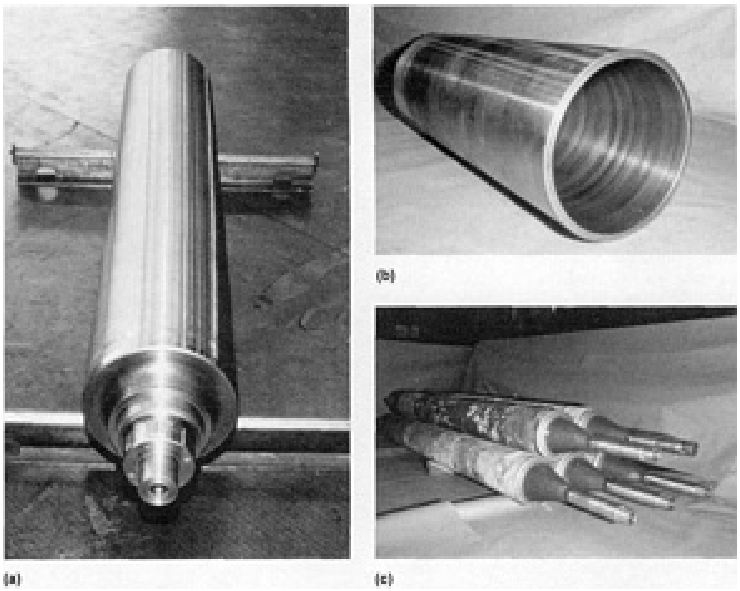

Fig. 5 Three applications for centrifugally cast parts in the iron and steel industry. (a) Continuous casting roller. (b) Winding spool. (c) Annealing furnace rollers.

Petroleum Production. Offshore production platforms in the oil and gas industry use centrifugally cast tubes in various applications (Fig. 6). Hot extruded bimetallic tubes are used in pipelines and gathering systems.

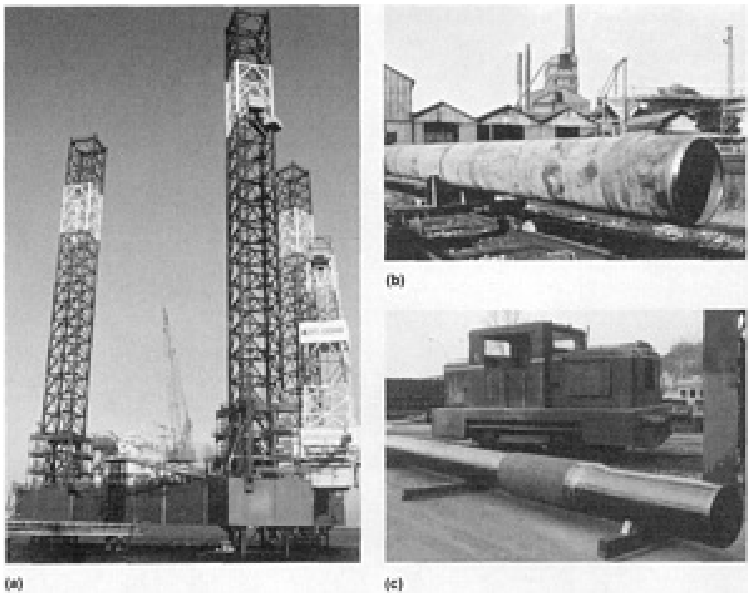

Fig. 6 Offshore petroleum production applications for centrifugally cast parts. (a) Jackup leg. (b) Risers. (c) Buckle-crack arrestor.

Other applications for centrifugally cast tubes include hydraulic cylinders, rollers for glass production, pipelines for the transport of abrasive materials, rollers in the pulp and paper industry, tubes for the chemical processing industry, foundation piles, and building columns. Some of these applications are shown in Fig. 7.

Vertical Centrifugal Casting

R.L. Dobson, The Centrifugal Casting Machine Company

There are essentially two basic types of centrifugal casting machines: the horizontal type, which rotates about a horizontal axis, and the vertical type, which rotates about a vertical axis. Horizontal centrifugal casting machines are generally used to make pipe, tubes, bushings, cylinder sleeves (liners), and cylindrical or tubular castings that are simple in shape (see the previous section "Horizontal Centrifugal Casting" in this article). The range of application of vertical centrifugal casting machines is considerably wider. Castings that are not cylindrical, or even symmetrical, can be made using vertical centrifugal casting. The centrifugal casting process uses rotating molds to feed molten metal uniformly into the mold cavity. Directional solidification provides for clean, dense castings with physical properties that are often superior to those of the static casting processes.

Centrifugal castings are produced by pouring molten metal into a rotating or spinning mold. The centrifugal force of the rotating mold forces the molten metal against the interior cavity (or cavities) of the mold under constant pressure until the molten metal has solidified. Cylindrical castings are generally preferred for the centrifugal casting process. Tubular castings produced in permanent molds by centrifugal casting usually have higher yields and higher mechanical properties

than castings produced by the static casting process. Centrifugal casting is the most economical method of producing a superior-quality tubular or cylindrical casting with regard to casting yield, cleaning room cost, and mold cost.

Centrifugal castings can be best described as isotropic, that is, having equal properties in all directions. This is not true of a forging. By utilizing the outstanding advantage created by the centrifugal force of rotating molds, castings of high quality and integrity can be produced because of their high density and freedom from oxides, gases, and other nonmetallic inclusions. An economic advantage of centrifugal castings is the elimination or minimization of gates and risers.

All metals that can be cast by static casting can be cast by the centrifugal casting process, including carbon and alloy steels, high-alloy corrosion- and heat-resistant steels, gray iron, ductile and nodular iron, high-alloy irons, stainless steels, nickel steels, aluminum alloys, copper alloys, magnesium alloys, nickel- and cobalt-base alloys, and titanium alloys. Nonmetals can also be cast by centrifugal casting, including ceramics, glasses, plastics, and virtually any material that can be made liquid or pourable.

Sand molds, semipermanent molds, and permanent molds can be used for the centrifugal casting process. Selection of the type of mold is determined by the shape of the casting, the degree of quality needed, and the production (number of castings) required.

Centrifugal Casting Processes

There are three types of centrifugal casting:

- True centrifugal casting
- Semicentrifugal casting
- Centrifuge centrifugal casting

True centrifugal casting is used to produce cylindrical or tubular castings by spinning the mold about its own axis. The process can be either vertical or horizontal, and the need for a center core is completely eliminated. Castings produced by this method will always have a true cylindrical bore or inside diameter regardless of shape or configuration. The bore of the casting will be straight or tapered, depending on the horizontal or the vertical spinning axis used. Castings produced in metal molds by this method have true directional cooling or solidification from the outside of the casting toward the axis of rotation. This directional solidification results in the production of high-quality defect-free castings without shrinkage, which is the largest single cause of defective sand castings.

Semicentrifugal casting is used to produce castings with configurations determined entirely by the shape of the mold on all sides, inside and out, by spinning the casting and mold about its own axis. A vertical spinning axis is normally used for this method. Cores may be necessary if the casting is to have hollow sections. Directional solidification is obtained by proper gating, as in static casting. Castings that are difficult to produce statically can often be economically produced by this method, because centrifugal force feeds the molten metal under pressure many times higher than that in static casting. This improves casting yield significantly (85 to 95%), completely fills mold cavities, and results in a high-quality casting free of voids and porosity. Thinner casting sections can be produced with this method than with static casting. Typical castings of this type include gear blanks, pulley sheaves, wheels, impellers, and electric motor rotors.

Centrifuge centrifugal casting has the widest field of application. In this method, the casting cavities are arranged about the center axis of rotation like the spokes of a wheel, thus permitting the production of multiple castings. Centrifugal force provides the necessary pressure on the molten metal in the same manner as in semicentrifugal casting. This casting method is typically used to produce valve bodies and bonnets, plugs, yokes, brackets, and a wide variety of various industrial castings.

Mold Design

Gating Practice. The practicality of casting a part using the semicentrifugal or centrifuge centrifugal process is determined by casting configuration. The gating system of centrifugal castings usually employs a single gate, which combines the function of gate and riser. Centrifugal force greatly magnifies the feeding action of the riser and produces a greater metal density in the casting than would otherwise result. Figure 8 shows that a centrifugal casting mold spinning at a peripheral velocity of 305 m/min (1000 ft/min) at the outer diameter of the casting(s) will have an equivalent head of 9 m (30 ft). This is equivalent to a pressure of 703 kPa (102 psi). A typical static casting has a head less than 0.3 m (1 ft) high. The centrifugal force acting on the molten metal will provide better feeding action than a static cast head; therefore, it is possible to feed molten metal into and through lighter and thinner mold sections into heavier mold sections much more easily than in static casting.

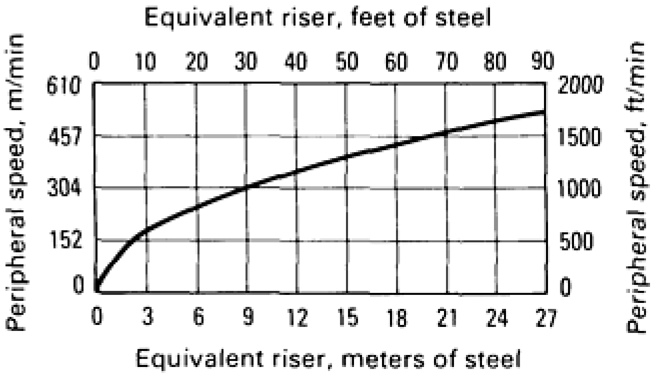

Fig. 8 Relationship between peripheral speed in centrifugal casting and equivalent riser.

Certain casting configurations that do not inherently produce directional solidification can be made to directionally solidify by certain molding practices. Pads, auxiliary gates, chills, or blind heads can be used. However, a casting of nonuniform section thickness might require such elaborate mold methods that molding and cleaning costs become too high.

Sand Molds. When sand molds are used, particularly green sand, it is usually necessary to begin pouring the molten metal at a slow mold-spinning speed. When the mold is partially or wholly poured, the spinning speed is increased to that required to prevent or reduce erosion of the mold cavities from the molten metal. Molds should almost always be poured while rotating, even if the speed of rotation is only 5 rpm. This ensures the proper distribution of hot and cold metal in the mold for the optimum feeding action.

Green Sand Molds. Centrifugal castings can be made in green sand or dry sand molds. When green sand molds are used, flasks (preferably round) are required. Three methods can be used to fasten the green sand mold to the table of the centrifugal casting machine.

In the first method, two pins are fastened to the table over which the flask is lowered. The cope and drag are held together by clamps in the usual manner of static casting.

In the second method, a device similar to a lathe chuck is fastened to the table. The cope and drag are clamped together as in static casting. The green sand mold is lowered onto the table, and the clamps are tightened to secure the mold.

In the third method, the green sand mold is transported on a roller conveyor into a flask body, which is fastened to the table. Rollers are also used in the casting machine to facilitate movement of the green sand mold. The flask body opens in half on a hinge. A cover, which holds a runner cup, serves to distribute equally the pressure from the clamping arrangement to the mold. The clamping arrangement, which is part of the flask body, keeps the cope and drag in firm contact.

Dry Sand Molds. Flasks are not required when dry sand molds are used. Two methods are available for handling dry sand molds on the casting machine.

In the first method, the dry sand molds are placed in a jacket somewhat similar to that used in conjunction with snap flasks. The jacketed mold is then carried to the casting machine and lowered to the table. Clamps are used to hold the cover onto the mold and to fasten the mold firmly to the table.

In the second method, the dry sand molds are transported on a roller conveyor into the casting machine, in which rollers are incorporated. Using a flask body of this type, both dry sand and green sand molds can be used interchangeably in the same casting machine.

Molding Costs. A green sand mold prepared for static casting generally costs the same as a green sand mold prepared for centrifugal casting. If dry sand molds are used for centrifugal casting rather than green sand, the molding cost may be higher, resulting in a reduced cost savings. There is an appreciable cost savings in the cleaning room because risers need not be removed from castings. This reduces the amount of cutting, chipping, and grinding required to clean the castings. The additional cleaning room savings might be offset by operating costs, depreciation of the centrifugal casting equipment, and possible increased molding costs due to the use of dry sand molds. An increase in yield primarily due to the elimination of riser heads is indicated in Table 2, which compares casting yields for static and centrifugal processes.

Table 2 Comparison of casting yields for miscellaneous static and centrifugal castings

Casting	**Casting weight**		**Static yield, %**	Centrifugal yield, %
	kg	**lb**		
A	27.7	61	39.0	**79.7**
B	18.1	40	53.4	**74.1**
C	7.7	17	49.2	**75.5**
D	14.1	31	38.0	**67.4**
E	27.2	60	36.3	**77.0**
F	14.3	31.5	41.5	**64.3**
G	28.6	63	40.0	**79.3**
H	20.0	44	36.4	**73.3**

Other Sand Molding Considerations. The requirements for a centrifugal sand mold or flask are more stringent than those for static cast molds because concentricity with the spinning axis must be more exact to prevent an imbalance that could cause vibration. However, most casting speeds required for centrifugal sand molding are relatively slow compared to true centrifugal casting in permanent molds. Molds made up of sections using dry sand cores are also used for centrifugal casting. The sand used can be sodium silicate, dry sand, chromite sand, or any molding material with sufficient strength to withstand the forces imposed by the spinning speed. It is desirable to use a suitable mold wash with most sand molds to reduce or minimize mold erosion from the molten metal. Excessive mold erosion generally does not occur, because of the relatively slow spinning speeds used.

Permanent Molds. Two basic types of permanent molds are in use: metal molds and graphite or carbon molds. Because of the faster heat extraction from permanent molds, there is usually an increase in the quality (especially properties) of the castings produced in this type of mold.

Metal Molds. A large number of cast iron molds are still used for centrifugal casting. However, steel molds are more common and much safer. Cast iron molds can be dangerous because of defects that may occur during the mold casting process and the fact that cast iron has relatively low tensile strength. In addition, when cast iron molds are water cooled, there is always the danger of cracking, rupture, or breakage. Most metal molds used in centrifugal casting are water cooled on the outside diameter using high-velocity water jets to increase solidification rates.

Steel molds are recommended for centrifugal casting. It is very important that the molds be perfect and free of any defects. The molds are machined all over to obtain a smooth surface and to ensure dynamic balance. A machined surface finish of 3 μm (125 μin.) RMS is recommended on the mold bore and outside diameter. If there are any defects on the portion of the mold that contacts the casting, it will be difficult, if not impossible, to remove the casting from the mold. Steel molds should always be thoroughly stress relieved (minimum temperature of 620 °C, or 1150 °F) before the finish-machining operations. In the case of small, simple molds machined from heavy-wall seamless steel tubing, it has been standard practice not to stress relieve, because there is no apparent difference in the operational life of the mold. Stress relieving effectively prevents warpage in most molds and therefore prolongs the service life of the mold.

A molybdenum disulfide lubricant is recommended for all threaded fasteners used on a mold, such as mold lock clamps, end plate bolts, mold attaching bolts, and mold centering bosses.

Various mold end plate designs (Fig. 9) can be used, depending on individual preference and the size of the mold being used.

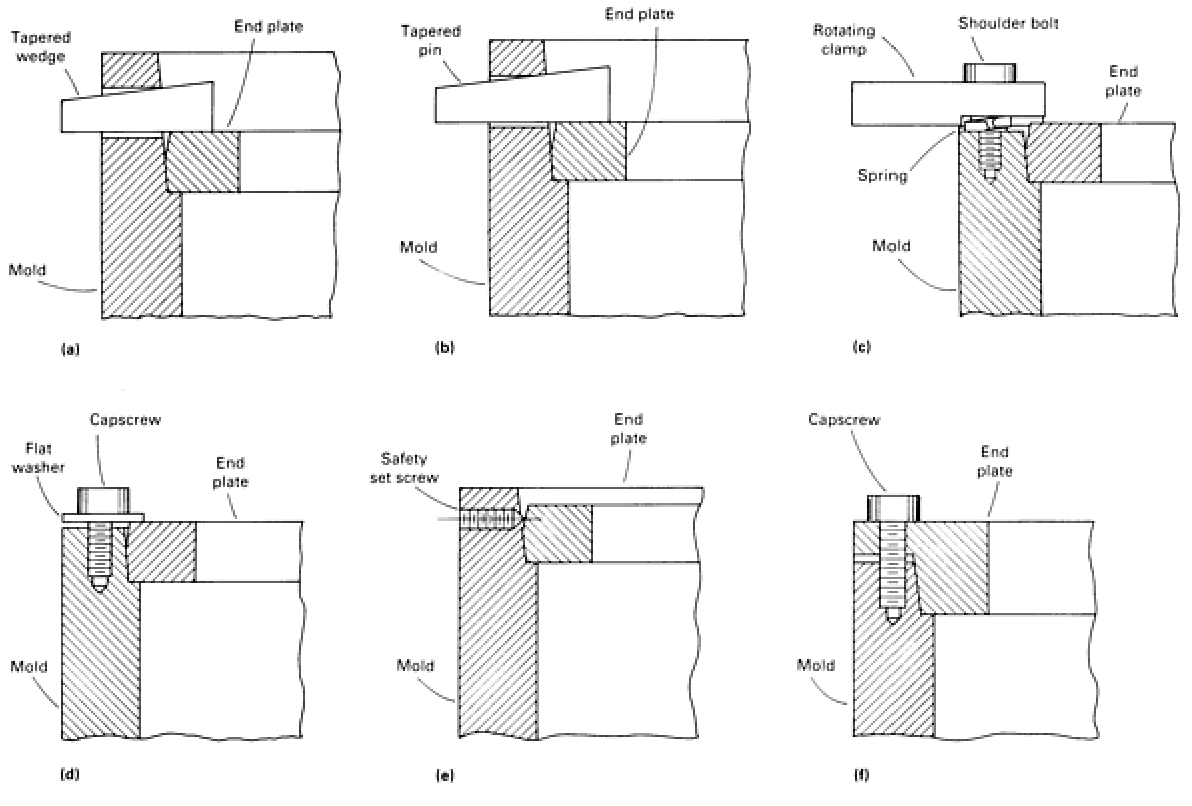

Fig. 9 Six end plate designs used in centrifugal casting. (a) through (c) are the most common.

It is recommended that low-carbon steels be used for centrifugal molds. Alloy steels and steels with more than 0.30% should not be used, because they are subject to cracking due to thermal shock and heat stresses from the casting of the molten metal. Satisfactory mold materials are 1018, 1020, or ASTM A106, grade A, steel. It is usually most convenient to make small molds from either hot-rolled solid bar stock or from heavy-wall seamless steel tubing. Larger-diameter molds

can be made from forgings or hot-rolled bar stock with the center trepanned or from centrifugally cast heavy-wall steel tubing.

Metal Mold Design. Machining allowances for castings depend on melting practices, the condition and thickness of the mold insulation coating, the volumetric shrinkage of the metal being cast, and the susceptibility of the metal to casting defects such as dross formation. The suggested machining allowances given in Table 3 can be used as a basis for mold design. With these minimum allowances, the mold can be remachined to allow for more machining allowance as determined by experience and the specific melting practices used.

Table 3 Minimum machining allowances for design of centrifugal casting molds

Casting size		Allowance on casting OD (each side)		Allowance on casting ID (each side)					
				Irons		Bronzes		Steels	
mm	in.	mm	in.	mm	in.	mm	in.	mm	in.
50-200	2-8	1.6	$\frac{1}{16}$	1.6	$\frac{1}{16}$	3.2	$\frac{1}{8}$	4.8	$\frac{3}{16}$
200-300	8-12	2.5	$\frac{3}{32}$	2.5	$\frac{3}{32}$	5	$\frac{3}{16}$	7.5	$\frac{9}{32}$
300-500	12-20	4	$\frac{5}{32}$	4	$\frac{5}{32}$	8	$\frac{5}{16}$	12	$\frac{5}{32}$
500-700	20-28	6	$\frac{7}{32}$	6	$\frac{7}{32}$	12	$\frac{7}{16}$	18	$\frac{21}{32}$
700-900	28-353	8	$\frac{5}{16}$	8	$\frac{5}{16}$	16	$\frac{5}{8}$	24	$\frac{15}{32}$

Patternmaker's shrinkage is the shrinkage allowance built into the pattern to compensate for the change in dimensions caused by the contraction of the cast metal as it cools. This shrinkage allowance is the factor with which the moldmaker is concerned. Different casting alloys have different shrinkage rates. Although average values for unrestricted cooling conditions are available (Table 4), it must be remembered that these can vary considerably according to the resistance offered by molds and cores.

Table 4 Guidelines for shrinkage allowances for various metals and alloys

Metal or alloy	Shrinkage allowance	
	in./ft	mm/m

Aluminum alloys	$\frac{5}{32}$	**13**
Aluminum bronze	$\frac{1}{4}$	**21**
Yellow brass (thick sections)	$\frac{5}{32}$	**13**
Yellow brass (thin sections)	$\frac{3}{16}$	**16**
Gray cast iron[(a)]	$\frac{1}{10}$ - $\frac{5}{32}$	**8-13**
White cast iron	$\frac{1}{4}$	**21**
Tin bronze	$\frac{3}{16}$	**16**
Gun metal	$\frac{1}{8}$ - $\frac{3}{16}$	**11-16**
Lead	$\frac{5}{16}$	**26**
Magnesium	$\frac{1}{4}$	**21**
Magnesium alloys (25%)	$\frac{3}{16}$	**16**
Manganese bronze	$\frac{1}{4}$	**21**
Copper-nickel	$\frac{1}{4}$	**21**
Nickel	$\frac{1}{4}$	**21**

Phosphor bronze	$\frac{1}{8}-\frac{3}{16}$	**11-16**
Carbon steel	$\frac{3}{16}-\frac{1}{4}$	**16-21**
Chromium steel	$\frac{1}{4}$	**21**
Manganese steel	$\frac{5}{16}$	**26**
Tin	$\frac{1}{4}$	**21**
Zinc	$\frac{5}{16}$	**26**

(a) Shrinkage in cast iron depends mainly on the speed with which the casting cools. Greater shrinkage results in more rapid cooling, less shrinkage from slower cooling.

Mold Wall Thickness. Figure 10 can be used as a general guideline for determining the proper mold wall thickness for water-cooled steel molds. Wall thicknesses may vary depending on the specific equipment and application involved. Mold wall thickness is independent of casting wall thickness for water-cooled steel molds. Casting wall thicknesses exceeding 305 mm (12 in.) have been made using these recommended mold wall thicknesses.

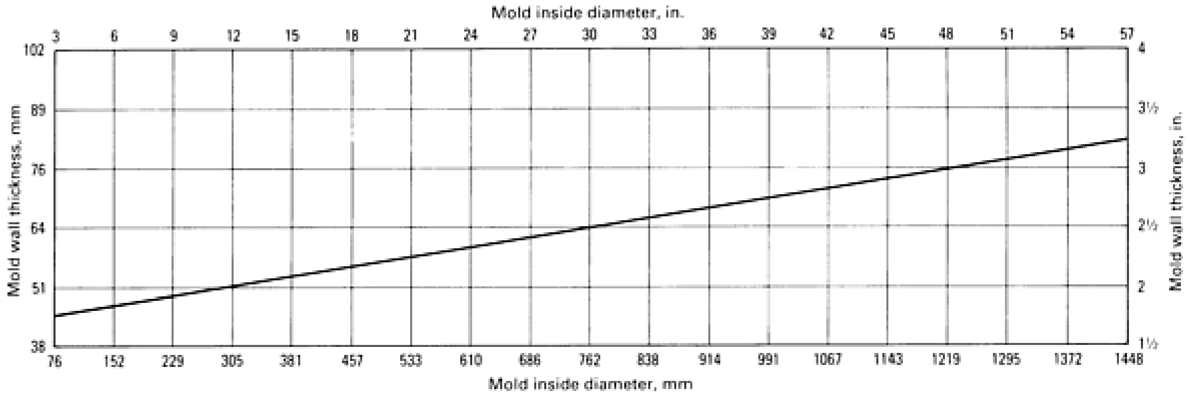

Fig. 10 Mold wall thickness as a function of mold inside diameter. Values are recommendations from one manufacturer for steel molds.

End plate thicknesses depend on casting wall thickness and end plate material. Commonly used end plate materials are ASTM A36 steel, 1015 steel, or 1018 steel plate. In cases of extremely large diameter plates (>450 mm, or 18 in.), the end plate material can be pressure vessel quality ASTM A285 grade C or A515 grade 70.

For maximum adhesion of the mold wash to flat surfaces of the mold top and bottom end plates, it is advisable to have a machined surface finish of about 9 to 13 μm (350 to 500 μin.) RMS, with the lay approximately circular relative to the center of the plate. The opening in the top plate should be at least 13 mm ($\frac{1}{2}$ in.) smaller in diameter than the casting inside diameter but large enough to permit the molten metal to enter the mold.

The end plate recess in the mold provides an effective seal to prevent leakage of the molten metal from the mold. The amount of end plate recess used depends on mold inside diameter and can be as high as the mold inside diameter plus 25 mm (1 in.) for mold inside diameters of 150 mm (6 in.) or more.

End Plate Mold Lock Design. Various removable end plates are shown in Fig. 9. These end plate types are recommended for all vertical molds. Preferred end plate types are those shown in Fig. 9(a), (b), and (c). Some end plates can be turned over to prolong their service lives, and it is recommended that they be turned over between each cast.

Mold end plate diametral clearance fit into the mold recess diameter should be a minimum of 1.2 mm ($\frac{3}{64}$ in.). This clearance is effective for end plates up to about 380 mm (15 in.) in diameter. On larger end plates, clearances as large as 2.5 mm ($\frac{3}{32}$ in.) may be necessary for easy removal and assembly. The standard draft angle of 3° will permit easy removal and assembly.

The number of fasteners or mold clamps or wedges used depends on mold diameter. Recommended numbers of fasteners are:

- Three for molds up to 250 mm (10 in.) bolt circle or outside diameter
- Four for molds from 250 to 380 mm (10 to 15 in.) bolt circle or outside diameter
- Five for molds from 380 to 480 mm (15 to 19 in.) bolt circle or outside diameter

Large diameter molds or molds for extremely heavy wall castings (>50 mm, or 2 in., in wall section) require additional fasteners for safe operation.

End Plate Wedge and Pin Design. Wedges for holding the end plate secure in the mold are principally of two different types: the tapered wedge and the tapered pin. The maximum allowable stress for tapered wedges and pins is 69 MPa (10 ksi). Wrought steel bar stock, such as cold-rolled carbon steel or stainless steel, can be used; cast pins or wedges should not be used.

The following allowable safe loads can be used regardless of the wedge or pin material:

Holder	**Maximum safe load**	
	kgf	**lbf**
Tapered wedge	1840	4060

Mold Adapter Tables. A mold adapter table (Fig. 11) is usually furnished or required with a vertical centrifugal casting machine to facilitate attachment of the molds to the machine. Also furnished or required with the mold adapter

table is a mold centering boss or index boss/plug for aligning and centering the mold so that it is concentric with the spinner shaft of the machine.

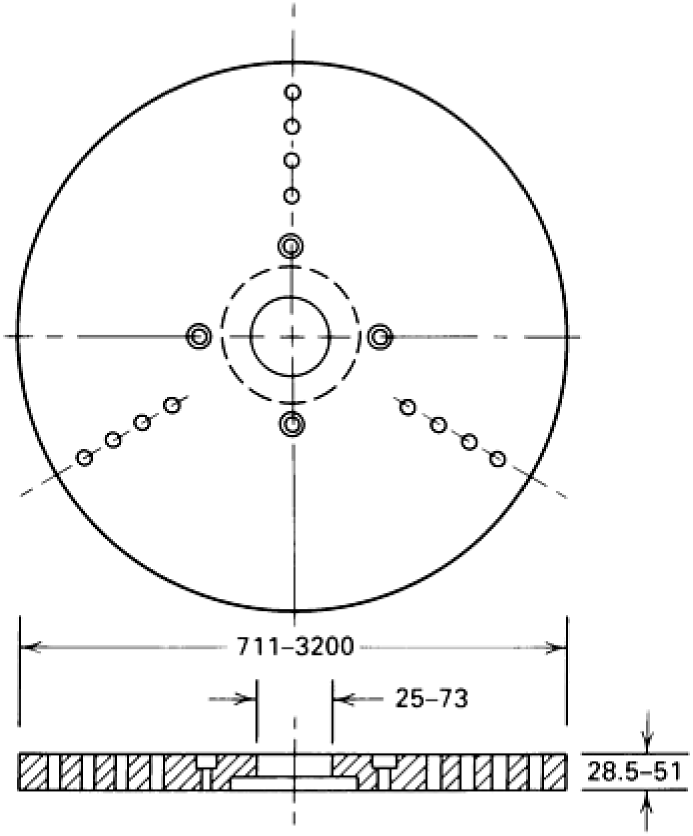

Fig. 11 Adapter table for mounting of molds on the centrifugal casting machine. Dimensional ranges are given in millimeters.

Two methods can be used to secure the mold to the adapter table. One method is to allow for a flanged extension of the bottom mold plate with holes for bolting directly into the table. The other method is to use a flanged extension of the mold bottom plate with dog clamps fastened to the table in the same manner in which a part is held on a mill table or vertical lathe.

The vertical centrifugal casting machine is available with a water-cooled bottom mold plate. Water cooling requires the machining of radial grooves or slots in the bottom of the bottom mold plate for water passage. Water cooling is sometimes advantageous for extremely heavy wall castings, which can transfer excessive heat into the bottom of the mold.

Pretreatment for Metal Molds. All molds, end plates, and surfaces to which mold wash is to be applied should be treated before use in the following manner:

- Preheat mold to approximately 150 °C (300 °F)
- Swab inside surface of mold with concentrated aqueous ammonium persulfate
- Flush mold with water to remove all contaminants. The mold can be put into service after this treatment

For new molds, the following treatment is recommended before use:

- Preheat mold to 205 to 260 °C (400 to 500 °F)

- Spray with a coating of mold wash approximately 0.8 mm ($\frac{1}{32}$ in.) thick
- Brush out mold wash, and repeat spray procedure. The mold should then be brushed out and resprayed a third time

The mold is ready for use after this treatment. If the wash still does not adhere, the mold should be cleaned again with ammonium persulfate as described above.

Mold Wash for Permanent Molds. The mold wash, when used on a permanent mold, serves as a refractory insulating material. When applied in sufficient thickness, the mold wash insulates the mold, thus reducing the surface temperature of the mold and increasing its useful life. A wide variety of centrifugal casting mold washes are commercially available, including silica, zirconia, and alumina washes. The centrifugal mold wash must be inert to the molten metal being cast.

The insulating characteristic of the mold wash is necessary to retard or slow the initial solidification rate in order to eliminate the formation of cold shuts, laps, droplets, and so on, and to produce a high-quality homogeneous outside surface on the casting. In most cases, a mold wash coating thickness of 0.8 mm ($\frac{1}{32}$ in.) is desired to obtain satisfactory castings. Spraying equipment is available for applying centrifugal casting mold washes.

Water Cooling of Permanent Steel Molds. The temperature of the mold increases with each casting poured. The mold can be operated at temperatures to 370 °C (700 °F). However, the usual operating temperatures of the mold should range from 150 to 260 °C (300 to 500 °F). To maintain this mold temperature for successive casting production, water cooling of the outside surface of the mold is generally employed. The high velocity of the water impinging upon the mold surface will prevent the formation of an insulating steam barrier, which would actually inhibit the extraction of heat from the mold. Quick-opening valves must be used to prevent warpage of the mold, and the spinning of the mold should be interlocked with the water valves to prevent spraying water on a mold that is not spinning and ultimately warping an expensive mold. In practice, the water cooling is usually activated immediately upon completion of the pouring and allowed to remain on long enough to permit the mold to be sprayed with the mold wash at the proper temperature range for the next casting cycle, after extracting the solidified casting.

Graphite and Carbon Molds. The choice between using a graphite or a carbon mold depends primarily on the availability to the user. Graphite has a higher rate of heat conductivity than carbon and is therefore sometimes used because of the desired metallurgical properties of the finished casting.

Graphite can be easily machined into a variety of intricate mold forms with a very good surface finish. Graphite molds have excellent chill characteristics, with thermal conductivity three times that of iron and a specific heat about double that of iron. The chilling ability of a material is roughly equal to the product of its mass multiplied by its specific heat. Graphite is nonreactive with most molten metals. In casting phosphorus bronze, graphite molds are not burned into as iron molds are. Carbon pickup is negligible in casting low-carbon stainless steel because of the quick chilling ability of the graphite, which almost instantaneously solidifies a skin layer of steel and therefore makes carbon pickup impossible. In certain cases where rapid chilling is not desired, an insulating mold wash is used. Graphite molds are extremely resistant to thermal shock, with a thermal conductivity about three times that of steel and a low Young's modulus. The strength of graphite molds increases with temperature.

Graphite molds are generally designed with two considerations: minimum wall thickness and weight ratio of mold to casting. A steel sleeve or master die holder is usually employed with a heat shrink-fit over the graphite mold. The steel is preheated to 425 °C (800 °F) for this shrink-fit; therefore, there is considerable compression upon the graphite mold. The graphite mold wall thickness must be sufficient to withstand the stress of the shrink-fit without breaking. For heat shrink-fit applications, the graphite mold wall should not be thinner than 19 mm ($\frac{3}{4}$ in.). The second factor is the minimum weight ratio of mold to casting to reduce the effects of graphite oxidation and to obtain the proper chilling effect. There are many factors involved in arriving at this ratio, but in general the ratio should be a minimum of 0.75. The factors that would influence a larger ratio include the heavy load imposed because of rapid succession of casts, greater chill depth desired, availability of graphite mold stock, and general flexibility in machining.

The graphite mold can be machined before or after the metal jacket or steel sleeve has been encased around the graphite. The expected life of a graphite mold depends on three major factors: stripping time, total cycle time, and permissible rebores.

Stripping time should be as long as possible to permit the casting to shrink away from the mold, particularly if the casting diameter is less than 150 to 200 mm (6 to 8 in.). With this precaution, the casting, with burrs, will not score the graphite mold wall nearly as much as when extracting the casting immediately after solidification when there is only negligible casting shrinkage.

Total cycle time between pours should be as long as possible to allow the graphite mold to cool to 95 to 150 °C (200 to 300 °F), thus reducing the time that the graphite will be above its oxidizing temperature of 425 to 480 °C (800 to 900 °F).

Permissible rebores are very influential in determining total mold life. If a casting size is of such tolerance that rebored molds cannot be considered and if there is no larger size of bushing or casting for which the mold can be used, it is obvious that total mold life will be considerably shortened.

Centrifugal Casting

Process Details

Casting Inside Diameters. When making castings on a vertical centrifugal casting machine, the inside diameter (bore) of the casting will be tapered in accordance with the following formula:

$$n = 264\sqrt{\frac{h}{r_1^2 - r_2^2}} \qquad \textbf{(Eq 2)}$$

where n is speed of rotation (in revolutions per minute), r_1 is the inside radius at the top of the casting (in inches), r_2 is the inside radius at the bottom of the casting (in inches), and h is casting height (in inches).

Actually, if the length of the casting does not exceed approximately twice its inside diameter, the amount of taper will be negligible. The optimal speed of rotation results in a centrifugal force of 75 g (75 times the force of gravity) on the inside diameter. It can be seen from Eq 2 that too slow a speed of rotation will result in excessive taper on the inside diameter of the casting.

There are castings for which it is desirable to cast the inside diameter with a predictable taper. Using Eq 2, the exact speed can be calculated to produce an approximate given taper on the inside diameter of the casting.

Speed of Rotation. To establish a temperature gradient of the molten metal from the outside diameter toward the center of rotation (that is, directional solidification), it is usually necessary for the mold to be spinning when the metal is poured. In some cases, in order to eliminate defects such as erosion and dirt in sand molds, it is desirable to pour at a slow speed of rotation. However, true centrifugal castings having a wall section of 12.7 mm ($\frac{1}{2}$ in.) or less must be poured at spinning speed because the metal in this thin section solidifies quickly.

Nomographs are available for determining the proper speed of rotation for centrifugal casting. However, Eq 3 can be used to calculate spinning speed:

$$g = 0.0000142Dn \qquad \textbf{(Eq 3)}$$

where g is the centrifugal force (in pounds per pound or number of times gravity), D is the inside diameter of the casting (in inches), and n is the speed of rotation (in revolutions per minute). Equation 3 can be easily manipulated to solve for speed.

Mold Speed Curves. Mold speeds are determined by the inside diameter of the castings to be made. The mold speed curve shown in Fig. 12 is based on the inside diameter of the casting. The length of the casting is not considered in determining mold speed.

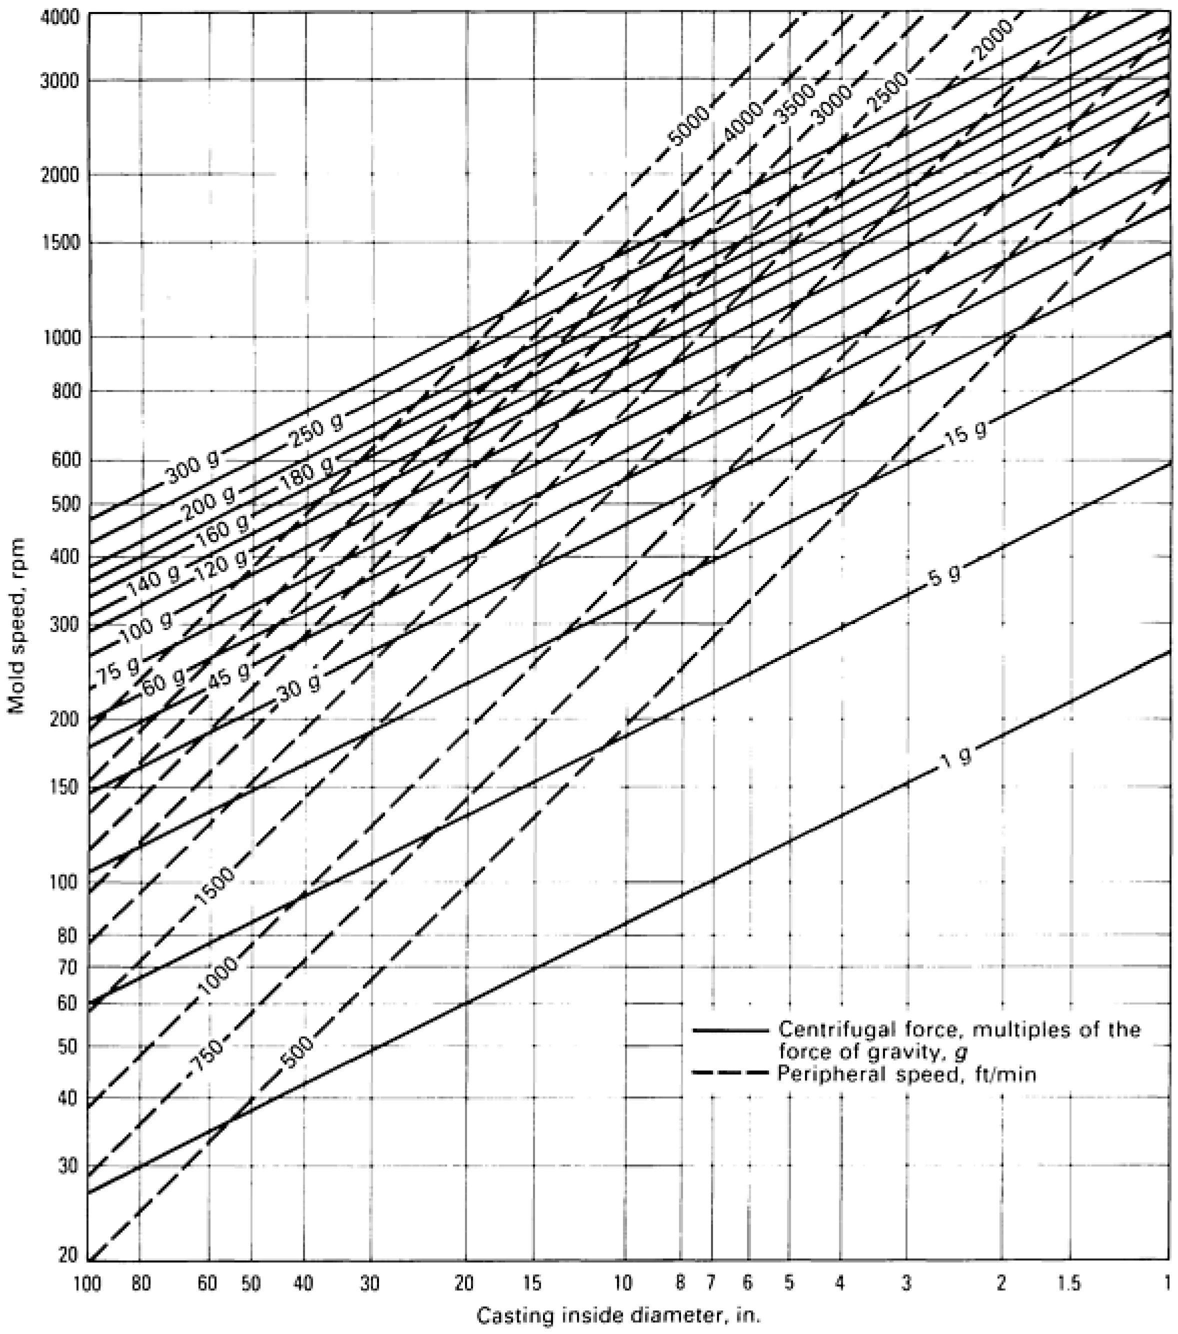

Fig. 12 Nomograph for determining mold speed based on the inside diameter of the casting and the required centrifugal force. See text for example of use.

For example, the mold speed for producing a casting 100 mm (4 in.) in outside diameter by 75 mm (3 in.) in inside diameter at a centrifugal force of 60 *g* is calculated as follows. Find the 3 in. diameter at the bottom of the curve. Move vertically from this point until the 3 in. line intersects the diagonal line marked 60 *g*. From this intersection, move directly to the right-hand edge of the curve; the speed of rotation of the mold in this case should be 1150 rpm.

Caution. From the standpoint of safety for vertical centrifugal casting, it is highly recommended that the *g* force acting on the outside diameter of the mold be considered. It is safe practice to limit this force to approximately 200 *g* on the outside diameter of the mold. After the proper mold speed is determined from the mold speed curve, this speed should be

checked with the mold outside diameter to limit the *g* force on the outside diameter to less than 200 *g*. If it is found that the force is more than 200 *g*, the speed of rotation should be slowed so that 200 *g* is not exceeded on the mold outside diameter.

Pouring Techniques. For permanent molds, the metal is generally poured about 40 °C (100 °F) higher than the temperature used for the same casting if poured statically in a sand mold. This is because of the more rapid chilling effect of permanent molds.

The pouring rates required for successful permanent mold centrifugal casting are quite high compared to those for static casting in sand molds. It is particularly important that the initial rate of pour at the beginning be very high to prevent cold laps and cold shuts. For most types of centrifugal castings weighing less than 45 kg (100 lb), a pour rate of about 9 kg/s (20 lb/s) is recommended. For castings weighing up to 450 kg (1000 lb), an initial pour rate of 9 to 23 kg/s (20 to 50 lb/s) is recommended. For castings weighing more than 450 kg (1000 lb), pour rates of 45 to 90 kg/s (100 to 200 lb/s) are recommended. When pouring into a vertically spinning mold, it is important to introduce the molten metal into the mold in such a way as to prevent or minimize turbulence of the molten metal, which can cause splashing, spraying, or droplets and can result in undesirable casting defects.

Although many vertical centrifugal castings can be poured directly into the mold from the ladle to produce a quality centrifugal casting, it is more often desirable to use a pouring funnel. With a pouring funnel, the nozzle can be lined to the required diameter so that, with a certain riser height of molten metal in the funnel, a controlled pour rate can be obtained for a particular casting weight. In addition, with a pouring funnel, the entry of molten metal into the mold can be made to impinge upon the body of the mold with initial metal flow in the direction of mold rotation. This type of pouring will provide superior casting quality by minimizing or eliminating any upsetting turbulence in the flow of molten metal that might cause defects. Figure 13 shows a pouring funnel and funnel position.

Extraction of Castings. Commercially available casting pulling tongs (Fig. 14) are recommended for extracting vertical centrifugally cast castings. These pullers engage onto the inside diameter of the casting and are used to lift the casting from the mold.

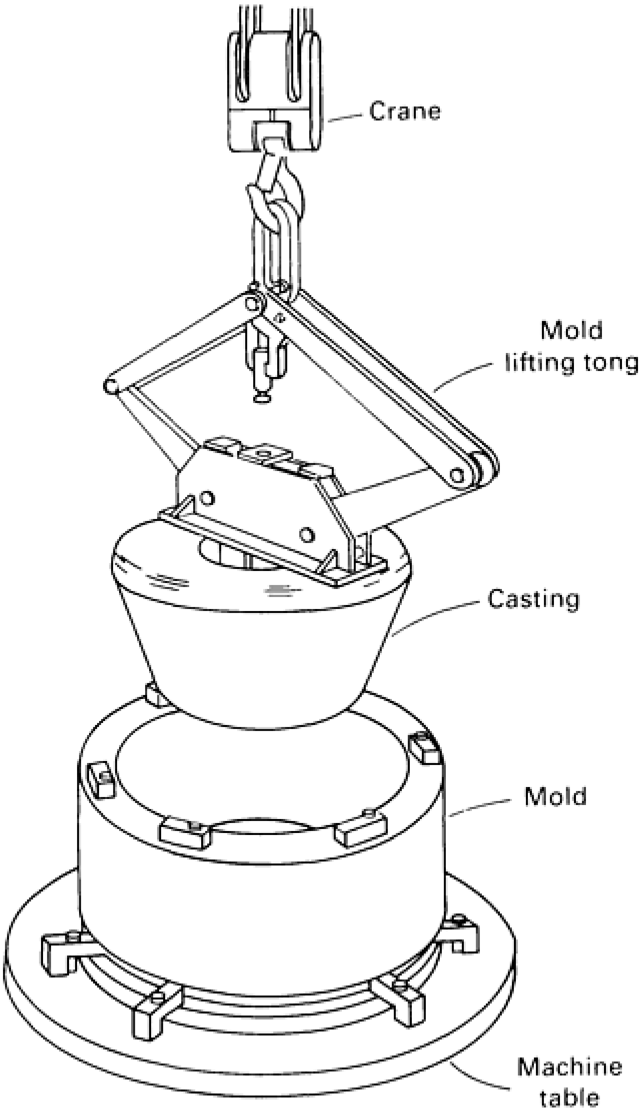

Fig. 14 Lifting tong assembly used to extract centrifugal castings from the mold.

Defects in Centrifugal Casting

Segregation banding occurs only in true centrifugal casting, generally where the casting wall thickness exceeds 50 to 75 mm (2 to 3 in.). It rarely occurs in thinner-wall castings. Banding can occur in both horizontal and vertical centrifugal castings.

Bands are annular segregated zones of low-melting constituents, such as eutectic phases and oxide or sulfide inclusions. They are characterized by a hard demarcation line at the outside edge of the band that usually merges into the base metal of the casting.

Most alloys are susceptible to banding, but the wider the solidification range and the greater the solidification shrinkage the more pronounced the effects may be. Banding has been found when some critical level of rotational speed is attained, and it has been associated with very low speeds, which can produce sporadic surging of molten metal. Therefore, both mechanisms may be involved. Minor adjustments to casting operation variables, such as rotational speed, pouring rate, and metal and mold temperatures, will usually reduce or eliminate banding.

Various theories have been presented to account for banding. One holds that vibration is the principal cause and that during solidification a zone of low-melting liquid exists immediately adjacent to the main crystal growth. Nucleation can occur, and if disturbed by vibration, banding results. This theory further states that growth takes place from these new nuclei in such a manner as to form a sandwich of liquid metal surrounded by solid metal, which is isolated from the liquid bath at the bore.

Another theory proposes that banding can be caused by variations in gravitational force between the top and bottom of the mold and that centrifugal separation of the constituents of the metal occurs once per revolution during the period of solidification. This theory does not bear close examination because it assumes that solidification will occur in a matter of seconds even in very thick sections. In reality, solidification takes place over a period of many minutes in thick sections.

Another explanation for banding supposes that the process is far less complicated and that there are irregularities in the flow of the liquid metal (incipient laps) as it enters the rotating mold. As the metal enters the mold, it forms a tubular casting that tends to solidify in the normal manner; however, if the additional liquid metal arrives at a particular position too late, the initial liquid metal has already partially solidified. This would result in a distinct lap, cold shut, or lamination and/or banding.

Raining. In a horizontal machine, raining can occur if the mold is rotated at too low a speed or if the metal is poured into the mold too fast. In this phenomenon, the metal actually rains or falls from the top of the mold to the bottom. More information on raining is available in the section "Horizontal Centrifugal Casting" in this article.

Vibration Defects. Vibration can cause a laminated casting. It can be held to a minimum by proper mounting, careful balancing of the molds, and frequent inspection of rollers, bearings, and other vital parts.

Equipment

Vertical centrifugal casting machines are used for producing bushings and castings that are relatively large in diameter and short in length. The usual maximum length of the casting is two times the outside diameter of the casting. Vertical axis machines are also used for producing castings of odd or asymmetrical configurations. Table 5 lists the load capacities of vertical centrifugal casting machines from one manufacturer.

Table 5 Load capacities of the vertical centrifugal casting machines of one manufacturer

All loads are based on balanced loads for thrust loads only and are calculated based on an L_{10} bearing life of 100,000 h.

Machine speed, rpm	Capacity of indicated proprietary model number			
	Model AS, Model C		Model VS, Model VSC, Model E	
	kg	**lb**	**kg**	lb
100	6930	15,270	21,260	**46,875**

200	6930	15,270	17,275	**38,085**
300	6130	13,520	15,355	**33,850**
400	5620	12,395	14,025	**30,925**
500	5260	11,595	13,140	**28,970**

Safety. The importance of safety in machine design, mold design, installation, and operation cannot be overemphasized. A centrifugal casting machine and installation should incorporate all of the safety factors possible. Centrifugal force increases directly as the square of the speed of rotation and directly as the length of the radius from the axis of rotation. Centrifugal force can be tremendous and very destructive. Speeds of rotation should never exceed those required to produce the casting. Molds must be centered on the spinning axis as accurately as possible and must be statically or dynamically balanced if necessary.

The method of attachment of both bottom and top cover plates to the mold is of great importance for withstanding and containing the force of the molten fluid metal while spinning. All clamping arrangements should be designed to tighten with, or to be unaffected by, centrifugal force. Molds should be firmly clamped to the table because unbalanced molds may fly off the table during operation. Adequate safety guards with interlocks should be used around all machines to protect workers from molten metal, which can spray from the mold if too much metal is poured.

Heat expansion can occur suddenly and rapidly in the mold body, top and bottom mold plates, and even into the centrifugal casting machine. This sudden expansion can put bending and shearing stresses into fasteners and other retention and clamping devices. A thorough understanding of the forces involved in centrifugal casting is necessary to ensure the utmost in safety for all concerned.

Moisture in a sand mold or moisture in the mold wash can turn into steam when the molten metal contacts it, and the resulting forces would be incalculable. Most vertical centrifugal casting machines should be installed completely below floor level for maximum operator safety. Figure 15 illustrates such an installation.

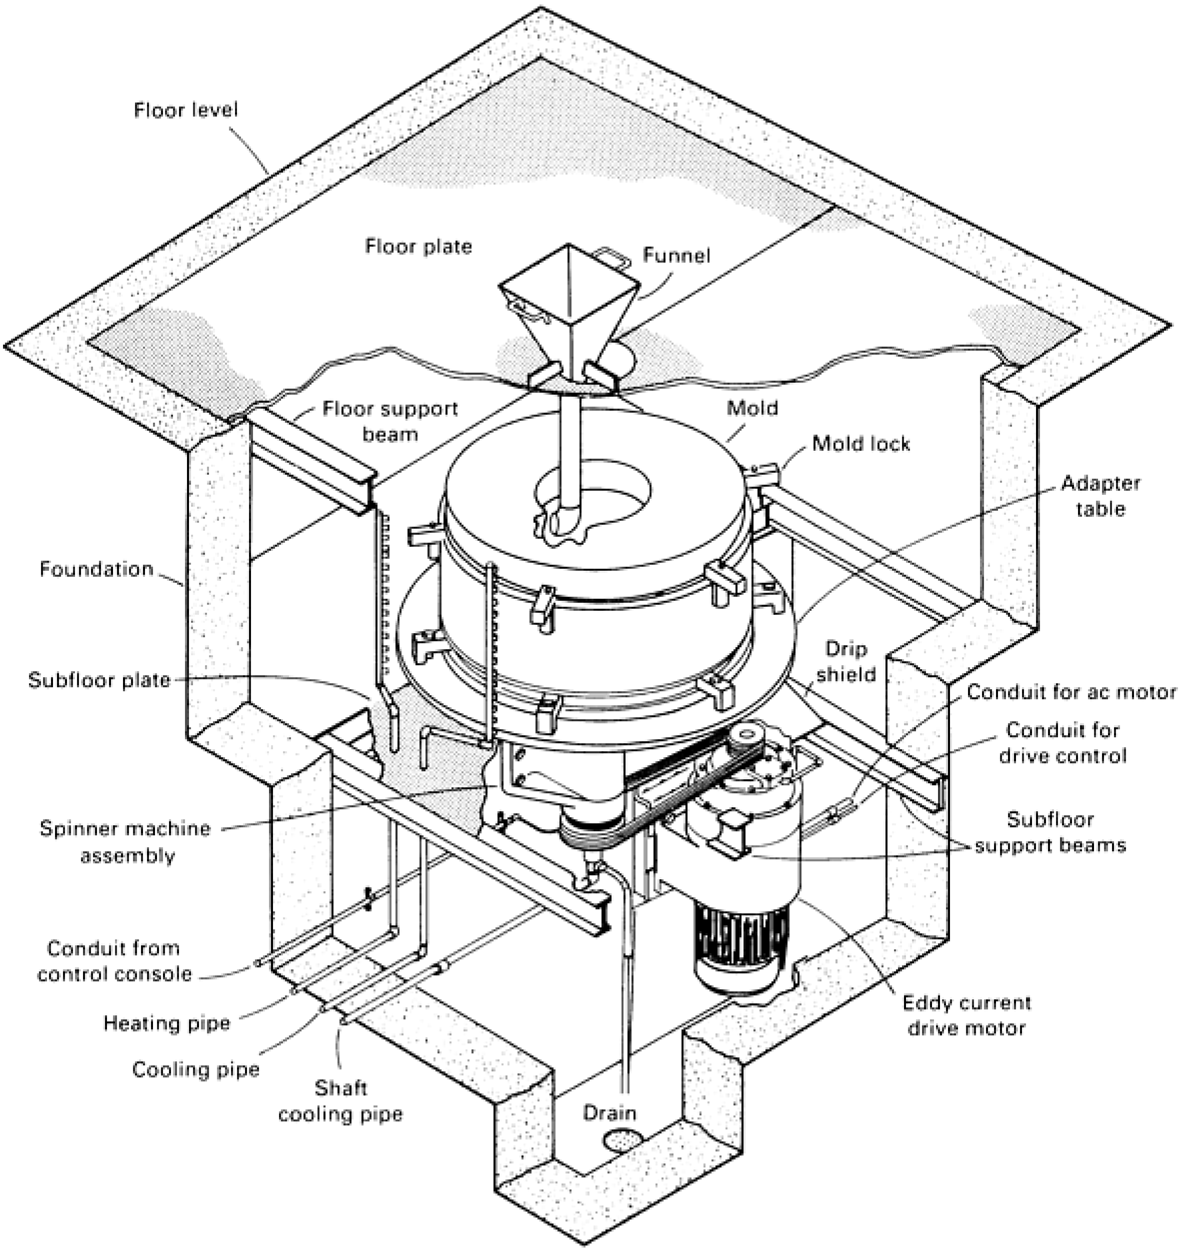

Fig. 15 Typical installation of a vertical centrifugal casting machine. The equipment is controlled from a remote console (not shown).

Continuous Casting

Introduction

THE ADVANTAGES OF CONTINUOUS CASTING in primary metals production have been recognized for more than a century. In recent decades, a dramatic growth of this processing technology has been realized in both ferrous and

nonferrous metal production. The principal advantages of continuous casting are a substantial increase in yield, a more uniform product, energy savings, and higher manpower productivity. These advantages and the ease of integration into metals production systems have led to the wide application of continuous casting processes.

Historical Aspects of Continuous Casting

One of the earliest references to continuous casting is a patent granted in 1840 to George Sellers, who had developed a machine for continuously casting lead pipe (Ref 1). There is some indication that this process had been underway before Sellers' patent, which was directed toward improvement of this continuous casting process. The first work on continuous casting of steel was by Sir Henry Bessemer, who patented a process for "manufacture of continuous sheets of iron and steel" in 1846 and made plant trials on continuous casting of steel in the 1890s (Ref 2).

Although continuous casting had its start before the beginning of the 20th century, it was not until the mid-1930s in Germany that commercial production of continuously cast brass billets was introduced. Sigfried Junghans, an active inventor of casting technology, provided many improvements in the process, in particular the introduction of the oscillating-mold system to prevent the casting from sticking to the mold. Further development of the process for the casting of nonferrous metals continued, including the installation of processing units in North America. Mold lubrication in the form of oil, or, more recently, low-melting slag powders, was introduced. Taper of the mold to compensate for metal shrinkage on solidification provided improved heat transfer and, more importantly, fewer cracks.

In 1935, a plant with casting rolls for continuous production of brass plates was operated at Scovill Manufacturing in the United States and the Vereinigte Leichtmetallwerke in 1936 started a semicontinuous casting machine for aluminum alloys. Immediately after World War II, commercial development of continuous casting of steel began in earnest, with pilot plants at Babcock and Wilcox Company (United States), Low Moor (Great Britain), Amagasaki (Japan), Eisenwerk Breitenfeld (Austria), BISRA (Great Britain), and Allegheny Ludlum Corporation (United States). These were followed by production plants for casting billets in the West and stainless slabs in the Soviet Union and Canada (the latter at Atlas Steels) (Ref 3).

The Schneckenburger and Kung patent on the curved strand was filed in Switzerland in 1956 and production was commercialized with a billet machine at Von Moosche Eisenwerke (Switzerland) in 1963. In 1961, at Dillingen Steelworks (West Germany), the first vertical-type large slab machine with bending of the strand to horizontal discharge was started up. In 1964, Shelton Iron and Steel (Great Britain) was the first new steelworks to turn out its entire production by continuous casting, consisting of four machines with 11 strands for medium to very large bloom sizes, and operating in connection with Kaldo converters. That same year, the first Concast S-type curved-mold machine for large slabs was started up at Dillingen Steelworks (West Germany). The height of this type of machine was less than 50% of the corresponding height of a vertical type of machine. In the same year, a bow-type slab caster was presented by Mannesmann (West Germany). In 1968, McLouth Steel (United States) started up four curved-strand slab casting machines immediately after the first four-strand low head caster for large slabs in the West was started up at the Weirton Steel Division of National Steel (United States). Subsequently, National pioneered the casting of slabs for tinplate applications (Ref 3).

Continuous Casting of Steel

Continuous casting of steel is entering a new era of development, not only with respect to its increasing application in the production process, but also in its own evolution as a process and its interaction with other processes in steel manufacture. Continuous casting output has shown an accelerating growth curve. More than 50% of current world steel production is continuously cast, and continuous casting in Japan exceeds 80%. The advantages of the process, along with its developments and current challenges for improvement, are outlined in the following sections.

General Description of the Process

The purpose of continuous casting is to bypass conventional ingot casting and to cast to a form that is directly rollable on finishing mills. The use of this process should result in improvement in yield, surface condition, and internal quality of product when compared to ingot-made material.

Continuous casting involves the following sequence of operations:

- Delivery of liquid metal to the casting strand
- Flow of metal through a distributor (tundish) into the casting mold
- Formation of the cast section in a water-cooled copper mold
- Continuous withdrawal of the casting from the mold
- Further heat removal to solidify the liquid core from the casting by water spraying beyond the mold
- Cutting to length and removing the cast sections

A diagram showing the main components of a continuous casting machine is presented in Fig. 1. Molten steel in a ladle is delivered to a reservoir above the continuous casting machine called a tundish. The flow of steel from the tundish into one or more open-ended, water-cooled copper molds is controlled by a stopper rod-nozzle or a slide gate valve arrangement.

To initiate a cast, a starter, or dummy bar, is inserted into the mold and sealed so that the initial flow of steel is contained in the mold and a solid skin is formed. After the mold has been filled to the desired height, the dummy bar is gradually withdrawn at the same rate that molten steel is added to the mold. The initial liquid steel freezes onto a suitable attachment of the dummy bar so that the cast strand can be withdrawn down through the machine. Solidification of a shell begins immediately at the surface of the copper mold. The length of the mold and the casting speed are such that the shell thickness is capable of withstanding the pressures of the molten metal core upon exiting from the copper mold. To prevent sticking of the frozen shell to the copper mold, the mold is normally oscillated during the casting operation and a lubricant is added to the mold. The steel strand is mechanically supported by rolls below the mold where secondary cooling is achieved by spraying cooling water onto the strand surface to complete the solidification process. After the strand has fully solidified, it is sectioned into desired lengths by a cutoff torch or shear. This final portion of the continuous casting machine also has provision for disengagement and storage of the dummy bar.

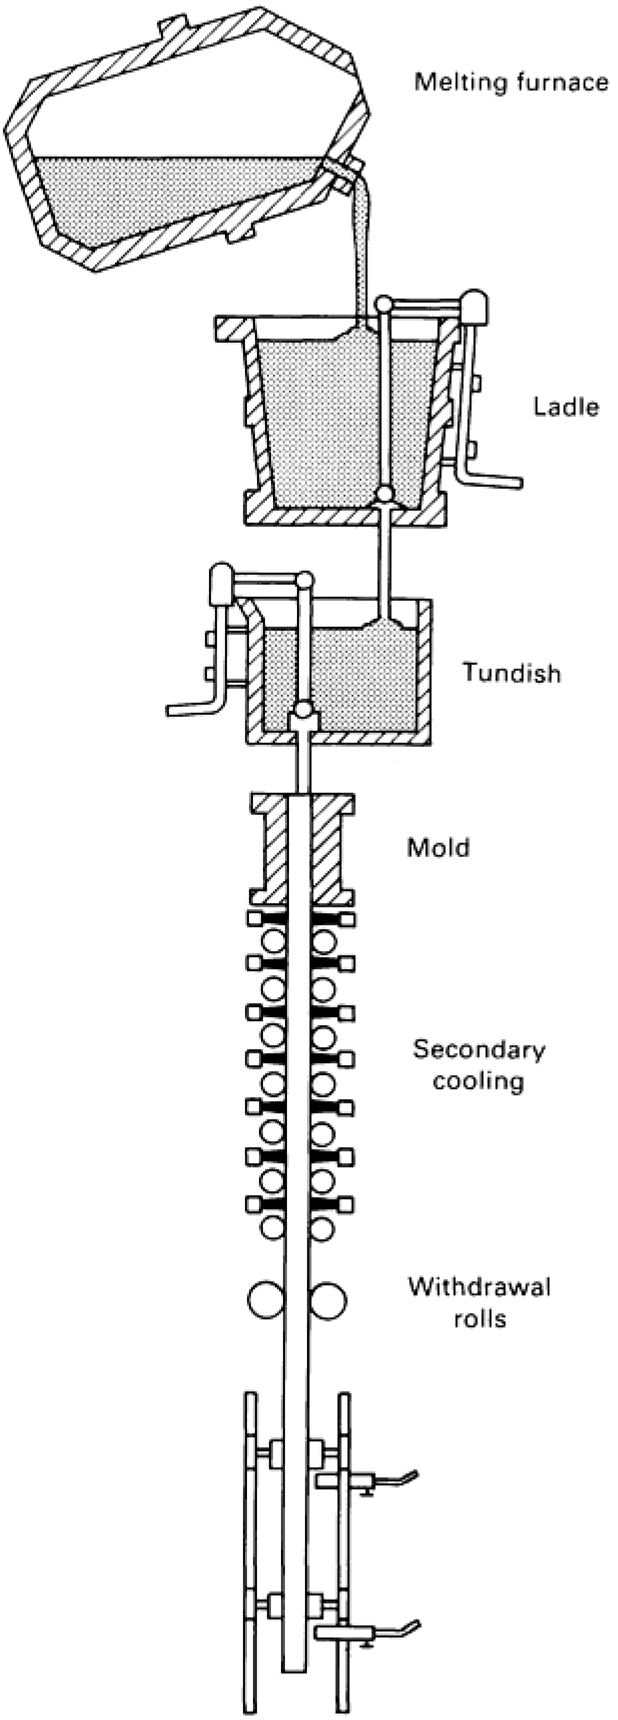

Fig. 1 Main components of a continuous casting strand. Source: Ref 4

Several arrangements are now in commercial use for the continuous casting of steel. The types of continuous casting machines in use include vertical, vertical with bending, curved or S-strand with either straight or curved mold, curved strand with continuous bending, and horizontal. Examples of the principal types of machines currently producing slabs are shown in Fig. 2.

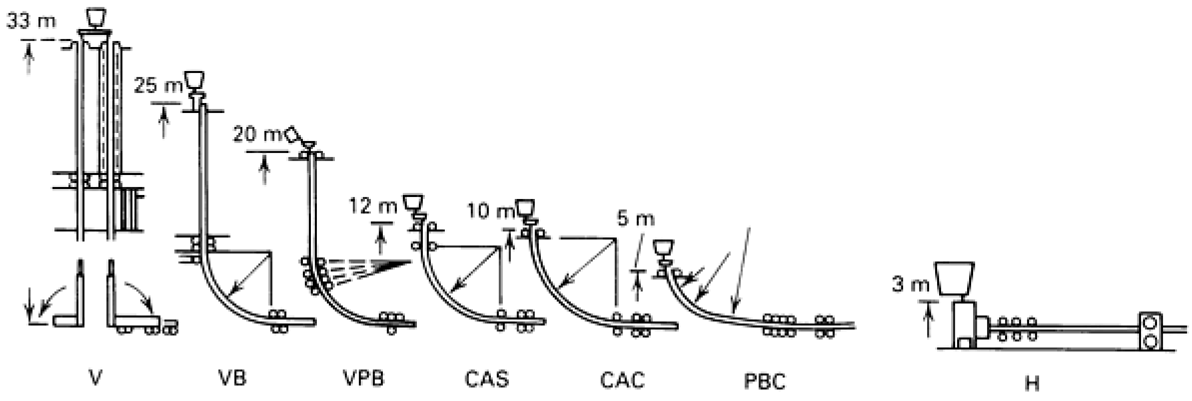

Fig. 2 Principal types of continuous casting. V, vertical; VB, vertical with bending; VPB, vertical with progressive bending; CAS, circular arc with straight mold; CAS, circular arc with curved mold; PBC, progressive bending with curved mold; H, horizontal. Source: Ref 5

Most of the original continuous casting machines for steel were vertical machines. Vertical machines with bending and curved strand machines, although more complicated in their construction, were developed to minimize the height of the machine and allow installation in existing plants without modification of crane height. Four basic caster designs for slabs are shown in Fig. 3, with an indication of the required installation height and the corresponding solidification distance or metallurgical length (ML).

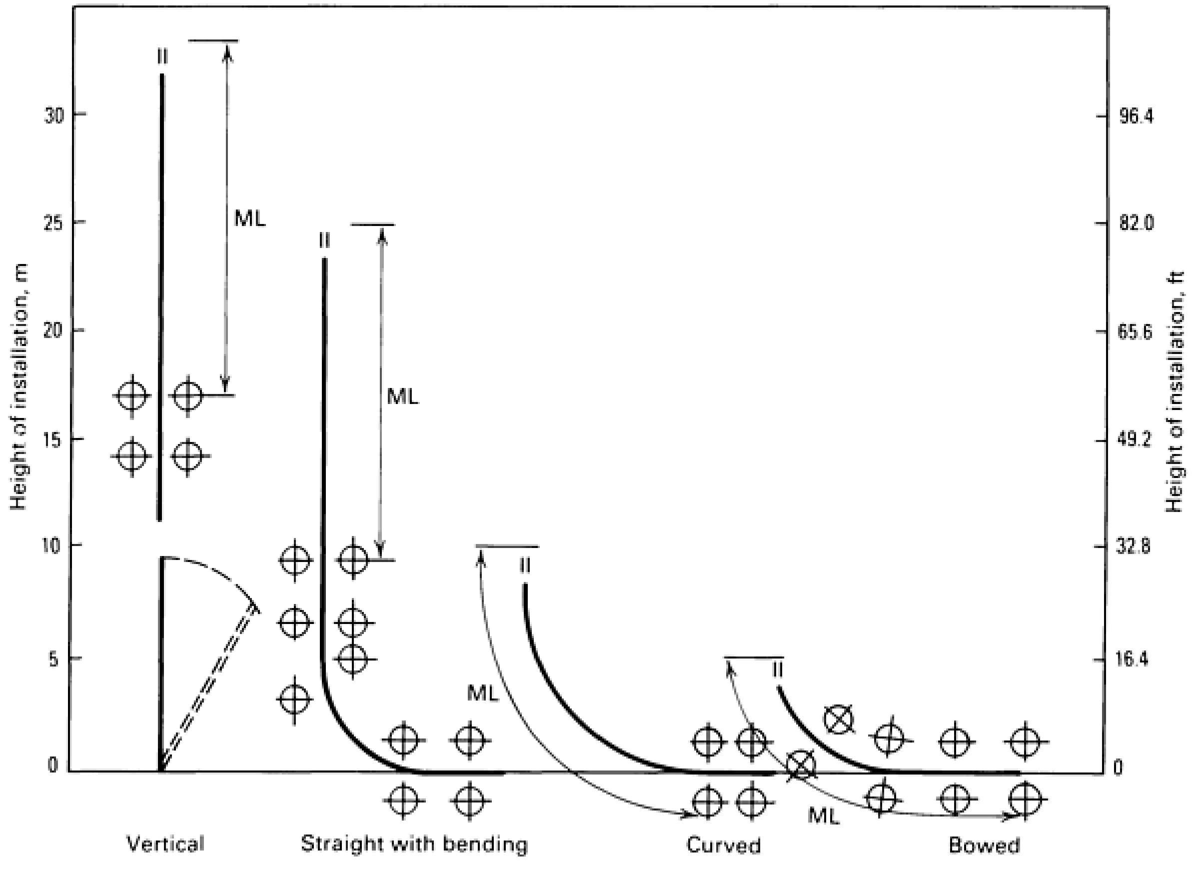

Fig. 3 Four basic designs for continuous casting machines. ML, metallurgical length. Source: Ref 6

Plant Layout

The design and layout of a steelmaking facility often focus initially on continuous casting. The optimum plant layout varies markedly from one installation to another. One major factor in the configuration is whether or not the steelmaking complex is being constructed on a greenfield site or being added ("shoehorned") into an existing works. Many of the major integrated steel works in Japan were constructed as greenfield installations during the period from 1960 to 1975. Most of the minimills constructed throughout the world, and in particular in the United States, were also built on greenfield sites.

In building a greenfield site, the plant layout should incorporate two major features: a smooth and well-organized arrangement for material handling and flow, and the capacity for future expansion. Generally, these plants are designed for 100% continuous casting, and no ingot facilities are included (Ref 7). Nearly all of the recently built minimills incorporate one or more electric furnaces and provide for 100% continuous casting of billets. Chaparral Steel Company at Midlothian, TX is an excellent example (Ref 8). A profile of a proposed large-scale electric furnace billet casting plant is shown in Fig. 4.

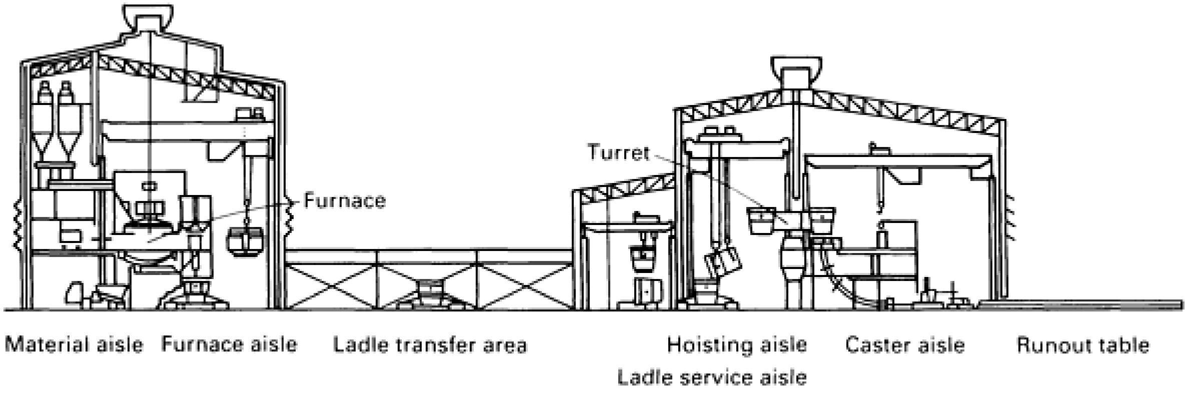

Fig. 4 Proposed melt shop capable of producing 1.2 million Mg (1.32 million tons) of billets annually. Source: Ref 9

A twin-strand slab caster was shoehorned into the Number 4 basic oxygen furnace shop at Inland Steel Company. The addition of this caster substantially increased the output of this facility, where ingot casting was the rate-limiting step in production. The arrangement of this installation showing the caster and ingot facilities is presented in Fig. 5.

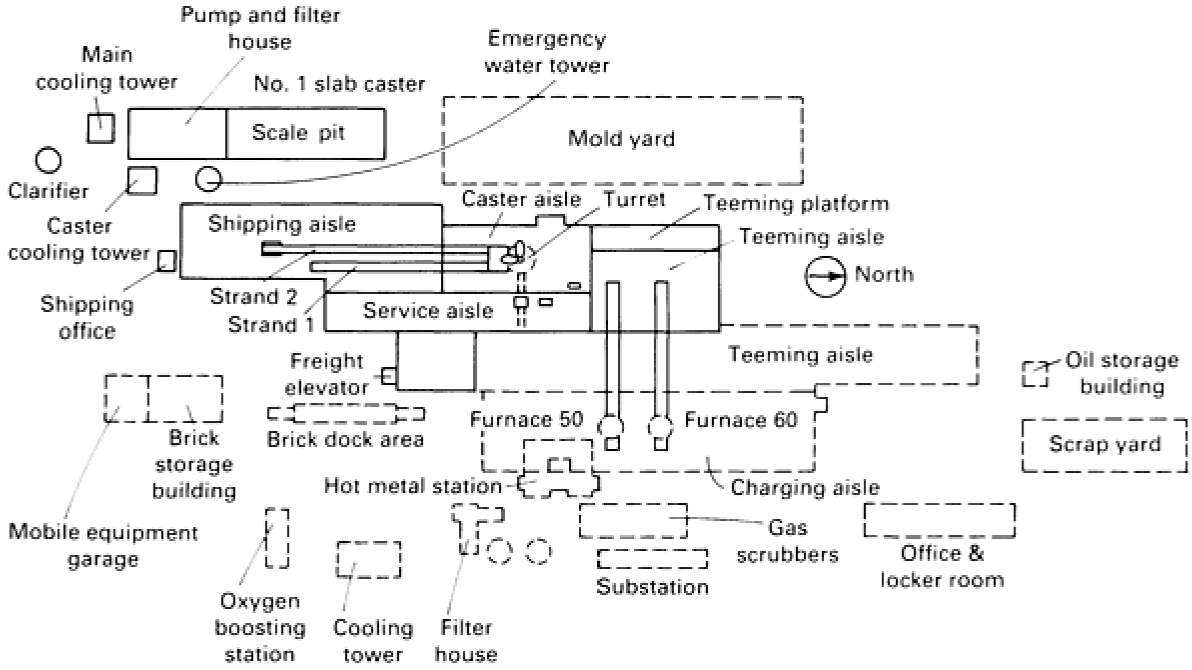

Fig. 5 Plant layout at the Inland Steel Company. Source: Ref 10

An important characteristic of the plant layout, and in particular of the material-handling facilities, is the concept that the continuous casting machine cannot wait. This design and operating concept has had a dramatic impact on steelmaking operations, which have now become a synergism to the continuous casting facilities. Because of this shift in priorities, marked improvements in productivity have been developed for continuous casting, as outlined below.

Dramatic increases in energy costs, as well as the desire for higher productivity, led to the development of the "hot connection". Substantial energy savings can be achieved by directly charging the hot continuously cast slab or billet to the reheating furnaces of the rolling mill. The latest installations have included direct in-line hot rolling of the cast product.

Process Development and Machine Design

A number of methods for distributing liquid steel to the mold or to several molds of the casting machine have been investigated. Use of a tundish with appropriate flow control has been found to be a superior method for the production of quality steel. Considerable effort has been directed toward improvement of refractories and development of methods for preventing nozzle blockage. Geometric arrangements in tundishes, including the use of dams and weirs, have provided suitable fluid flow characteristics to maximize the separation of nonmetallic inclusions, resulting in improved quality. Another factor in separation of nonmetallic inclusions in the tundish is tundish size because of its effect on residence time. Figure 6 indicates the trend in tundish size for major slab casting installations over the past 20 years.

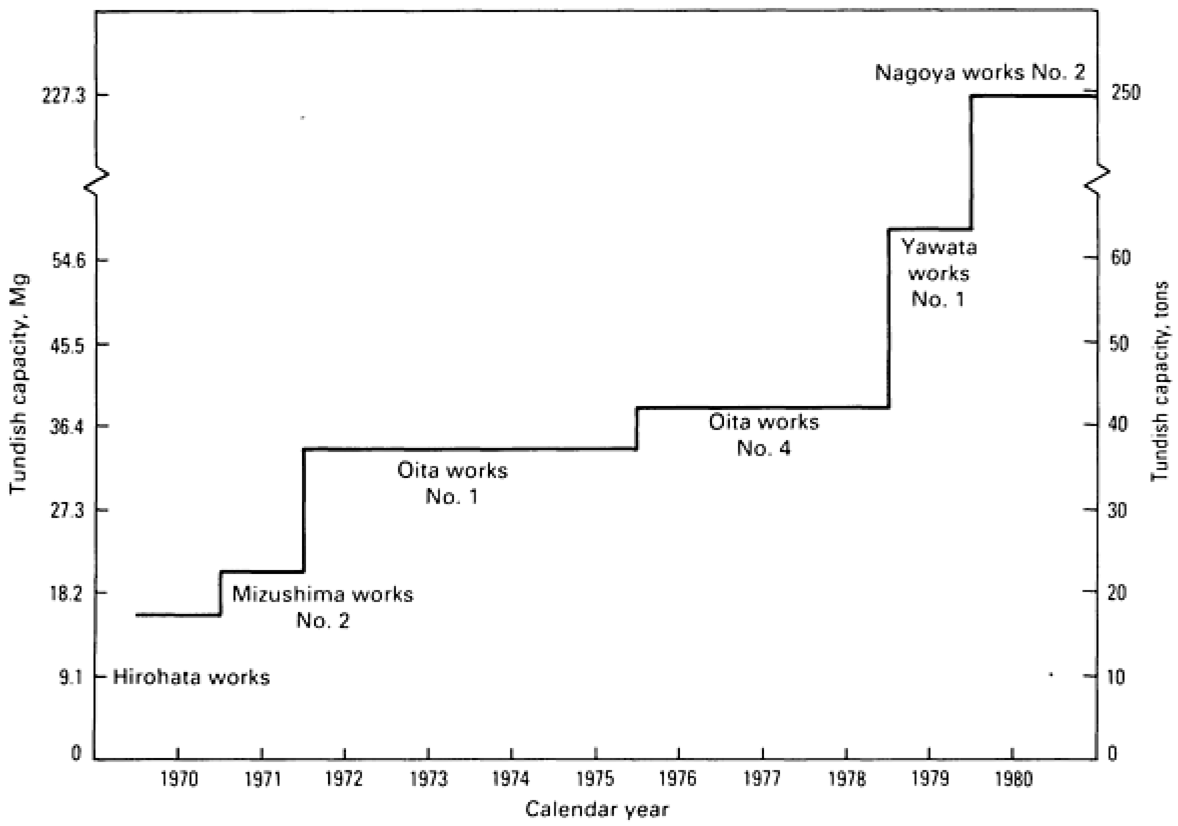

Fig. 6 Increases in capacity of tundishes for a two-strand slab caster. Source: Ref 11

Reoxidation of the molten steel is to be avoided. The use of refractory shrouds between the ladle and the tundish and the tundish and the mold have been adopted for slab casting (Fig. 7).

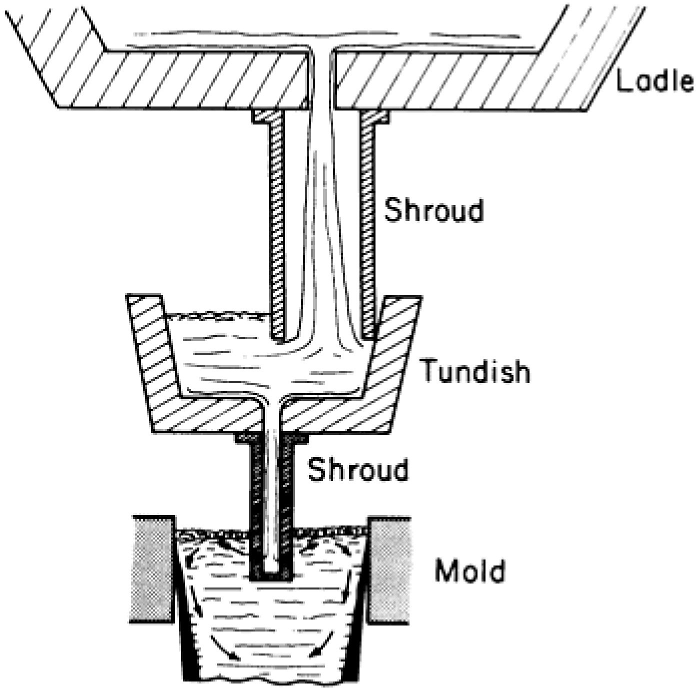

Fig. 7 Pouring shrouds from ladle to tundish to mold. Source: Ref 12

One of the difficulties encountered in continuous casting of small sections has been the protection of the pouring stream from tundish to mold because of the inapplicability of a pouring tube and the mechanical difficulty caused by the oscillation of the mold relative to the fixed tundish. In one instance, this has been overcome by the use of a flexible bellows (Fig. 8) and successfully applied to the continuous casting of special product quality steel bars. Recently, further development has been made in the use of ceramic shrouds to protect pouring streams on billet machines.

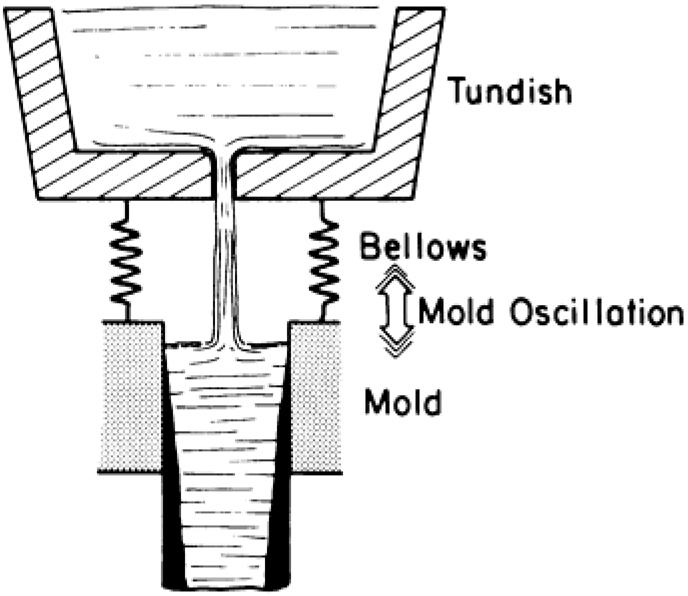

Fig. 8 Bellows between tundish and mold for casting billets. Source: Ref 12

Protection of the surface of the molten steel pool in the tundish has been achieved through the use of suitable synthetic oxide slags, inert-gas blanketing, and a refractory cover to seal the tundish. The metal level in the tundish, as well as the fluid flow pattern, is important in avoiding the ingestion of the slag layer into the metal stream flowing downward into the mold.

The tundish is supported with either two tundish cars or a two-position turret. Frequently, the double turret provides for changing of the tundish while continuing the casting process, which allows extended sequence casting. The changing of the tundish not only occurs at an appropriate time, but also allows a change in steel composition with a minimal length of transition in the cast product.

The flow-through water-cooled copper mold is the key element of the casting machine. Special attention has been given to problems associated with the design and material requirements for molds. A number of different designs have been used, including thin-wall tube-type molds, solid molds, and molds made from plate. Plate molds were found to provide excellent mold life and to avoid the necessity for manufacture of molds from solid copper blocks. Steel and brass, as well as copper, have been used for molds, but the most outstanding material is nearly pure copper with small additions of elements that promote precipitation hardening or raise the recrystallization temperature, because both effects apparently provide longer mold life. Mold coatings are applied to extend service life. A chromium coating is generally used, often with an intermediate layer of nickel for improved coherence.

The most suitable length for a continuous casting mold has been found to be 510 to 915 mm (20 to 36 in.), a range that seems to remain constant regardless of section size. This surprising result can be explained by the higher rates of heat removal achieved with smaller sections and higher casting rates. Also, a thinner skin can be permitted for smaller sections exiting from the mold than for larger sections because bulging of the solidifying shell will be less severe. At higher

casting rates, the use of an increased taper in the mold is necessary to maintain high heat removal rates, particularly for the narrow faces of slab molds.

Oscillating molds, as used by Junghans, have been adopted almost universally, although fixed molds can be successfully used with efficient lubricating systems. The oscillation is usually sinusoidal, a motion that can be achieved easily with simple mechanical arrangements. A fairly short stroke and a high frequency are used to provide a short period of "negative strip" during each oscillation, in which the mean downward velocity of the mold movement is greater than the speed of withdrawal of the casting strand in the casting direction. Oscillating frequencies are being increased from 50 to 60 cycles per minute (cpm) up to 250 to 300 cpm, with the benefits of shallower oscillation marks, less cracking, and reduced conditioning requirements.

Molten metal in the slab mold is normally covered with a layer of mold powder to protect the metal from reoxidation and absorb inclusions. The powder has a low melting point and flows over the liquid steel to provide mold lubrication and to help control heat transfer. Rapeseed oil, which has since been replaced by synthetic oils, has typically been used to prevent sticking to the mold in billet casting. Metal flow rates are matched with slab casting speeds using a stopper rod in the tundish, a slide gate, or a metering nozzle just above the shroud to control the delivery rate. Billets are normally cast with fixed metering nozzles, and the strand speed is adjusted to any changes in steel flow rate.

Support of the thin steel shell exiting the mold is required, particularly for slab casters. Several systems have been used (Fig. 9), all of which provide intensified direct water cooling.

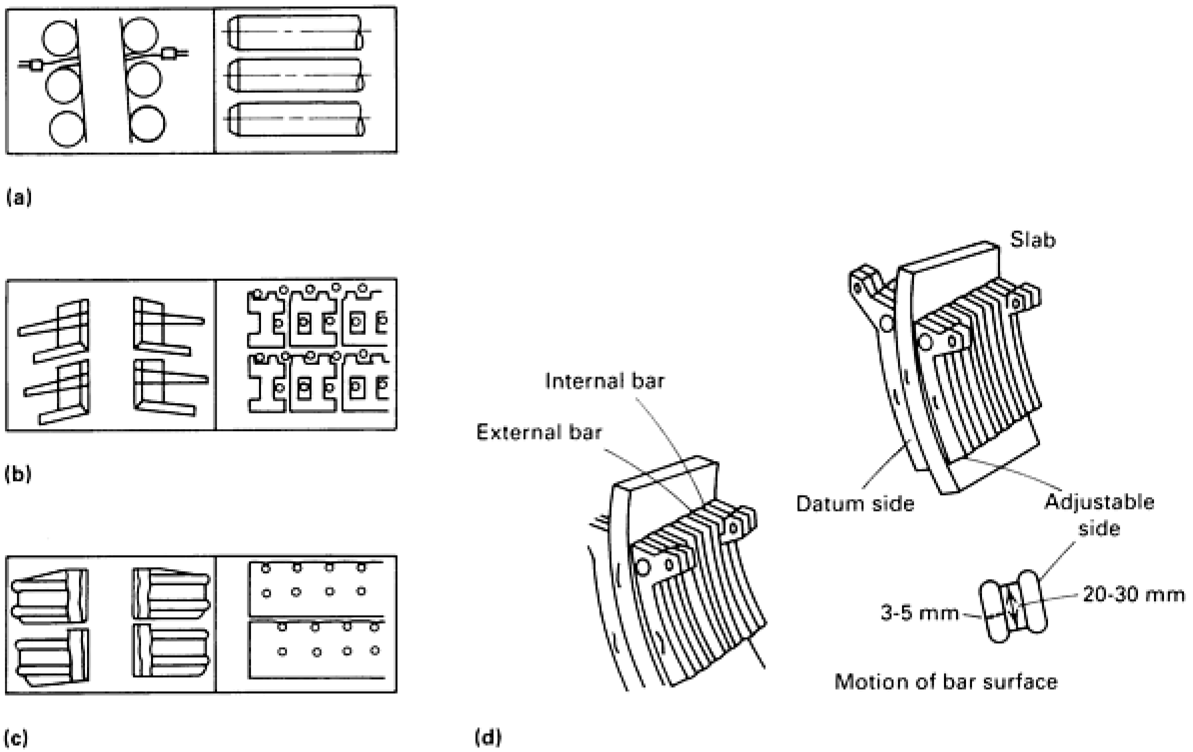

Fig. 9 Four types of shell supporting systems used in continuous casting. (a) Roll. (b) Cooling grid. (c) Cooling plate. (d) Walking bar. Source: Ref 13

Water spraying (secondary cooling) is critical to the process in that maximum cooling should be accomplished, but overcooling and large temperature increases must be avoided. The amount of heat removed by water sprays depends on the volume of the water, its temperature, and in particular the method of delivery, including spray pressure. Pressure is important in that the spray should be sufficiently intense to penetrate the blanket of steam on the surface of the solidifying strand. The thermal conductivity of steel is relatively low; consequently, as the surface temperature decreases and the shell thickness increases, cooling water has less influence on the solidification characteristics. The interrelationship between support rolls and the spray water and its delivery characteristics is quite important, particularly for the casting of wide slabs.

Mixed spraying of air and water develops a unique secondary cooling system with a uniform water droplet size. Air-mist cooling is illustrated in Fig. 10, along with the conventional water spray, as applied to slab casting. Although more costly, the air-mist spray system has a more uniform spray pattern and intensity that offers excellent spray cooling control. Decreases in transverse and longitudinal cracking with air-mist cooling have been reported (Ref 15, 16).

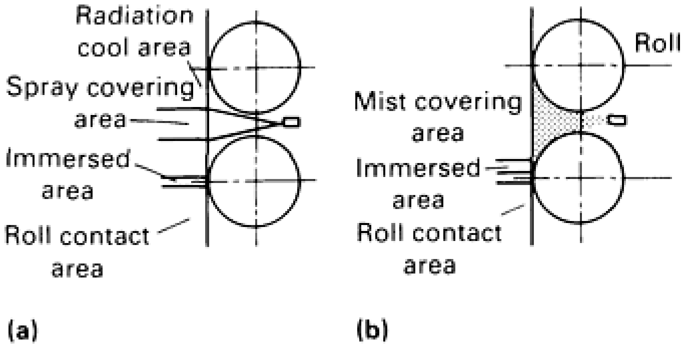

Fig. 10 Comparison of spray systems used in continuous casting. (a) Conventional spray. (b) Air-water mist spray. Source: Ref 14

The straightening operation on curved strand casters has required special design and operating control. In general, temperatures at or above 900 to 1050 °C (1650 to 1920 °F) have been recommended to avoid conditions under which certain grades of steel have limited ductility and are susceptible to cracking. Multipoint and four-point straighteners have reduced imposed strains, and compression casting systems have reduced tensile stresses. Uniform temperature of the strand, including corners, which tend to cool more quickly, is required.

The dummy bar, which is used to stopper the mold for the initiation of a cast, can be inserted from above or below, depending on the individual installation. Some arrangements are shown in Fig. 11. The top feeding arrangement, which "chases" the last metal cast through the machine, offers a productivity advantage.

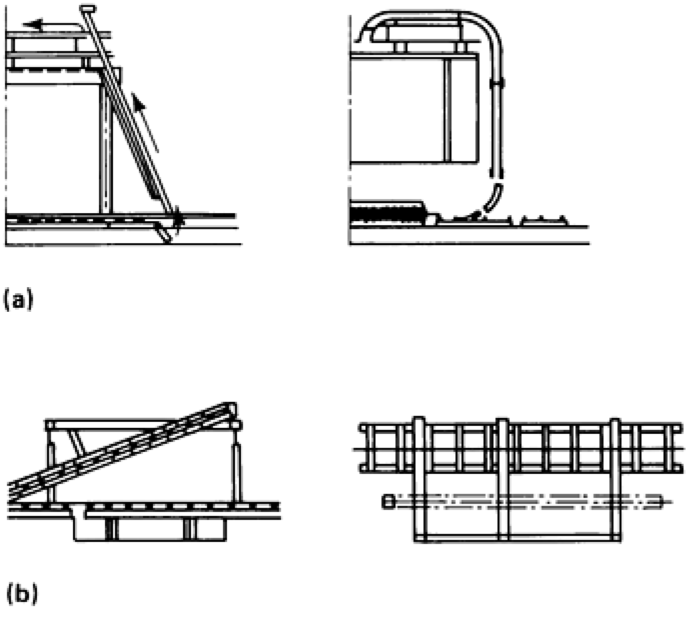

Fig. 11 Dummy bar arrangement. (a) Top feeding. (b) Bottom feeding. Source: Ref 17

Productivity Improvements

While continual increases in casting speeds over the years have led to improvement in casting machine productivity, the most dramatic factor has been sequence casting, that is, continuous-continuous casting. Perfection of this development has required extraordinary achievement in the design of ladle and tundish handling systems, and in design and maintenance considerations for long-term operation with processing times that extend for several days. A summary of sequence casting records in Japan has been presented by T. Harabuchi (Ref 18) and is reported in Table 1. In comparison, the Jan 1983 casting record at Great Lakes Steel Corporation in the Detroit district involved a large slab caster (240 mm × 2.5 m, or $9\frac{1}{2}$ × 99 in.), which cast 402 ladles and 83 160 Mg (91,480 tons) of steel continuously. In addition to the bulk steel handling requirements of sequence casting, the ability to change nozzles, shrouds, and tundishes at frequent intervals is also required. The string of casts at Great Lakes Steel Corporation involved 35 tundish changes and 177 shroud changes over a period of $13\frac{2}{3}$ days. This record has been exceeded more recently at the Gary Works of United States Steel International, Inc.

Table 1 Record of sequence casting in Japan

Product	**Company**	**Continuous casting plant**	**Heats per cast**	**Weight of steel per cast**		Time of achievement
				Mg	**tons**	
Slab	Nippon Kokan	Keihin	270	22,523	24,775	**Sept 1974**
Slab	Nippon Kokan	Fukuyama	244	54,360	59,796	**Aug 1981**

While it has been shown that sequence casting extending beyond five or six heats does not dramatically increase productivity, provided a reasonable turnaround time and interactive scheduling with the steelmaking facilities exist, the

capability for long-term sequence casting represents the opportunity for increased productivity with high quality at an essentially steady state operation of the caster.

An important characteristic of a casting operation with regard to productivity is the percentage of total clock time that steel is being processed in the machine. These percentages in high productivity casters can exceed 90% for frequently used casting operations. The turnaround time required for the dummy bar to restart a cast is one of the factors in producing steel-in-mold results, but under ideal conditions scheduled maintenance will be a major factor, and other items, such as problems in steelmaking or mechanical difficulty on the strand, will be minimized.

In the past and in many present installations, interruption of continuous casting production is required in order to make a width change. Several developments that avoid this requirement are now in operation. In one such arrangement, used at Great Lakes Steel Corporation, a very wide slab was cast and then slit into two or three optimum widths. Another approach is taken at Oita Works of Nippon Steel Corporation, where a sizing mill adjusts the slabs to various desired widths. Another, more versatile, system involves the use of a variable width mold in which the taper and width are adjusted continuously during the casting process. These techniques have permitted the adoption of sequence casting with a minimum mold inventory based on width.

Another barrier to increasing productivity of continuous casting has been the accommodation of ladle-to-ladle composition changes with adoption of sequence casting. Under ideal circumstances, as when a plant produces a narrow range of compositions, often with overlapping compositional requirements, compositional changes can be slowly stepped through each grade to accommodate the desired sequence of heats. However, when substantial variations in composition must be accommodated, physical barriers in the form of steel plates have been used to provide isolation of the grade changes in the strand. In this way, the transition zone can be minimized, and compositional changes can be accommodated without substantial losses in yield or quality.

Quality Improvements

The operation of a continuous casting strand to produce good-quality steel uniformly and reliably on a routine basis can be the most valuable asset of the process. Development work continues in an effort to improve control and production reliability, particularly with regard to avoidance of inclusions and cracking for internal and surface quality.

Internal cracking is less important for those products (for example, sheet) that have large reduction ratios. Radial cracks, center looseness or centerline cracking, minor amounts of gas evolution, and other internal defects are not deleterious in heavily rolled products. In the manufacture of heavy plates, however, these conditions can represent serious product defects.

For aluminum-killed steel, subsurface inclusions are usually in the form of aluminum oxide. In some cases, surface scarfing can be effective in removing these inclusions, which could provide a surface defect in a final rolled product. Unfortunately, this surface conditioning results in substantial yield losses. It has been reported (Ref 4) that use of multiport shrouded nozzles can produce a fluid flow action in slab molds, which brings inclusions in contact with the molten mold powder covering to flux and dissolve oxide particles. This provides a clean subsurface zone that requires no scarfing. However, this method leads to the entrapment of complex nonmetallic inclusions containing mold powder. Clean steel practices in combination with nozzle configurations optimized for specific casting conditions are necessary to minimize nonmetallic inclusions. As noted above, the control of fluid flow and promotion of separation in ladle, tundish, and mold can provide a substantial reduction in large inclusions.

Depending on steel grade, cracking can result from intensive cooling or deformation in the casting strand. Surface cracking can be minimized by proper control of lubrication and cooling within the mold, and cooling and alignment in the upper spray zone. Other critical factors in cracking are control of spray cooling to avoid surface temperature rebound (resulting in midway cracks) or nonuniformity of cooling across or along the strand. Control of temperature distribution at the straightener and proper roll gap settings for slabs and blooms have also been noted as being very important.

Horizontal Continuous Casting

Horizontal casting systems have been explored for many years, but only in the recent past have they been successfully applied to steels. Oldsmobile Division of General Motors Corporation started casting 95 mm (3.75 in.) steel bars in a horizontal mold in 1969 (Ref 19, 20), with uninterrupted casts of up to 24 h. This is believed to be the longest sustained continuous casting operation for steel up to that time.

Voest-Alpine is developing a horizontal continuous casting machine for steels, and the Nippon Kokan (NKK) Steel Company of Japan has been producing horizontally cast steel sections up to 210 mm (8 in.) square (Ref 21). These systems depend on a refractory nozzle or "break ring" at the entrance end of a stationary water-cooled metallic mold, and an intermittent motion for translating the bar, each forward stroke being followed by a discrete rest or dwell. A cross section of the tundish and mold arrangement of the NKK machine is shown in Fig. 12. Casting of larger sections is being explored throughout the world, as are continuous casting processes for high-speed casting of thin sections. As the technologies for cleaner steels evolve, these processes will come closer to commercial adoption.

Continuous Casting of Steel

Continuous casting of steel is entering a new era of development, not only with respect to its increasing application in the production process, but also in its own evolution as a process and its interaction with other processes in steel manufacture. Continuous casting output has shown an accelerating growth curve. More than 50% of current world steel production is continuously cast, and continuous casting in Japan exceeds 80%. The advantages of the process, along with its developments and current challenges for improvement, are outlined in the following sections.

General Description of the Process

The purpose of continuous casting is to bypass conventional ingot casting and to cast to a form that is directly rollable on finishing mills. The use of this process should result in improvement in yield, surface condition, and internal quality of product when compared to ingot-made material.

Continuous casting involves the following sequence of operations:

- Delivery of liquid metal to the casting strand
- Flow of metal through a distributor (tundish) into the casting mold
- Formation of the cast section in a water-cooled copper mold
- Continuous withdrawal of the casting from the mold
- Further heat removal to solidify the liquid core from the casting by water spraying beyond the mold
- Cutting to length and removing the cast sections

A diagram showing the main components of a continuous casting machine is presented in Fig. 1. Molten steel in a ladle is delivered to a reservoir above the continuous casting machine called a tundish. The flow of steel from the tundish into one or more open-ended, water-cooled copper molds is controlled by a stopper rod-nozzle or a slide gate valve arrangement. To initiate a cast, a starter, or dummy bar, is inserted into the mold and sealed so that the initial flow of steel is contained in the mold and a solid skin is formed. After the mold has been filled to the desired height, the dummy bar is gradually withdrawn at the same rate that molten steel is added to the mold. The initial liquid steel freezes onto a suitable attachment of the dummy bar so that the cast strand can be withdrawn down through the machine. Solidification of a shell begins immediately at the surface of the copper mold. The length of the mold and the casting speed are such that the shell thickness is capable of withstanding the pressures of the molten metal core upon exiting from the copper mold. To prevent sticking of the frozen shell to the copper mold, the mold is normally oscillated during the casting operation and a lubricant is added to the mold. The steel strand is mechanically supported by rolls below the mold where secondary cooling is achieved by spraying cooling water onto the strand surface to complete the solidification process. After the strand has fully solidified, it is sectioned into desired lengths by a cutoff torch or shear. This final portion of the continuous casting machine also has provision for disengagement and storage of the dummy bar.

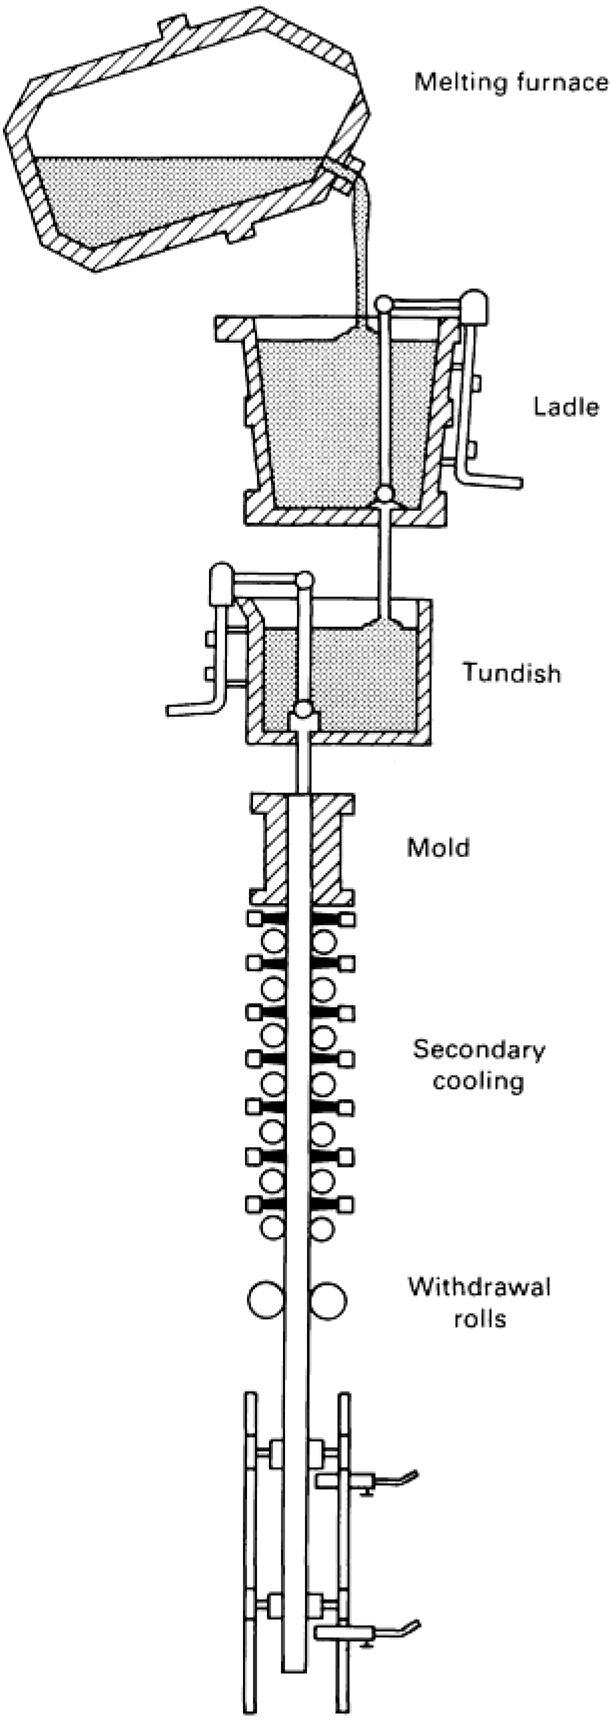

Fig. 1 Main components of a continuous casting strand. Source: Ref 4

Several arrangements are now in commercial use for the continuous casting of steel. The types of continuous casting machines in use include vertical, vertical with bending, curved or S-strand with either straight or curved mold, curved strand with continuous bending, and horizontal. Examples of the principal types of machines currently producing slabs are shown in Fig. 2.

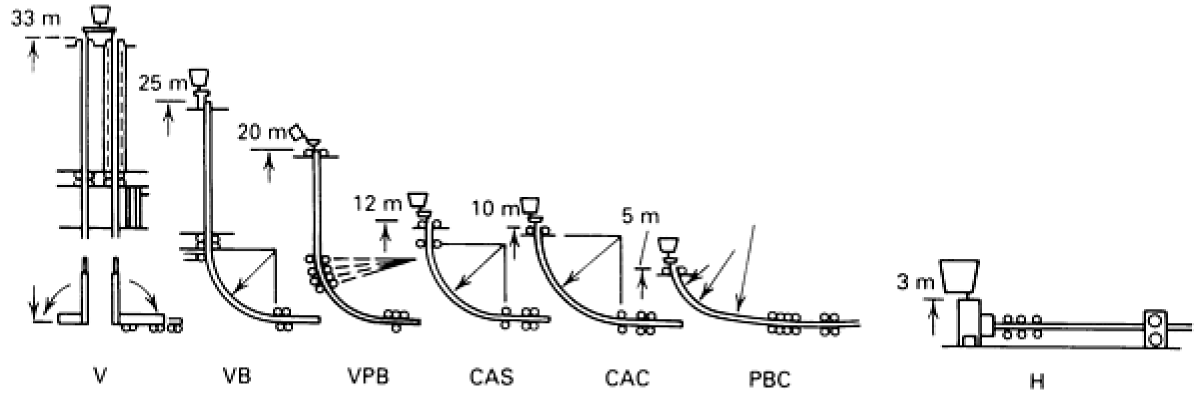

Fig. 2 Principal types of continuous casting. V, vertical; VB, vertical with bending; VPB, vertical with progressive bending; CAS, circular arc with straight mold; CAS, circular arc with curved mold; PBC, progressive bending with curved mold; H, horizontal. Source: Ref 5

Most of the original continuous casting machines for steel were vertical machines. Vertical machines with bending and curved strand machines, although more complicated in their construction, were developed to minimize the height of the machine and allow installation in existing plants without modification of crane height. Four basic caster designs for slabs are shown in Fig. 3, with an indication of the required installation height and the corresponding solidification distance or metallurgical length (ML).

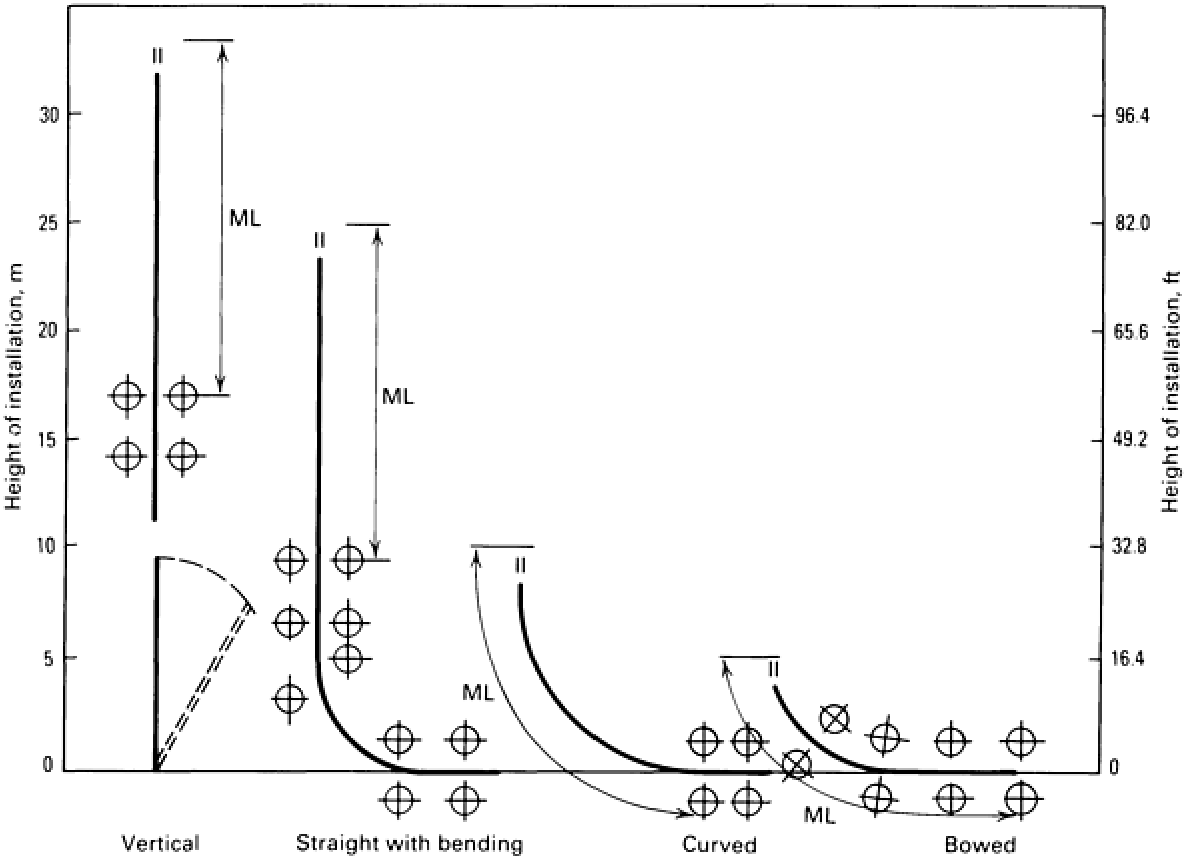

Fig. 3 Four basic designs for continuous casting machines. ML, metallurgical length. Source: Ref 6

Plant Layout

The design and layout of a steelmaking facility often focus initially on continuous casting. The optimum plant layout varies markedly from one installation to another. One major factor in the configuration is whether or not the steelmaking complex is being constructed on a greenfield site or being added ("shoehorned") into an existing works. Many of the major integrated steel works in Japan were constructed as greenfield installations during the period from 1960 to 1975. Most of the minimills constructed throughout the world, and in particular in the United States, were also built on greenfield sites.

In building a greenfield site, the plant layout should incorporate two major features: a smooth and well-organized arrangement for material handling and flow, and the capacity for future expansion. Generally, these plants are designed for 100% continuous casting, and no ingot facilities are included (Ref 7). Nearly all of the recently built minimills incorporate one or more electric furnaces and provide for 100% continuous casting of billets. Chaparral Steel Company at Midlothian, TX is an excellent example (Ref 8). A profile of a proposed large-scale electric furnace billet casting plant is shown in Fig. 4.

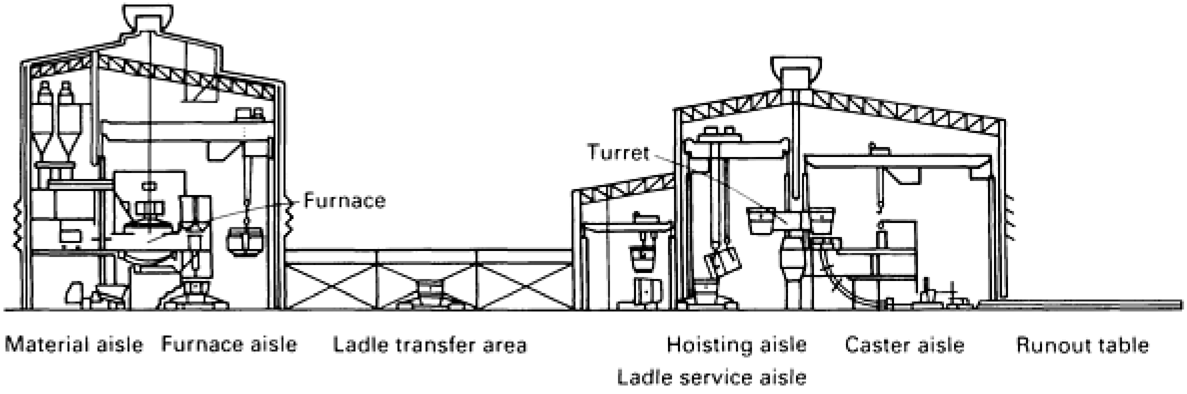

Fig. 4 Proposed melt shop capable of producing 1.2 million Mg (1.32 million tons) of billets annually. Source: Ref 9

A twin-strand slab caster was shoehorned into the Number 4 basic oxygen furnace shop at Inland Steel Company. The addition of this caster substantially increased the output of this facility, where ingot casting was the rate-limiting step in production. The arrangement of this installation showing the caster and ingot facilities is presented in Fig. 5.

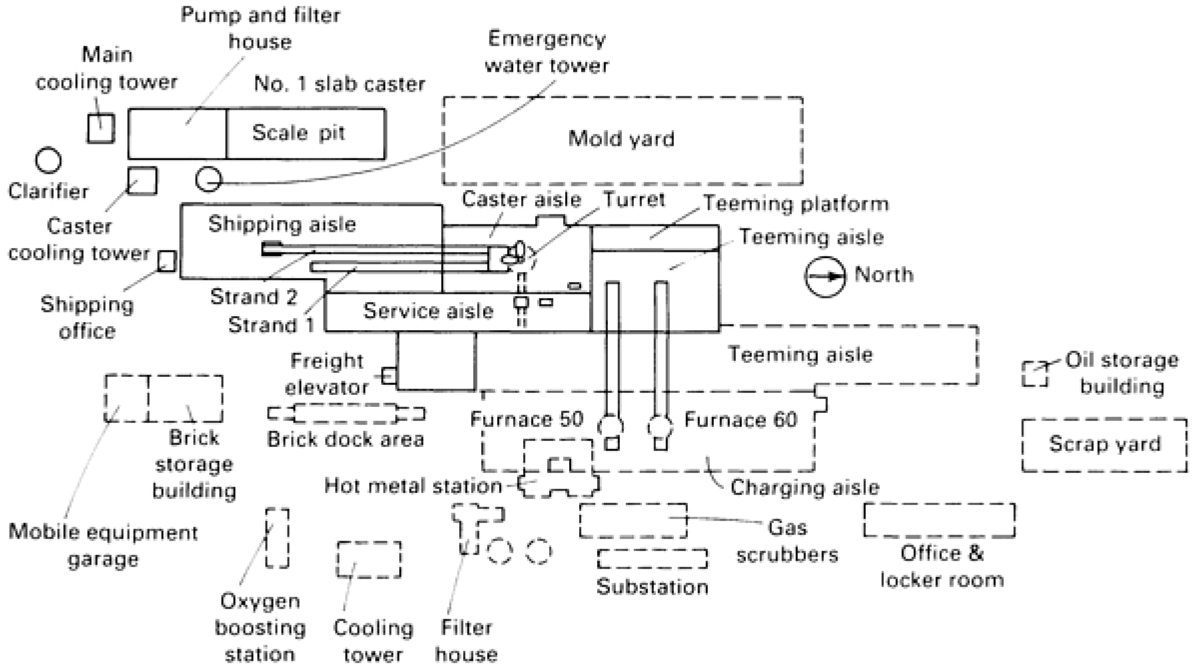

Fig. 5 Plant layout at the Inland Steel Company. Source: Ref 10

An important characteristic of the plant layout, and in particular of the material-handling facilities, is the concept that the continuous casting machine cannot wait. This design and operating concept has had a dramatic impact on steelmaking operations, which have now become a synergism to the continuous casting facilities. Because of this shift in priorities, marked improvements in productivity have been developed for continuous casting, as outlined below.

Dramatic increases in energy costs, as well as the desire for higher productivity, led to the development of the "hot connection". Substantial energy savings can be achieved by directly charging the hot continuously cast slab or billet to the reheating furnaces of the rolling mill. The latest installations have included direct in-line hot rolling of the cast product.

Process Development and Machine Design

A number of methods for distributing liquid steel to the mold or to several molds of the casting machine have been investigated. Use of a tundish with appropriate flow control has been found to be a superior method for the production of quality steel. Considerable effort has been directed toward improvement of refractories and development of methods for preventing nozzle blockage. Geometric arrangements in tundishes, including the use of dams and weirs, have provided suitable fluid flow characteristics to maximize the separation of nonmetallic inclusions, resulting in improved quality. Another factor in separation of nonmetallic inclusions in the tundish is tundish size because of its effect on residence time. Figure 6 indicates the trend in tundish size for major slab casting installations over the past 20 years.

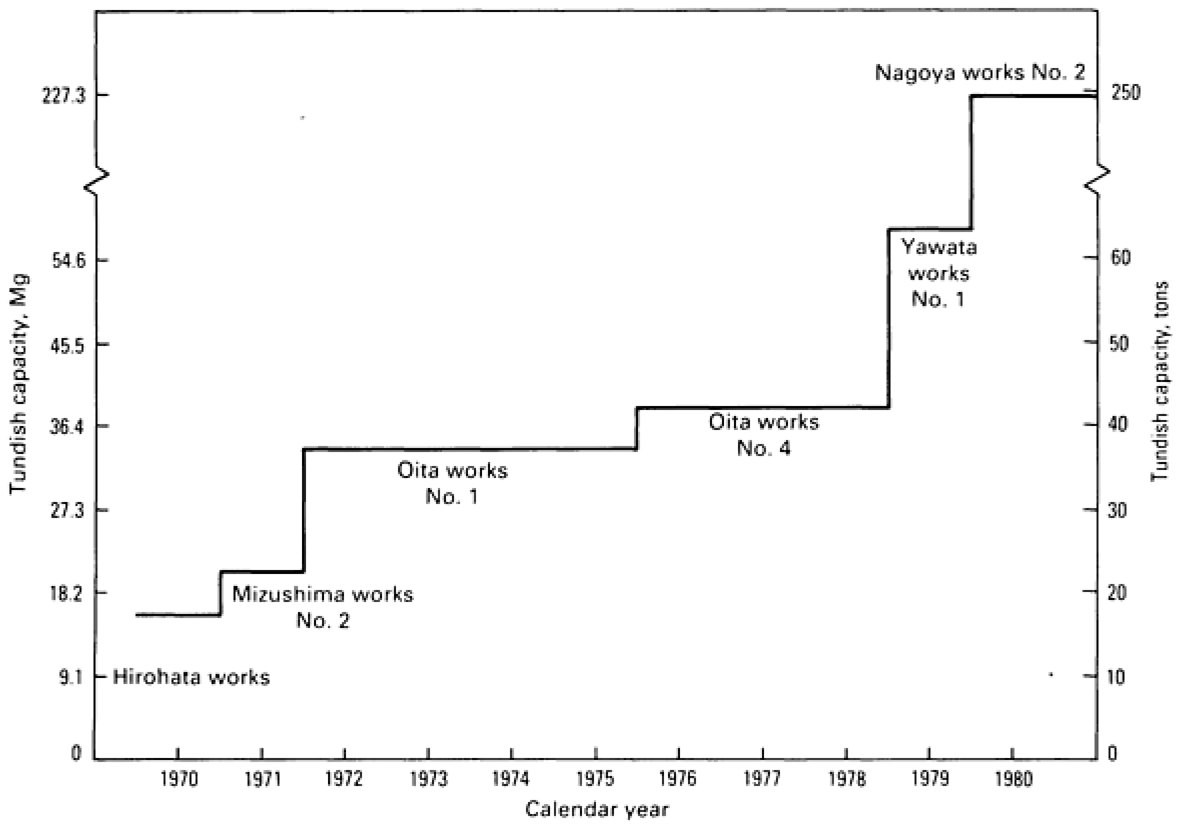

Fig. 6 Increases in capacity of tundishes for a two-strand slab caster. Source: Ref 11

Reoxidation of the molten steel is to be avoided. The use of refractory shrouds between the ladle and the tundish and the tundish and the mold have been adopted for slab casting (Fig. 7).

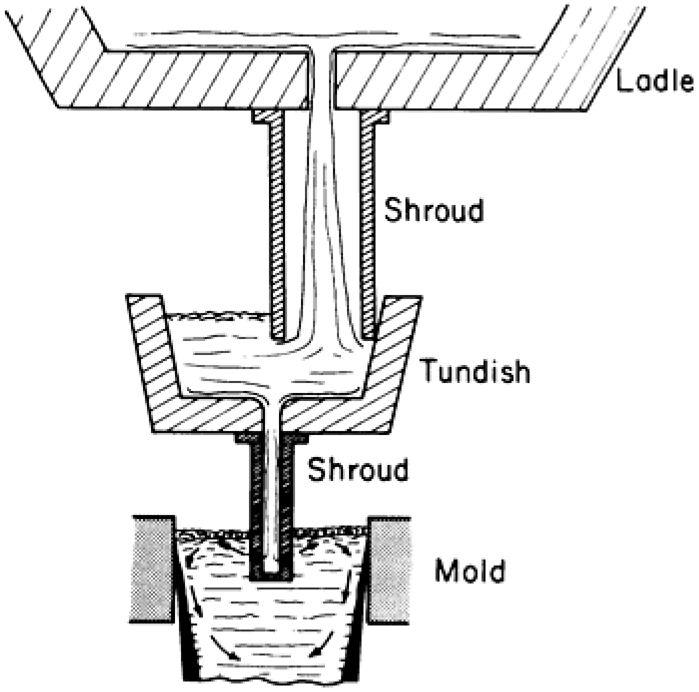

Fig. 7 Pouring shrouds from ladle to tundish to mold. Source: Ref 12

One of the difficulties encountered in continuous casting of small sections has been the protection of the pouring stream from tundish to mold because of the inapplicability of a pouring tube and the mechanical difficulty caused by the oscillation of the mold relative to the fixed tundish. In one instance, this has been overcome by the use of a flexible bellows (Fig. 8) and successfully applied to the continuous casting of special product quality steel bars. Recently, further development has been made in the use of ceramic shrouds to protect pouring streams on billet machines.

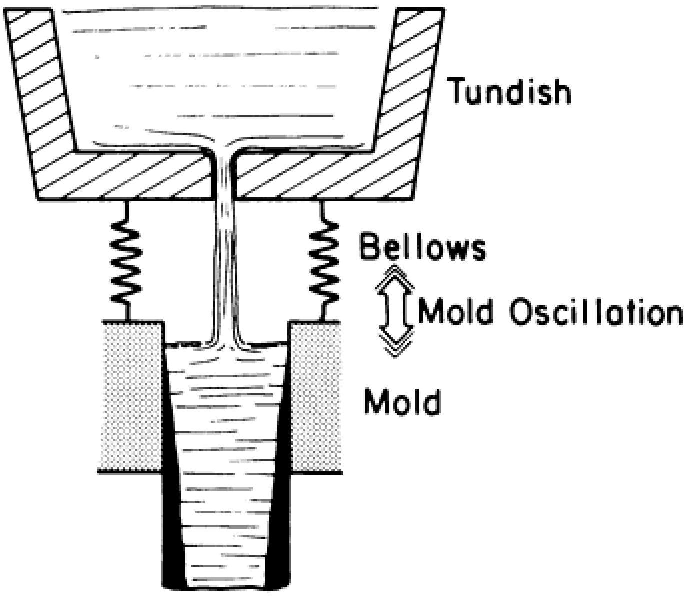

Fig. 8 Bellows between tundish and mold for casting billets. Source: Ref 12

Protection of the surface of the molten steel pool in the tundish has been achieved through the use of suitable synthetic oxide slags, inert-gas blanketing, and a refractory cover to seal the tundish. The metal level in the tundish, as well as the fluid flow pattern, is important in avoiding the ingestion of the slag layer into the metal stream flowing downward into the mold.

The tundish is supported with either two tundish cars or a two-position turret. Frequently, the double turret provides for changing of the tundish while continuing the casting process, which allows extended sequence casting. The changing of the tundish not only occurs at an appropriate time, but also allows a change in steel composition with a minimal length of transition in the cast product.

The flow-through water-cooled copper mold is the key element of the casting machine. Special attention has been given to problems associated with the design and material requirements for molds. A number of different designs have been used, including thin-wall tube-type molds, solid molds, and molds made from plate. Plate molds were found to provide excellent mold life and to avoid the necessity for manufacture of molds from solid copper blocks. Steel and brass, as well as copper, have been used for molds, but the most outstanding material is nearly pure copper with small additions of elements that promote precipitation hardening or raise the recrystallization temperature, because both effects apparently provide longer mold life. Mold coatings are applied to extend service life. A chromium coating is generally used, often with an intermediate layer of nickel for improved coherence.

The most suitable length for a continuous casting mold has been found to be 510 to 915 mm (20 to 36 in.), a range that seems to remain constant regardless of section size. This surprising result can be explained by the higher rates of heat removal achieved with smaller sections and higher casting rates. Also, a thinner skin can be permitted for smaller sections exiting from the mold than for larger sections because bulging of the solidifying shell will be less severe. At higher

casting rates, the use of an increased taper in the mold is necessary to maintain high heat removal rates, particularly for the narrow faces of slab molds.

Oscillating molds, as used by Junghans, have been adopted almost universally, although fixed molds can be successfully used with efficient lubricating systems. The oscillation is usually sinusoidal, a motion that can be achieved easily with simple mechanical arrangements. A fairly short stroke and a high frequency are used to provide a short period of "negative strip" during each oscillation, in which the mean downward velocity of the mold movement is greater than the speed of withdrawal of the casting strand in the casting direction. Oscillating frequencies are being increased from 50 to 60 cycles per minute (cpm) up to 250 to 300 cpm, with the benefits of shallower oscillation marks, less cracking, and reduced conditioning requirements.

Molten metal in the slab mold is normally covered with a layer of mold powder to protect the metal from reoxidation and absorb inclusions. The powder has a low melting point and flows over the liquid steel to provide mold lubrication and to help control heat transfer. Rapeseed oil, which has since been replaced by synthetic oils, has typically been used to prevent sticking to the mold in billet casting. Metal flow rates are matched with slab casting speeds using a stopper rod in the tundish, a slide gate, or a metering nozzle just above the shroud to control the delivery rate. Billets are normally cast with fixed metering nozzles, and the strand speed is adjusted to any changes in steel flow rate.

Support of the thin steel shell exiting the mold is required, particularly for slab casters. Several systems have been used (Fig. 9), all of which provide intensified direct water cooling.

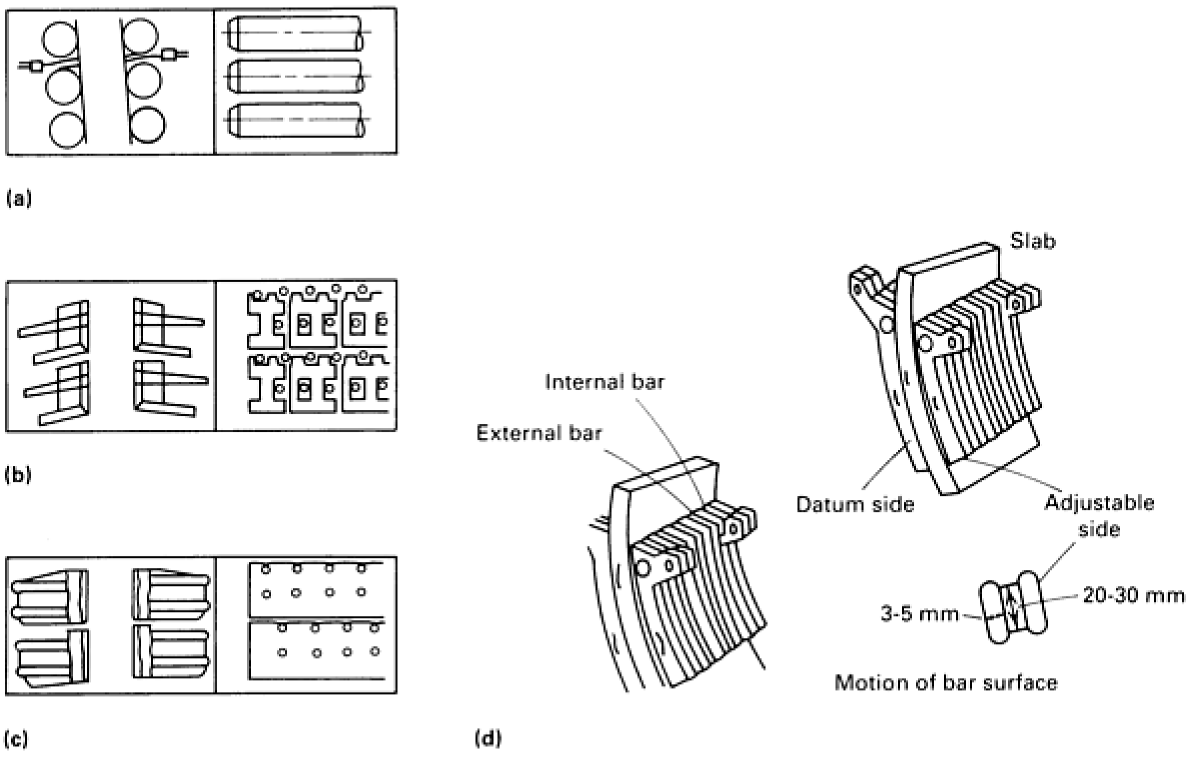

Fig. 9 Four types of shell supporting systems used in continuous casting. (a) Roll. (b) Cooling grid. (c) Cooling plate. (d) Walking bar. Source: Ref 13

Water spraying (secondary cooling) is critical to the process in that maximum cooling should be accomplished, but overcooling and large temperature increases must be avoided. The amount of heat removed by water sprays depends on the volume of the water, its temperature, and in particular the method of delivery, including spray pressure. Pressure is important in that the spray should be sufficiently intense to penetrate the blanket of steam on the surface of the solidifying strand. The thermal conductivity of steel is relatively low; consequently, as the surface temperature decreases and the shell thickness increases, cooling water has less influence on the solidification characteristics. The interrelationship between support rolls and the spray water and its delivery characteristics is quite important, particularly for the casting of wide slabs.

Mixed spraying of air and water develops a unique secondary cooling system with a uniform water droplet size. Air-mist cooling is illustrated in Fig. 10, along with the conventional water spray, as applied to slab casting. Although more costly, the air-mist spray system has a more uniform spray pattern and intensity that offers excellent spray cooling control. Decreases in transverse and longitudinal cracking with air-mist cooling have been reported (Ref 15, 16).

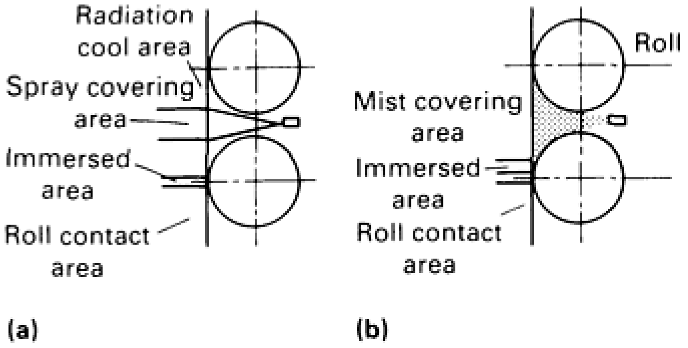

Fig. 10 Comparison of spray systems used in continuous casting. (a) Conventional spray. (b) Air-water mist spray. Source: Ref 14

The straightening operation on curved strand casters has required special design and operating control. In general, temperatures at or above 900 to 1050 °C (1650 to 1920 °F) have been recommended to avoid conditions under which certain grades of steel have limited ductility and are susceptible to cracking. Multipoint and four-point straighteners have reduced imposed strains, and compression casting systems have reduced tensile stresses. Uniform temperature of the strand, including corners, which tend to cool more quickly, is required.

The dummy bar, which is used to stopper the mold for the initiation of a cast, can be inserted from above or below, depending on the individual installation. Some arrangements are shown in Fig. 11. The top feeding arrangement, which "chases" the last metal cast through the machine, offers a productivity advantage.

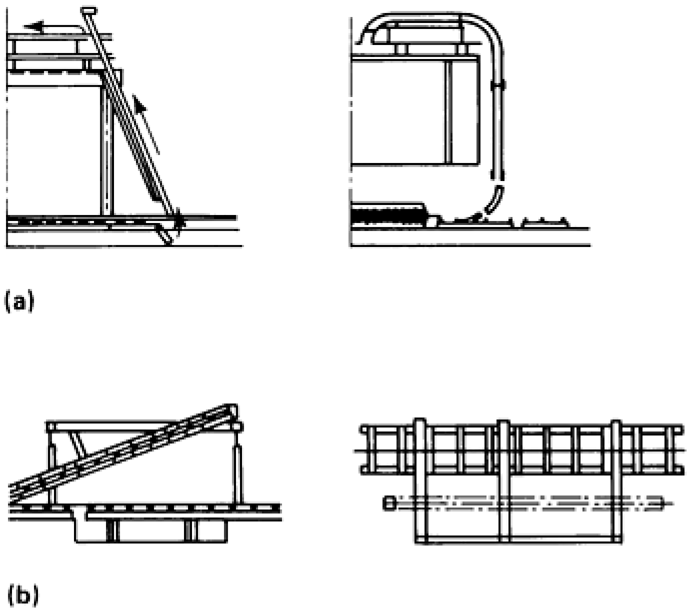

Fig. 11 Dummy bar arrangement. (a) Top feeding. (b) Bottom feeding. Source: Ref 17

Productivity Improvements

While continual increases in casting speeds over the years have led to improvement in casting machine productivity, the most dramatic factor has been sequence casting, that is, continuous-continuous casting. Perfection of this development has required extraordinary achievement in the design of ladle and tundish handling systems, and in design and maintenance considerations for long-term operation with processing times that extend for several days. A summary of sequence casting records in Japan has been presented by T. Harabuchi (Ref 18) and is reported in Table 1. In comparison, the Jan 1983 casting record at Great Lakes Steel Corporation in the Detroit district involved a large slab caster (240 mm × 2.5 m, or 9 × 99 in.), which cast 402 ladles and 83 160 Mg (91,480 tons) of steel continuously. In addition to the bulk steel handling requirements of sequence casting, the ability to change nozzles, shrouds, and tundishes at frequent intervals is also required. The string of casts at Great Lakes Steel Corporation involved 35 tundish changes and 177 shroud changes over a period of 13 days. This record has been exceeded more recently at the Gary Works of United States Steel International, Inc.

Table 1 Record of sequence casting in Japan

Product	Company	Continuous casting plant	Heats per cast	Weight of steel per cast		Time of achievement
				Mg	tons	
Slab	Nippon Kokan	Keihin	270	22,523	24,775	Sept 1974
Slab	Nippon Kokan	Fukuyama	244	54,360	59,796	Aug 1981
Slab	Kawasaki Steel	Mizushima No. 5	204	51,000	56,100	Nov 1980
Slab	Nippon Steel	Yamata No. 2	186	30,199	33,219	July 1974

Billet	Kokko Steel	Main Plant	174	5,063	5,569	Aug 1978
Billet	Funabashi Steel	Main Plant	99	5,535	6,089	Oct 1975

While it has been shown that sequence casting extending beyond five or six heats does not dramatically increase productivity, provided a reasonable turnaround time and interactive scheduling with the steelmaking facilities exist, the capability for long-term sequence casting represents the opportunity for increased productivity with high quality at an essentially steady state operation of the caster.

An important characteristic of a casting operation with regard to productivity is the percentage of total clock time that steel is being processed in the machine. These percentages in high productivity casters can exceed 90% for frequently used casting operations. The turnaround time required for the dummy bar to restart a cast is one of the factors in producing steel-in-mold results, but under ideal conditions scheduled maintenance will be a major factor, and other items, such as problems in steelmaking or mechanical difficulty on the strand, will be minimized.

In the past and in many present installations, interruption of continuous casting production is required in order to make a width change. Several developments that avoid this requirement are now in operation. In one such arrangement, used at Great Lakes Steel Corporation, a very wide slab was cast and then slit into two or three optimum widths. Another approach is taken at Oita Works of Nippon Steel Corporation, where a sizing mill adjusts the slabs to various desired widths. Another, more versatile, system involves the use of a variable width mold in which the taper and width are adjusted continuously during the casting process. These techniques have permitted the adoption of sequence casting with a minimum mold inventory based on width.

Another barrier to increasing productivity of continuous casting has been the accommodation of ladle-to-ladle composition changes with adoption of sequence casting. Under ideal circumstances, as when a plant produces a narrow range of compositions, often with overlapping compositional requirements, compositional changes can be slowly stepped through each grade to accommodate the desired sequence of heats. However, when substantial variations in composition must be accommodated, physical barriers in the form of steel plates have been used to provide isolation of the grade changes in the strand. In this way, the transition zone can be minimized, and compositional changes can be accommodated without substantial losses in yield or quality.

Quality Improvements

The operation of a continuous casting strand to produce good-quality steel uniformly and reliably on a routine basis can be the most valuable asset of the process. Development work continues in an effort to improve control and production reliability, particularly with regard to avoidance of inclusions and cracking for internal and surface quality.

Internal cracking is less important for those products (for example, sheet) that have large reduction ratios. Radial cracks, center looseness or centerline cracking, minor amounts of gas evolution, and other internal defects are not deleterious in heavily rolled products. In the manufacture of heavy plates, however, these conditions can represent serious product defects.

For aluminum-killed steel, subsurface inclusions are usually in the form of aluminum oxide. In some cases, surface scarfing can be effective in removing these inclusions, which could provide a surface defect in a final rolled product. Unfortunately, this surface conditioning results in substantial yield losses. It has been reported (Ref 4) that use of multiport shrouded nozzles can produce a fluid flow action in slab molds, which brings inclusions in contact with the molten mold powder covering to flux and dissolve oxide particles. This provides a clean subsurface zone that requires no scarfing. However, this method leads to the entrapment of complex nonmetallic inclusions containing mold powder. Clean steel practices in combination with nozzle configurations optimized for specific casting conditions are necessary to minimize nonmetallic inclusions. As noted above, the control of fluid flow and promotion of separation in ladle, tundish, and mold can provide a substantial reduction in large inclusions.

Depending on steel grade, cracking can result from intensive cooling or deformation in the casting strand. Surface cracking can be minimized by proper control of lubrication and cooling within the mold, and cooling and alignment in the upper spray zone. Other critical factors in cracking are control of spray cooling to avoid surface temperature rebound (resulting in midway cracks) or nonuniformity of cooling across or along the strand. Control of temperature distribution at the straightener and proper roll gap settings for slabs and blooms have also been noted as being very important.

Horizontal Continuous Casting

Horizontal casting systems have been explored for many years, but only in the recent past have they been successfully applied to steels. Oldsmobile Division of General Motors Corporation started casting 95 mm (3.75 in.) steel bars in a horizontal mold in 1969 (Ref 19, 20), with uninterrupted casts of up to 24 h. This is believed to be the longest sustained continuous casting operation for steel up to that time.

Voest-Alpine is developing a horizontal continuous casting machine for steels, and the Nippon Kokan (NKK) Steel Company of Japan has been producing horizontally cast steel sections up to 210 mm (8 in.) square (Ref 21). These

systems depend on a refractory nozzle or "break ring" at the entrance end of a stationary water-cooled metallic mold, and an intermittent motion for translating the bar, each forward stroke being followed by a discrete rest or dwell. A cross section of the tundish and mold arrangement of the NKK machine is shown in Fig. 12. Casting of larger sections is being explored throughout the world, as are continuous casting processes for high-speed casting of thin sections. As the technologies for cleaner steels evolve, these processes will come closer to commercial adoption.

Continuous Casting

Robert D. Pehlke, University of Michigan

Nonferrous Continuous Casting

The early development of continuous casting processes occurred to a large extent at production installations for nonferrous alloys.

Direct-Chill Casting

The principal casting process for light metals is the direct-chill process (Ref 22, 23, 24, 25). The vertical direct-chill casting process was patented by Alcoa in 1942 (Ref 26), and is shown schematically in its present form in Fig. 13. The process can directly prepare billets for extrusion, blocks for rolling, and sheet for fabrication, thus eliminating intermediate mechanical working processes by casting near-net shapes.

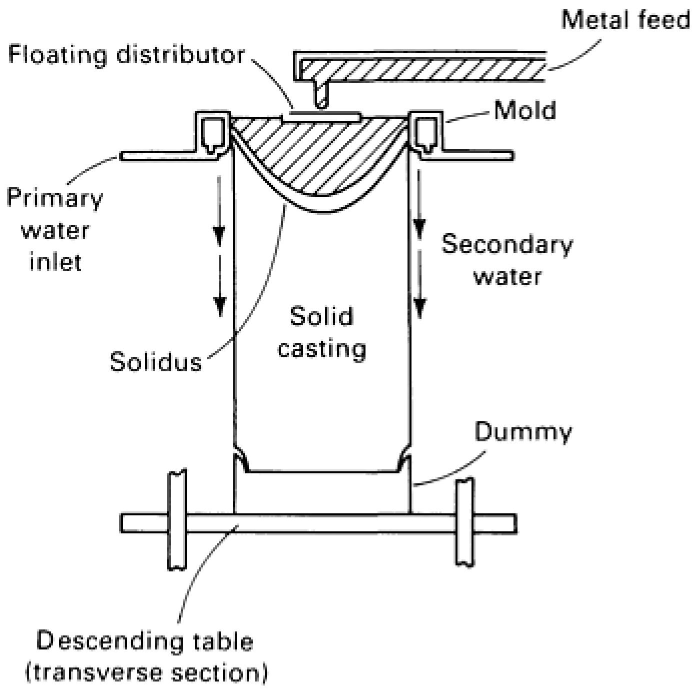

Fig. 13 Conventional vertical direct-chill casting arrangement. Source: Ref 22

Most direct-chill casting capacity is of the vertical type for semicontinuous casting, but more importance is being assumed by the continuous horizontal direct-chill casting process (Fig. 14). The section sizes in which aluminum alloys are cast range from 1.5 × 0.5 m (5 × 1.6 ft) blocks for rolling to 5 to 30 mm (0.2 to 1.2 in.) thick by 2 m (6.6 ft) wide for plate and strip. There is considerable economic advantage in wide strip casting. This processing, which is far ahead of steel continuous casting of wide strip, could portend the future for steel.

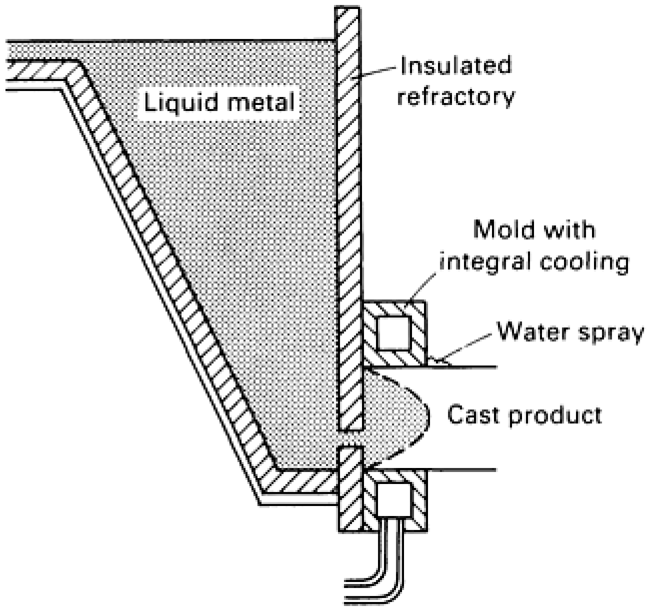

Fig. 14 Horizontal direct-chill casting system. Source: Ref 22

The key operating requirement in direct-chill casting is that a sufficiently strong shell be developed in the limited time of contact with the mold to retain the interior molten pool. Withdrawal rates of up to 0.2 m/min (0.66 ft/min) can be achieved in conventional casters. Withdrawal speeds of 2.5 m/min (8.2 ft/min) for a 10 mm (0.4 in.) thick section have been reported for horizontal casters producing pure aluminum strip (Ref 27). Pure aluminum or dilute alloys are easier to cast than higher alloys with wide freezing ranges. Higher casting speeds have led to problems in maintaining casting shape and have also caused higher internal stresses in the solidified ingot. Control of heat extraction rates is required to limit the extent of these difficulties.

Vertical direct-chill casting is used extensively to produce rectangular stabs and cylindrical billets of copper alloys, and, to a lesser extent, of pure copper. A diagram of an entire vertical direct-chill unit for casting copper slabs is shown in Fig. 15. For copper and copper-base alloys, the liquid metal is poured through a water-cooled, oscillating, graphite-lined collar or mold. The graphite produces a smooth surface on the casting and minimizes oxidation.

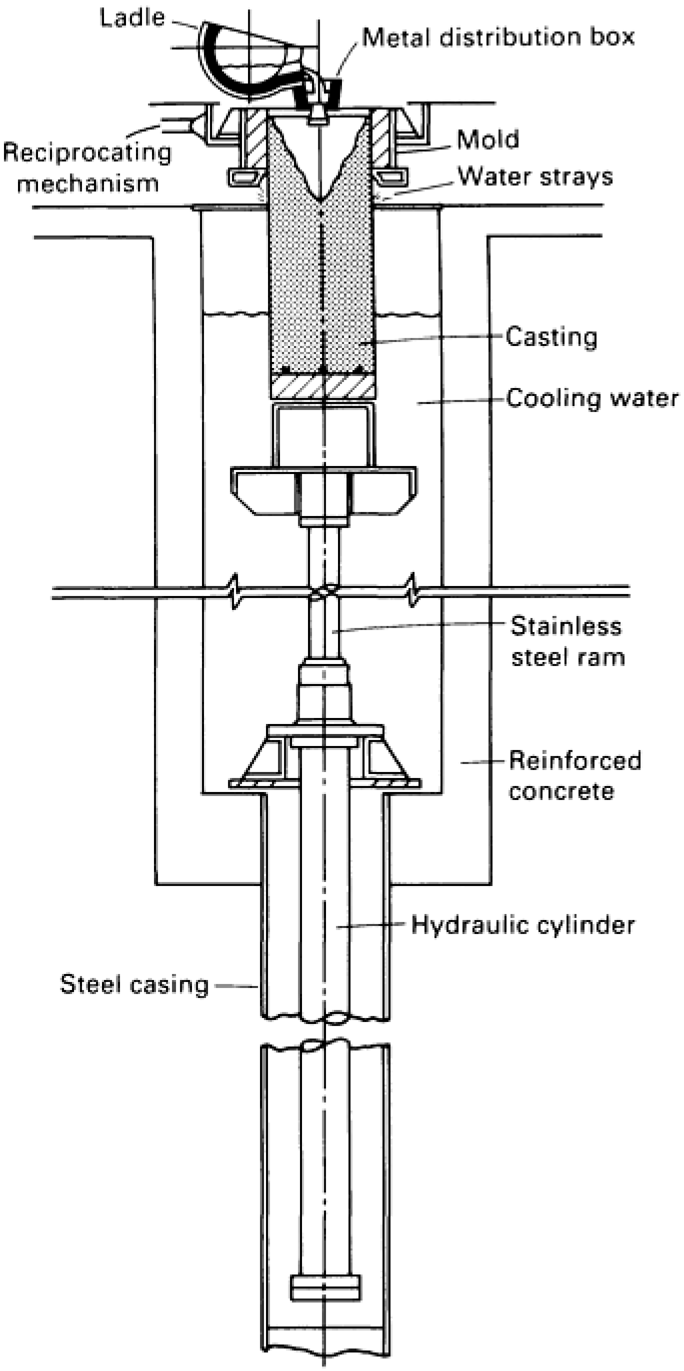

Fig. 15 A direct-chill unit for casting copper alloy slabs. The slabs produced by this unit are approximately 9 m (29.5 ft) long. Source: Ref 28

Other Processes

There are numerous types of continuous casting processes that commercially produce nonferrous metals, principally aluminum and copper alloys (Ref 29). These processes can be characterized by their products. The more common processes are discussed below.

Wheel-and-Band Machines. Rod and bar are continuously cast on wheel-and-band machines, such as the Properzi process (Fig. 16), or the more recent Southwire casting system, which is illustrated in Fig. 17. These processes involve casting between the circumference of a large copper-rimmed wheel containing the mold configuration and a steel band (Fig. 18). The metal solidifies in the gap as the wheel and band rotate through a portion of a circular path, which includes

water sprays. Casting rates of 32 Mg/h (35 tons/h) for a 450 × 450 mm (18 × 18 in.) copper billet have been reported (Ref 31). The Southwire process has recently been applied to the production of steel billets.

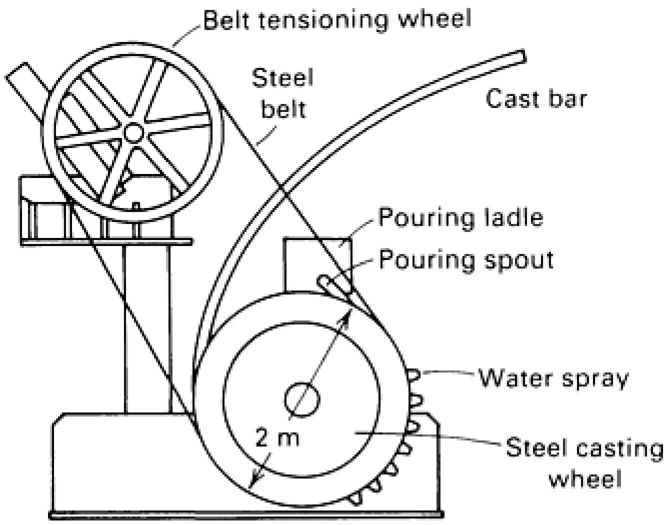

Fig. 16 The Properzi casting machine. Source: Ref 30

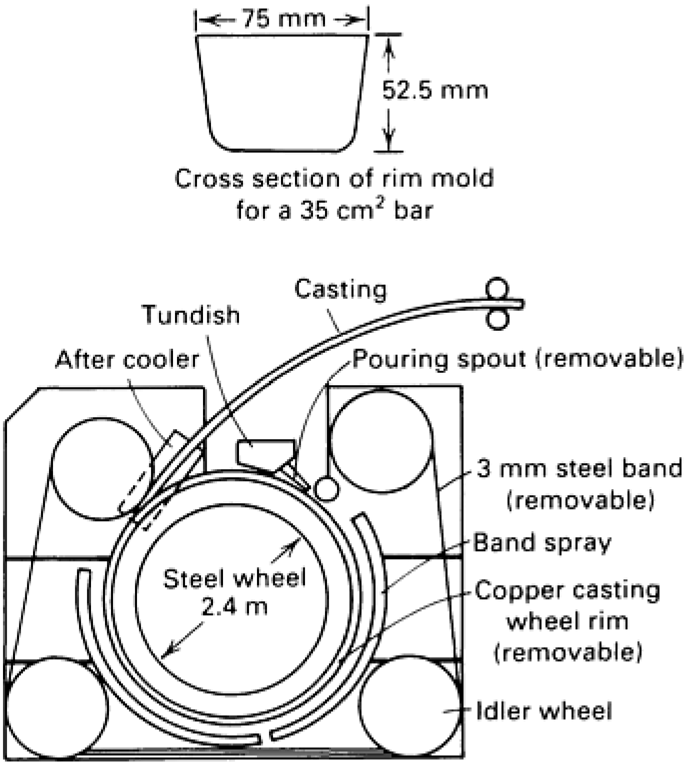

Fig. 17 The Southwire wheel-and-band continuous casting machine. Source: Ref 31

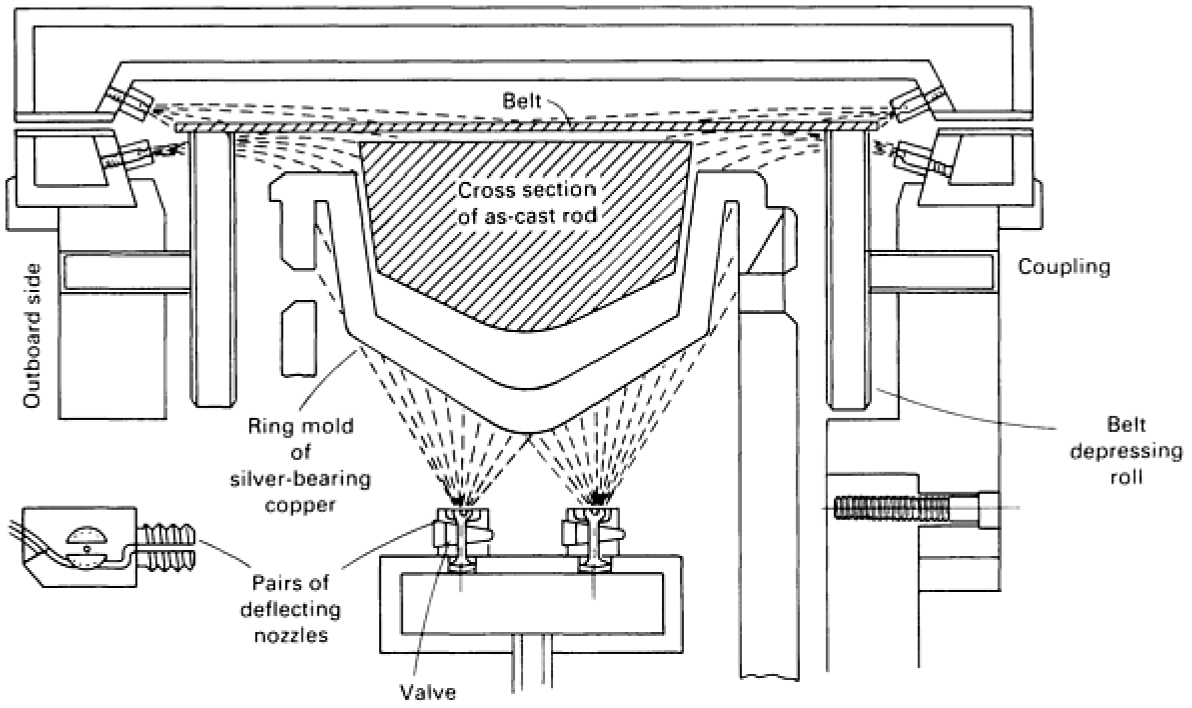

Fig. 18 The Properzi ring mold, belt, and as-cast rod. Source: Ref 32

Wide, thick strip is normally produced on a twin band machine, such as the Hazelett caster (Fig. 19).

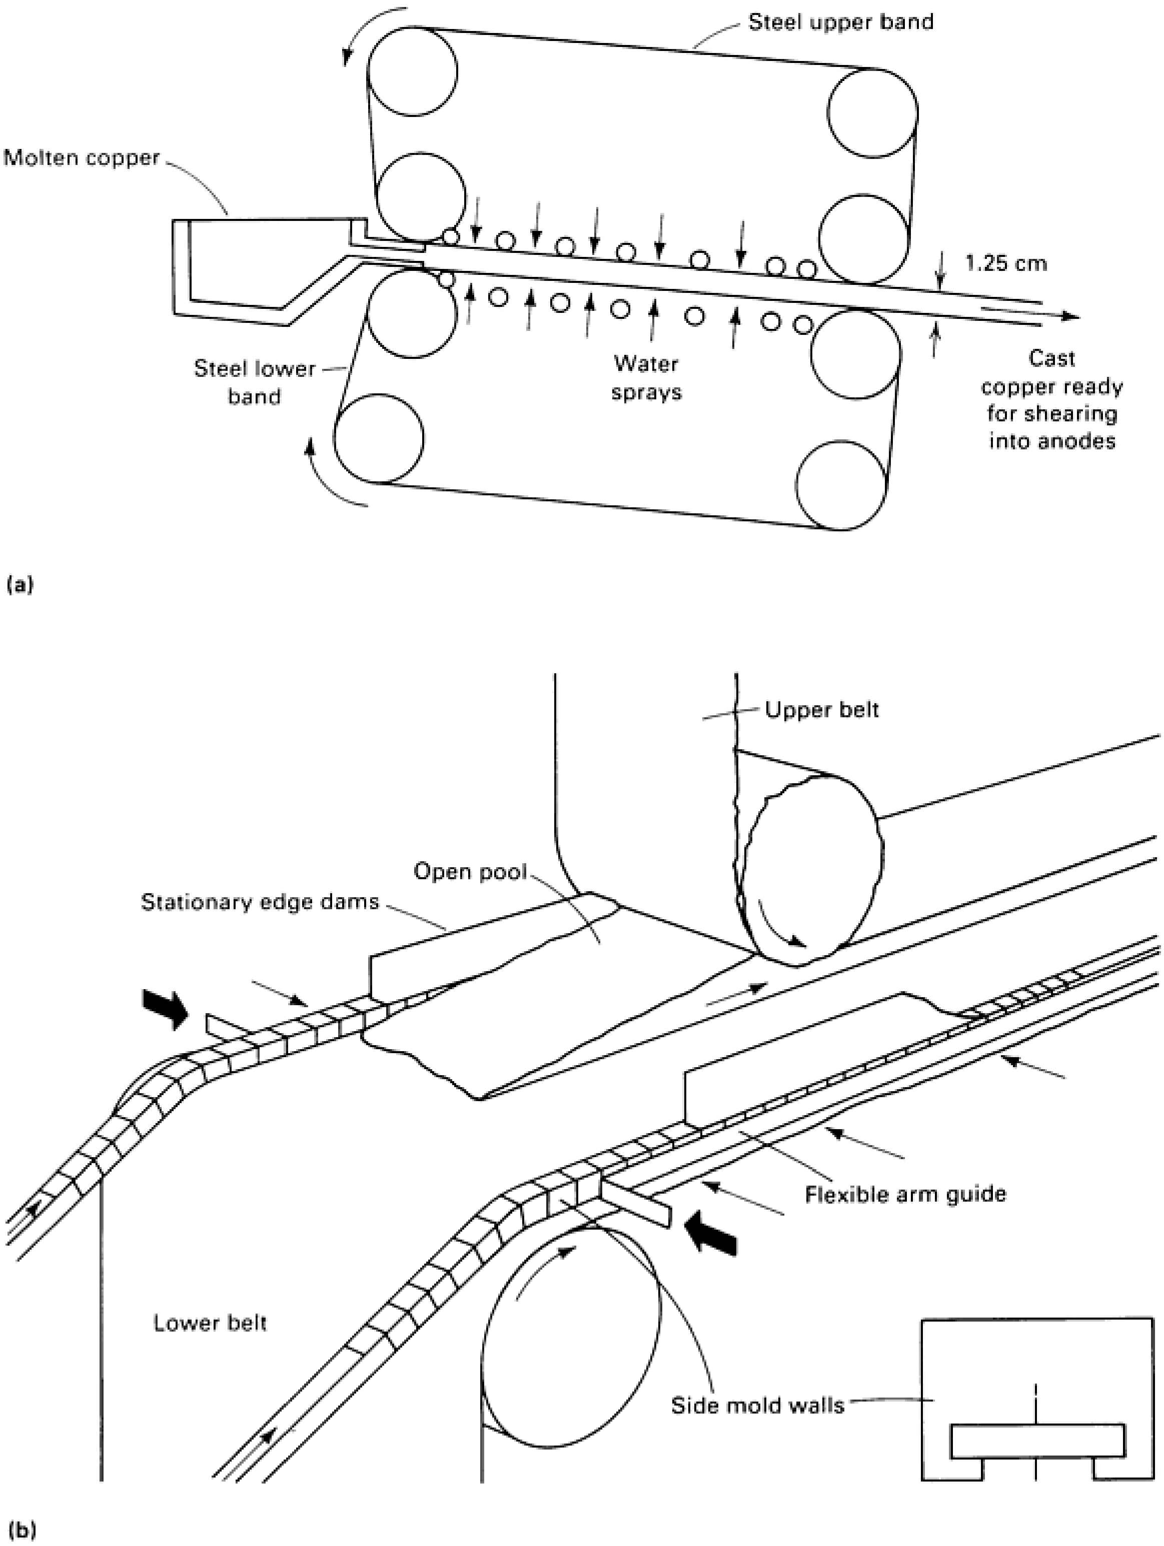

Fig. 19 The Hazelett machine for continuous casting of copper anode strip. Source: Ref 33

The bands are separated by edge dams on each side of the castings; these dams can be moved to set the width of the strip.

Twin roll casting has been used for the production of wide, thin aluminum strips. Several twin roll processes are used to cast 6 to 12 mm (0.24 to 0.48 in.) thick by 1500 to 2000 mm (59 to 79 in.) wide strip.

Many product quality problems relate to mold and air gap formation, as well as interaction of the ingot shell and liquid core. These could be eliminated by moldless casting, wherein an electromagnetic field supports the liquid metal until it enters the direct-quench zone. Such a process was developed in the Soviet Union (Ref 34). Electromagnetic casting is currently being used in the aluminum industry (Ref 35) and has been developed for copper-base alloys (Ref 36). The process is shown in Fig. 20.

Future Developments

The emphasis on the further development of continuous casting will focus on control systems and automation, with the objective of maintaining high quality and high productivity. Accomplishing this will include monitoring metal quality and ensuring that all aspects of the process are under proper control. Various operating parameters, such as mold, slag, or flux levels in ladle, and tundish, also will be monitored directly. Sensors will be developed to control automatically the process for proper cooling in the mold, first zone, and secondary cooling systems. Hot inspection techniques will be developed that will provide a direct measure of product quality as it leaves the casting machine and moves to hot-rolling processing.

Also, current worldwide efforts on steel processing are in the area of the belt casting of thin slabs, the roll casting of thin strip, and the electromagnetic casting of steel.

Counter-Gravity Low-Pressure Casting

Dixon Chandley, Metal Casting Technology, Inc.

Introduction

ENGINEERS have made various attempts, since early in this century, at drawing metal up into molds against the flow of gravity to produce castings. Molds were typically put into a vacuum box with a fill pipe extending from the mold out of the box. The fill pipe was submerged in molten metal, and a vacuum was generated around the mold, causing the metal to rise into the mold. Metal molds were generally used, and by World War II, many premium-quality aluminum castings were made in such molds by counter-gravity filling. Metal molds were vented to permit the vacuum to exhaust the mold cavities properly and to draw in the metal. In the early 1970s, new methods were developed for counter-gravity casting into nonmetal permeable molds, first using ceramic investment molds and later using low-temperature bonded sand molds. The processes described in this article are covered by U.S. and other patents and are in high-volume production in nine countries and fourteen companies worldwide. Counter-gravity low-pressure casting processes are widely known by acronyms; therefore, these acronyms will be used here for convenience. Counter-gravity low-pressure casting processes include:

- Counter-gravity low-pressure casting of air-melted alloys (CLA)
- Counter-gravity low-pressure casting of vacuum-melted alloys (CLV)
- Check-valve casting (CV)
- Counter-gravity low-pressure air-melted sand casting (CLAS)

Counter-Gravity Low-Pressure Casting

Dixon Chandley, Metal Casting Technology, Inc.

The CLA Process

The CLA process (Fig. 1) is used to cast metals that are normally melted in air. The economies of the process are based on casting more parts per mold, high gating efficiencies (because most of the gating metal flows back into the furnace), and fewer casting defects (especially melt inclusions, which are reduced because the fill pipe is always submerged into clean metal). Thin-wall parts (wall thickness as small as 0.75 mm, or 0.03 in.) are easily made at high volume and low cost.

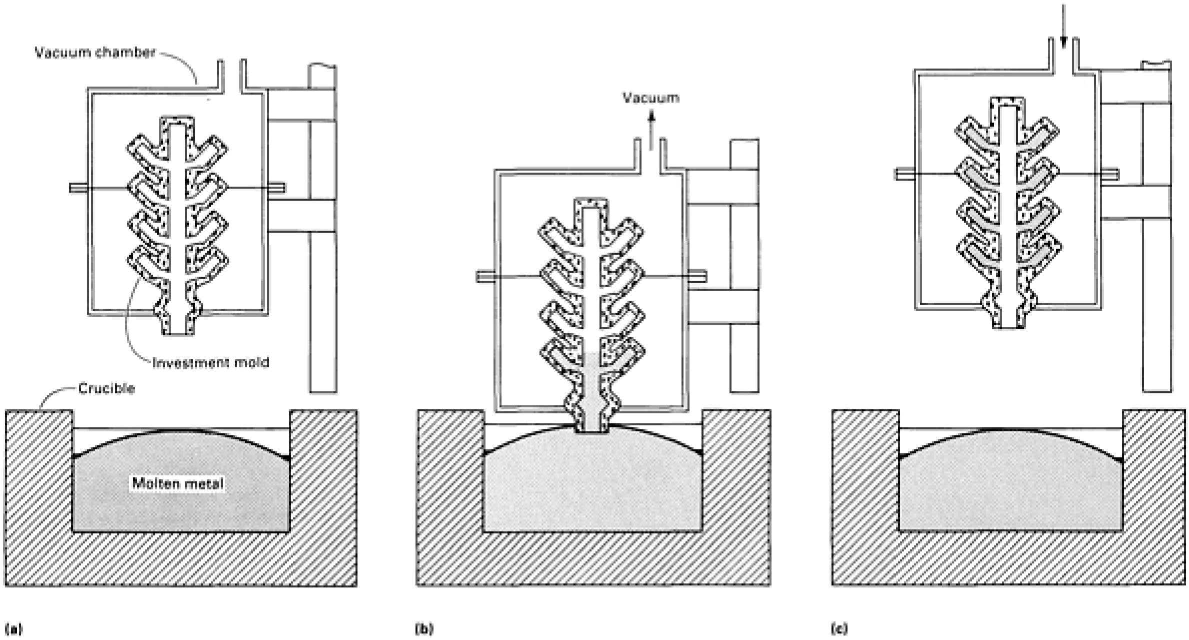

Fig. 1 Schematic of the operations in the CLA process. (a) Investment shell mold in the casting chamber. (b) Mold lowered to filling position. (c) Mold containing solidified castings; most of the gating has flowed back into the melt.

Applications. The CLA process is used to make parts from all types of alloys for many industries. For the automotive industry, steering system components, transmission parts, diesel precombustion chambers, rocker arms, mounts, and hinges are made. Among the components produced for the aircraft and aerospace industries are temperature probes, fuel pump impellers, missile wings, brake parts, pump housings, and structural parts. Other applications include golf club heads, innumerable machine parts, wood router tool bits, tin snip blades, small wrenches, lock parts, gun parts, valves and fittings, and power tools.

Counter-Gravity Low-Pressure Casting

Dixon Chandley, Metal Casting Technology, Inc.

The CLV Process

The CLV process (Fig. 2) is used for alloys containing reactive metals, especially the superalloys which may contain aluminum, titanium, zirconium, and hafnium. It can be seen that the advantages of the CLA process also apply to the CLV process. The outstanding features of this process include the ability to fill thin sections and to make castings that are free of the small oxides that plague gravity pouring methods. It is possible to make castings of large area in wall thicknesses down to 0.5 mm (0.02 in.) and without the small oxides that would render such parts defective.

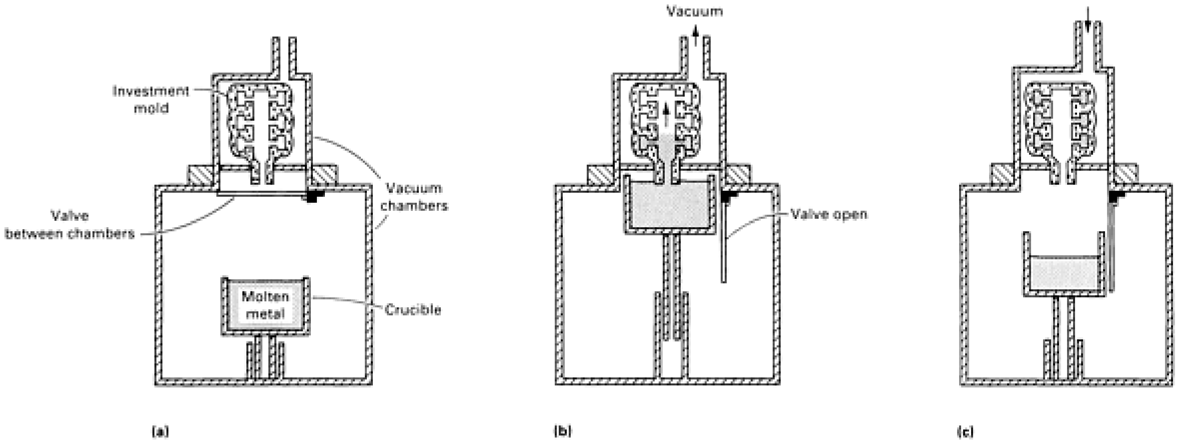

Fig. 2 Schematic showing steps in the CLV process. (a) Metal is melted in vacuum, and the hot mold is introduced into a separate upper chamber. A vacuum is then created in the second chamber. (b) Both chambers are partially flooded with argon, the valve between the chambers is opened, and the fill pipe enters the molten metal. Additional vacuum is then applied to the upper chamber to draw metal upward. (c) The vacuum is released after the parts are solidified, and the remaining molten metal in the gating system returns to the crucible.

Applications. For gas turbine engines, the CLV process provides parts with the lowest level of melt oxide inclusions for alloys such as MAR-M 509 and René 125, which are noted for hafnium and zirconium inclusions when gravity poured. The process enables a new approach to the design of jet engine burner cans, in which the rolled and welded sheet metal design has been replaced with an assembly of thin-wall (0.5 mm, or 0.02 in.) castings shaped for maximum heat transfer and mechanically assembled to reduce thermal fatigue. Such burner cans provide a much higher temperature capability. Important cost and quality improvements have been achieved in cast airfoils, turbine seals, conduits, clamps, and turbocharger wheels.

Counter-Gravity Low-Pressure Casting

Dixon Chandley, Metal Casting Technology, Inc.

The CV Process

The CV process (Fig. 3) is used for castings that are too thick to solidify in the manner required by the CLA or CLV process. As shown in Fig. 3, this process uses a flexible fill pipe, which is crimped shut by a check valve when the mold is filled. The CV process provides a good fill of thin castings, along with the improved metal cleanliness of the other processes, and it applies to all molding methods.

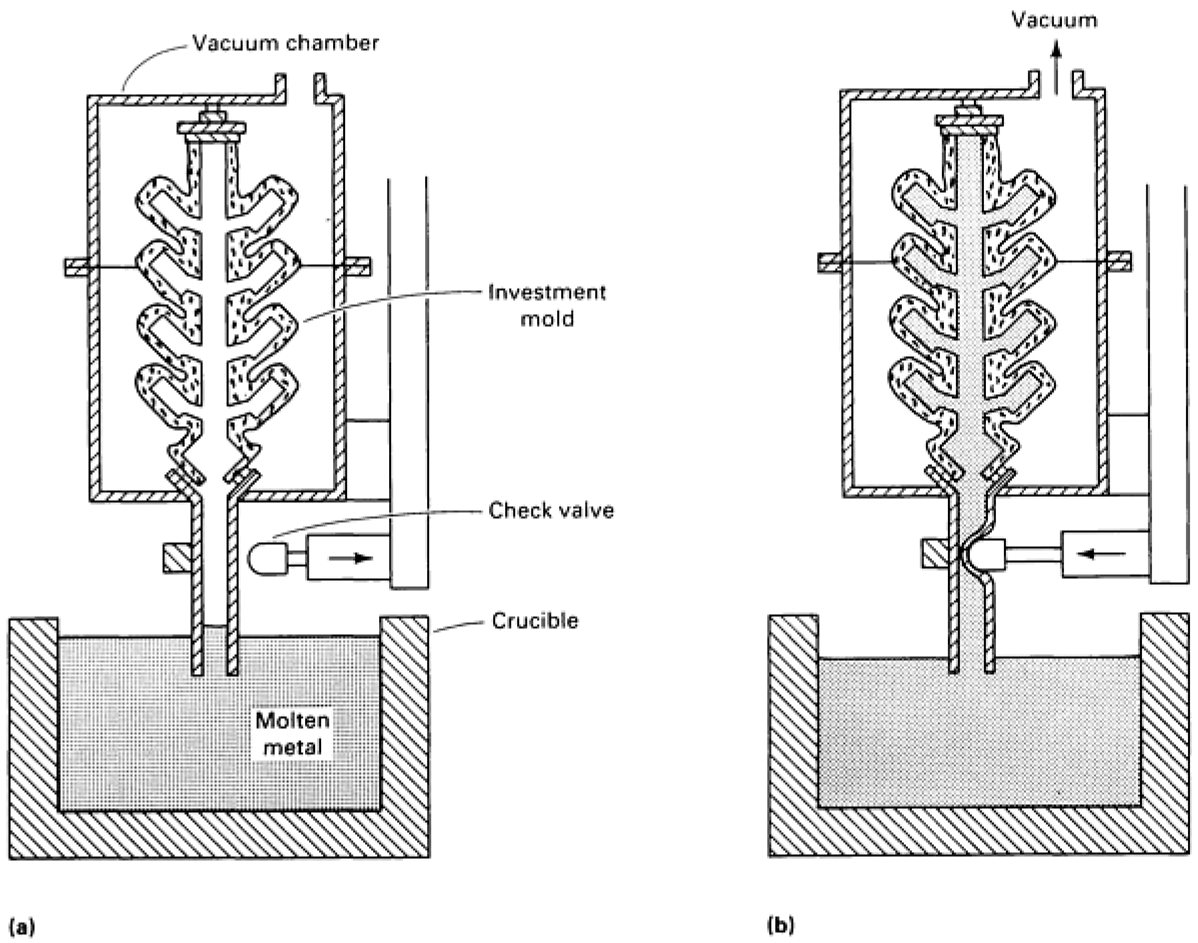

Fig. 3 Schematic of the CV process. (a) Fill pipe is submerged and vacuum is used to fill the mold as in the CLA process. (b) When the mold is filled, a check valve crimps the fill pipe shut. Metal is trapped in the mold, which is then moved away and allowed to solidify as in gravity-filled molds.

Applications of the process include large missile wings, valve bodies, hinges, and other large parts with varying section thickness.

Counter-Gravity Low-Pressure Casting

Dixon Chandley, Metal Casting Technology, Inc.

The CLAS Process

The CLAS process (Fig. 4) is used for sand casting and is quite different from the other processes discussed above. It has a unique ability to make thin castings at low vacuum levels. Because the metal is taken from the clean portion of the melt and because castings are made at low metal temperatures, melt inclusions are very low in volume as compared to those found in gravity casting.

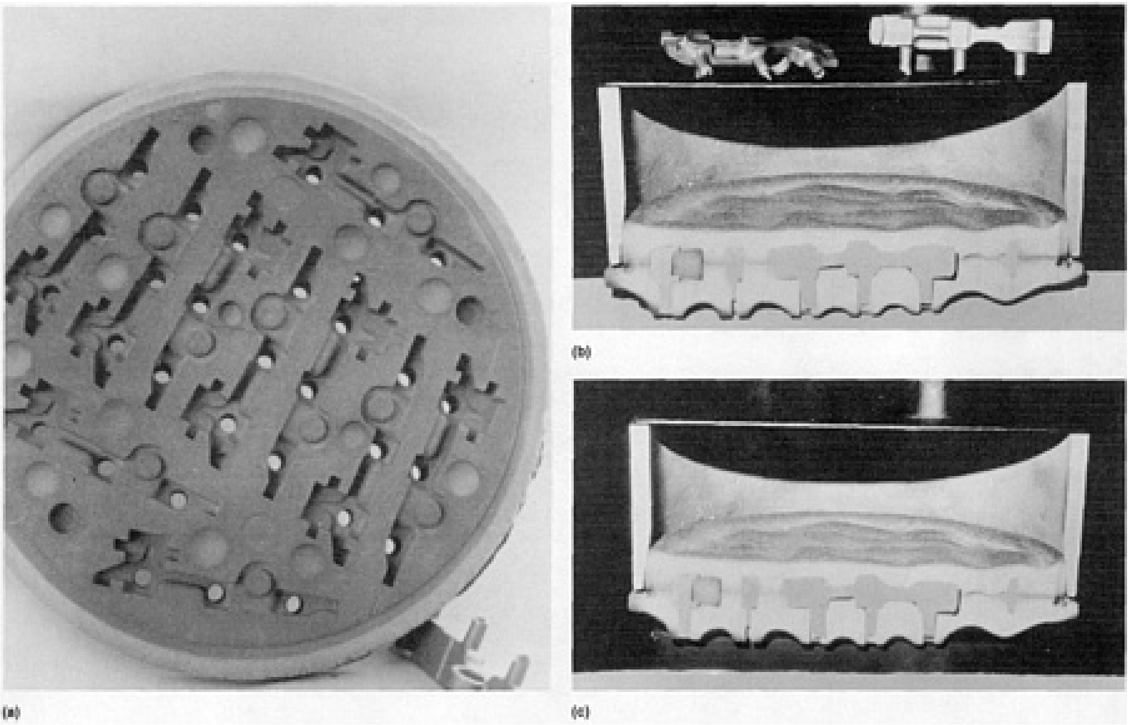

Fig. 4 Essential features of the CLAS process. (a) View of CLAS mold showing high pattern density and open bottom gates. The mold shown uses direct gating into parts. (b) Cross section of mold and casting head during mold filling. (c) Cross section of mold and casting head after solidification. Blind risers can be used for thick-wall castings.

Applications. Connecting rods and thin, hollow cam shafts for automotive use can be made with wall thicknesses of only 1.5 mm (0.06 in.) in steels and cast irons. Stainless steel truck wheel centers that are lighter than aluminum wheels can be made, owing to the thin walls that are possible with this process.

Directional and Monocrystal Solidification

Thomas S. Piwonka, Metal Casting Technology Center, University of Alabama

---

Introduction

Most castings are employed in applications in which stress fields are isotropic, but there are a few important uses in which the stresses are primarily unidirectional along a single axis. In such cases, casting practices that enhance the properties along that axis have been developed. Two of the most widely used methods are directional solidification and monocrystal (single-crystal) casting.

Directional and Monocrystal Solidification

Thomas S. Piwonka, Metal Casting Technology Center, University of Alabama

---

Directional Solidification

The process used to manufacture directionally solidified castings with a columnar structure requires careful control to ensure that castings which are of acceptable quality are produced. Specialized furnaces are used, and mold design is quite different from that used for conventional investment castings.

Metallurgical Effects of Columnar Structures

An important application of directional solidification is in the manufacture of blades (rotating parts) for gas turbine engines (Fig. 1). These components are subjected to high stresses along their major axes, as well as high temperatures. Because grain boundaries are weaker than grains at high temperatures, it is logical to align them parallel to the axis of principal stress to minimize their effect on properties.

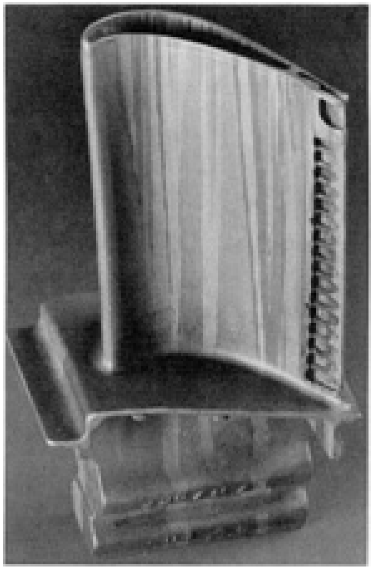

Fig. 1 Directionally solidified thin-wall turbine blade cast from Alloy CM 247 LC (modified MAR M-247 composition)

Materials. The alloy that was originally used in directionally solidified turbine components was MAR M-200, a nickel-base alloy containing 12.5% W (Ref 1). The solidified structure consisted of tungsten-rich dendrites with high strength and creep resistance that grew to the length of the casting. The grain-boundary material, which was parallel to the dendrites, was strong enough to withstand the transverse stresses on the components. The properties of the directionally solidified alloy were far superior to those of the equiaxed alloy, as shown in Fig. 2. Other alloys have since been designed to make use of the process.

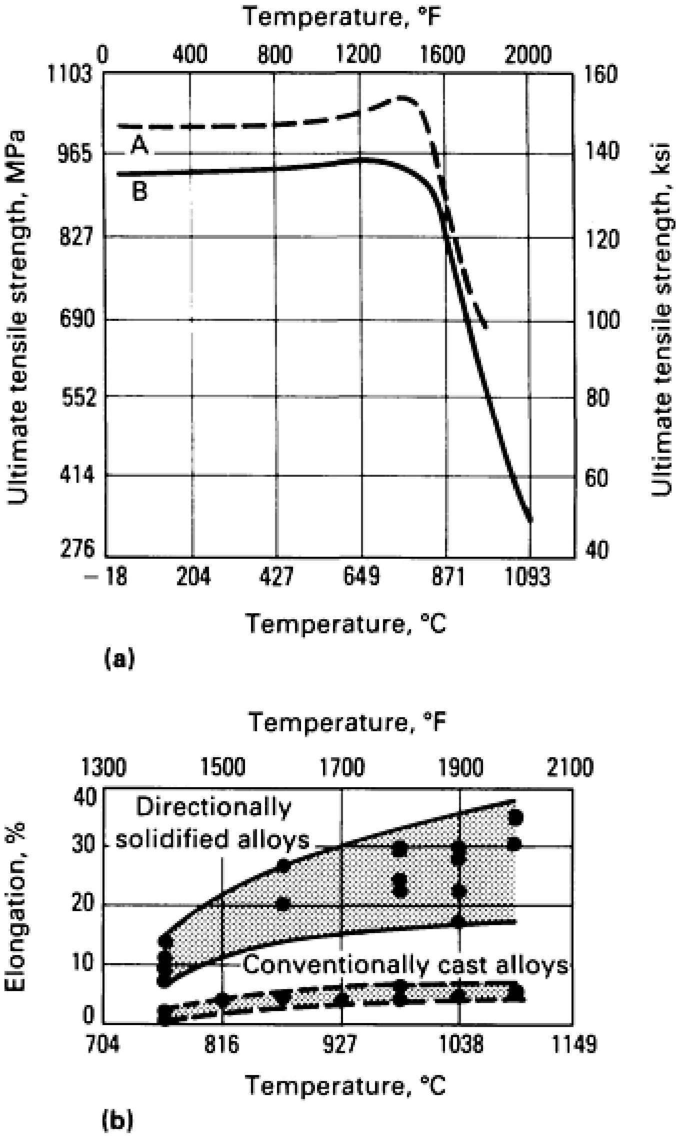

Fig. 2 Comparison of properties of directionally solidified and conventionally cast alloys. (a) Ultimate tensile strength of MAR M-200 alloy. Curve A, directionally solidified; curve B, conventionally cast. Source: Ref 1. (b) Average rupture elongation of various alloys

In columnar structures, the primary dendrites are aligned, as are the grain boundaries. The primary dendrites form around spines of the highest-melting constituent to freeze. As freezing continues, the solid rejects solute into the residual liquid (segregation occurs) until the final low-melting eutectic has frozen at the grain boundaries. Because segregation products collect in the grain boundaries, it is important to consider the composition of these grain boundaries in directional structures.

An ideal composition for directional solidification is one in which the primary dendrites form around a strong spine, while the grain boundaries also retain their strength. A poor alloy is one in which the segregation products form embrittling phases, especially adjacent to secondary dendrite arms, which are normal to the primary stress axis.

Heat Flow Control

To obtain a directionally solidified structure, it is necessary to cause the dendrites to grow from one end of the casting to the other. This is accomplished by removing the bulk of the heat from one end of the casting. To this end, a strong thermal gradient is established in the temperature zone between the liquidus and solidus temperatures of the alloy and is passed from one end of the casting to the other at a rate that maintains the steady growth of the dendrite, as shown in Fig. 3. If the thermal gradient is moved through the casting too rapidly, nucleation of grains ahead of the solid/liquid interface

will result; if the gradient is passed too slowly, excessive macrosegregation will result, along with the formation of freckles (equiaxed grains of interdendritic composition) (Ref 3). Therefore, the production of directionally solidified castings requires that both the thermal gradient and its rate of travel be controlled. For the case of nickel-base alloys, thermal gradients of 36 to 72 °C/cm (165 to 330 °F/in.) have been found to be effective (Ref 4), and rates of travel of 30 cm/h (12 in./h) can be used. There is, however, no upper limit on the allowable gradient, and higher gradients usually produce better castings than lower gradients. The lower limit on the thermal gradient is a function of alloy composition and casting geometry.

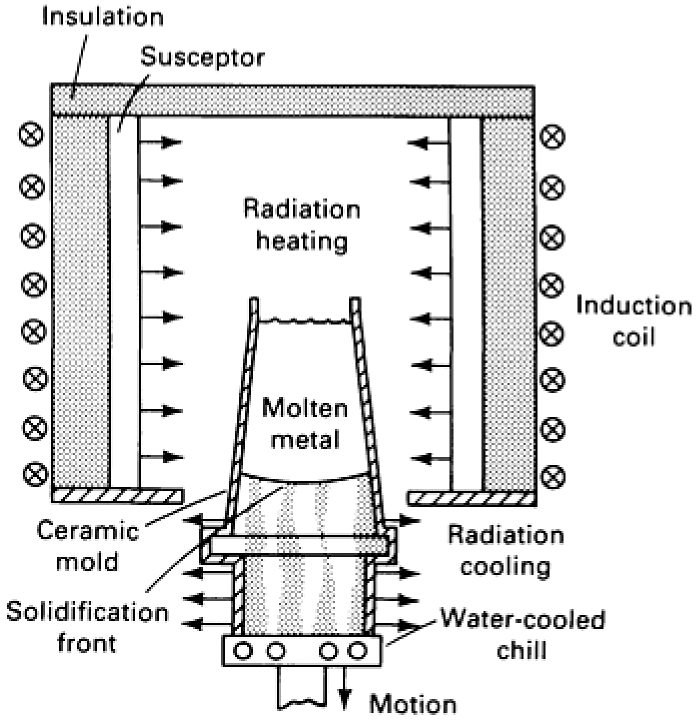

Fig. 3 Schematic showing the directional solidification process. Source: Ref 2

The most effective way to control heat flow is to use a thin-wall mold, such as an investment casting mold, that is open at the bottom. The mold is placed on a chill (which is usually water cooled) and heated above the liquidus temperature of the alloy. Molten metal is poured into the mold, and the mold is cooled from the chilled end by withdrawing the mold from the mold-heating device.

The chill is used to ensure that there is good nucleation of grains to start the process. Because of the low thermal conductivity of nickel-base alloys, the thermal effect of the chill extends only about 50 to 60 mm (2 to 2.4 in.) (Ref 5, 6). Although the grains originally nucleate with random orientations, those with the preferred growth direction normal to the chill surface grow and crowd out the other grains. Therefore, those grains that grow through the casting are all aligned in the direction of easiest growth. For nickel-base alloys, the preferred growth direction is <001>; therefore, in castings made of these alloys, the grains are aligned in the <001> direction. Passing the thermal gradient through the casting at a uniform rate ensures that the secondary dendrite arm spacing is uniform throughout the casting (Ref 5).

Processing of Directionally Solidified Castings

In the most common directional solidification process, an investment casting mold, open at the bottom as well as the top, is placed on a water-cooled copper chill and raised into the hot zone of the furnace (Fig. 4). The mold is heated to a temperature above the liquidus temperature of the alloy to be poured. Meanwhile, the alloy is melted (usually under vacuum) in an upper chamber of the furnace. When the mold is at the proper temperature and the charge is molten, the alloy is poured into the mold. After a pause of a few minutes to allow the grains to nucleate and begin to grow on the chill, during which the most favorably oriented grains are established, the mold is withdrawn from the hot zone to the cold zone.

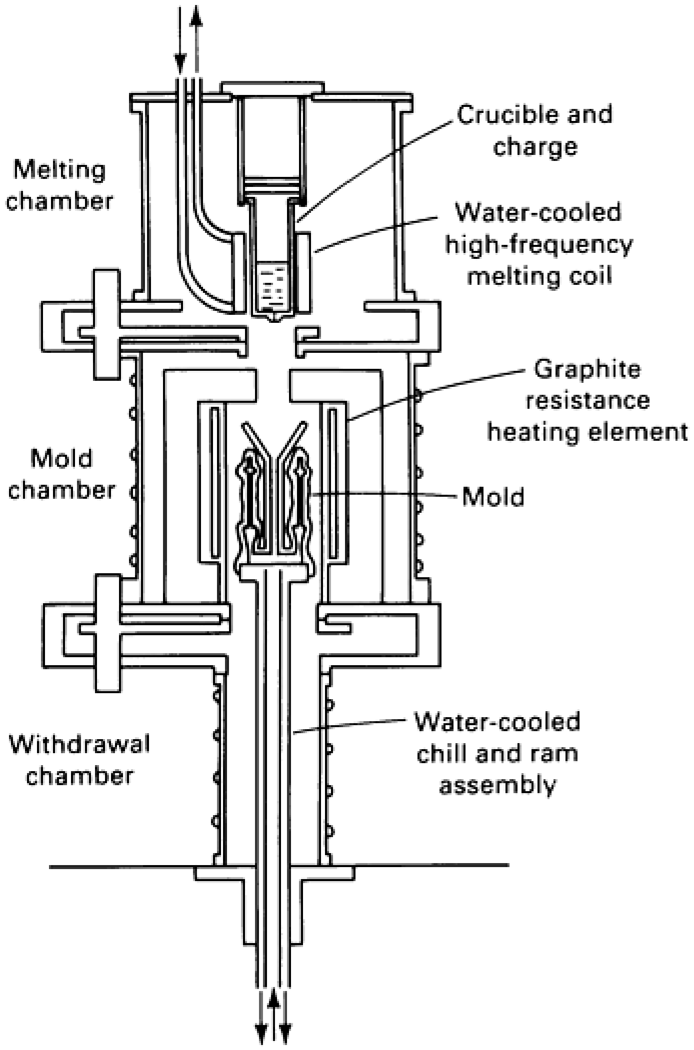

Fig. 4 Configuration of one type of directional solidification furnace. Source: Ref 7

Furnaces. The furnace shown in Fig. 4 has a relatively small chill diameter (140 mm, or 5.5 in.) to enhance the thermal gradient, a resistance-heated hot zone, and an unconventional melting method in which the charge melts through a plate in a bottom-pour crucible instead of being poured. However, other furnace designs use larger chill plates (up to 500 mm, or 20 in.), induction-heated graphite susceptors in their hot zones, and conventional pouring to produce these castings. Additional information on furnaces and other equipment for directional solidification is available in the section "Vacuum Induction Remelting and Shape Casting" in the article "Vacuum Melting and Remelting Processes" in this Volume.

Gating. Castings can be gated either into the top of the mold cavity or the bottom. Bottom gating heats the mold just above the chill and sets up a very high gradient that encourages well-aligned dendrites. Particular care is taken to keep the transition between the hot and cold zones as sharp as possible through the use of radiation baffles made of refractory materials; these baffles are placed at the chill level between the hot and cold zones.

Mold Design. In designing molds for the process, consideration must be given to the orientation of the part on the cluster. Because heat transfer is by radiation, parts must be placed to minimize shadowing. Internal radiation baffles are sometimes added to the mold, particularly around the center downsprue, to distribute radiation energy to those parts of the mold that would otherwise be shadowed, and some furnace designs use a heating source or a cooling baffle around the center downpole (the chill is designed with a circular cutout at its center) to increase the gradient. Because castings solidify directionally, it is possible to stack them on top of each other to increase the number of castings that can be made in each heat.

Process Control. A very high degree of control must be exercised over the process; therefore, the furnaces are highly automated. Completely automated furnaces (which charge, melt, heat the mold, pour, hold, and withdraw according to a programmed cycle) are commonly used, and even in those furnaces in which melting is done manually the solidification (withdrawal) cycle is automated. Thermocouples are placed within the mold cavity on large clusters to ensure that the molds are at the proper temperature before pouring.

Withdrawal rates during solidification are not necessarily constant. Large differences in section size in specific castings change the solidification rate, and the withdrawal rate can be changed to compensate for this. In selecting a solidification cycle for a hollow part, the effect of the core must be included. Cores lengthen the time required to preheat the mold and slow the withdrawal rate because the heat they contain must also be removed in the process.

Defects Unique to Directional Solidification

Directionally solidified castings are routinely inspected by etching their surfaces and examining the surface visually for defects. The most obvious defect is the presence of an equiaxed or misoriented grain. Equiaxed grains are most often freckles, which are caused by segregation of eutectic liquid that is less dense than the bulk liquid in many alloys. This liquid forms jets within the mushy zone, and as these jets freeze they form equiaxed grains. Freckles are usually cured by increasing the thermal gradient and solidification rate in the casting.

Misoriented grains occur when the temperature ahead of the interface falls below the liquidus temperature and new grains nucleate. These grains will have a random orientation, but because they are growing in gradient, they will be columnar. They can be eliminated by increasing the gradient.

Shrinkage is sometimes encountered on the upper surfaces of directionally solidified castings. There is no way to feed these surfaces; the addition of risers to these surfaces usually interferes with radiation heat transfer from another part of the casting. The most common solution is to invert the casting in order to minimize the surface area that is susceptible to shrinkage.

Microporosity may occur in directionally solidified castings if the length of the mushy zone (length of the casting that is between the liquidus and solidus temperatures during solidification) becomes too great for feed metal to reach into the areas where solidification is taking place. Increasing the thermal gradient (which shortens the length of the mushy zone) usually solves this problem.

Mold or Core Distortion. A frequent cause of scrap in directionally solidified castings results from mold or core distortion. Because the mold and core are held at high temperatures for long times while the casting solidifies, it is possible for the mold or core to sag or to undergo local allotropic transformations of the refractory materials from which they are made. The resulting changes in mold or core dimensions are reflected in the casting dimensions. Careful control of the core and mold composition, their uniformity, and the firing conditions under which they are made is required in order to avoid these dimensional problems.

Other Directional Solidification Methods

The process described above is the most widely used method of producing directionally solidified castings. However, other methods can be used as well. For example, instead of using electrical means to heat the mold before pouring, the mold can be invested with an exothermic material (Ref 8). When ignited, the material burns in the classic thermit reaction, heating the mold to a temperature above the liquidus of the alloy. The mold and hot exothermic material are placed on a water-cooled copper chill, and the alloy is poured. Both the exothermic material and the metal are cooled by the chill, thus causing solidification to proceed directionally. This process is limited by the properties of the exothermic mixture, and it is most useful for small solid parts. It can also be used in sand molds, for which the grain size and alignment specifications are not as stringent as they are for aerospace castings.

A variation on the mold withdrawal method described above, which is used when very high thermal gradients are desired (as in the production of directionally solidified eutectic alloys), is the liquid metal cooling process (Ref 9). In this method, the mold is immersed in a bath of a liquid metal, such as tin. Heat is removed from the mold by conduction; in addition, the liquid metal bath is an extremely efficient baffle for the radiation in the hot zone.

Directional and Monocrystal Solidification

Thomas S. Piwonka, Metal Casting Technology Center, University of Alabama

Monocrystal Casting

It was early recognized that if columnar-grain castings could be produced, the production of castings that contained only a single crystal (more accurately, a single grain or primary dendrite) could be produced by suppressing all but one of the columnar grains (Ref 10). Such a casting is compared with equiaxed and directionally solidified castings in Fig. 5. The fact that the castings consisted of a single crystal removed the limitations on transverse strength imposed by the grain boundaries, but overall properties were only slightly improved.

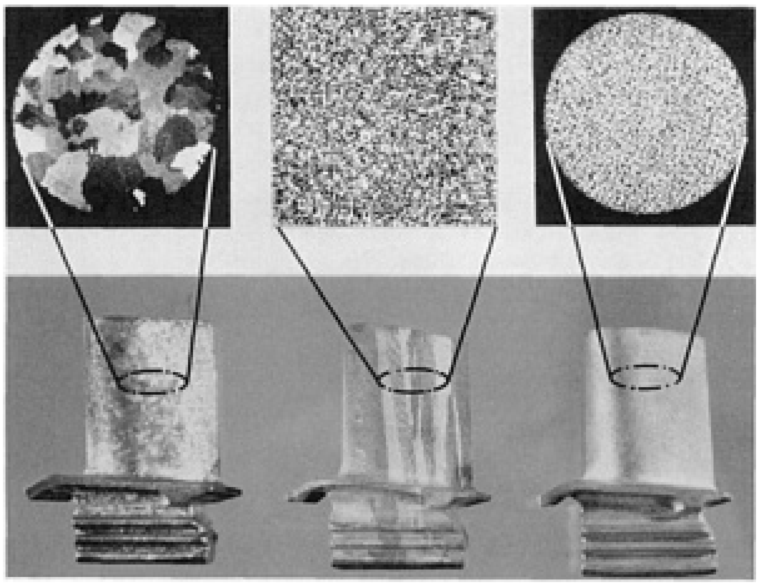

Fig. 5 Comparison of microstructures in (from left) equiaxed, directionally solidified, and single-crystal blades. Courtesy of P.R. Sahm, Giesserei-Institut der RWTH (West Germany)

Metallurgy of Monocrystal Casting

Many alloys contain elements added as grain-boundary strengtheners. These elements lower the incipient melting temperature and therefore limit the temperature at which the alloys can be solutionized.

After it was recognized that alloys having no grain boundaries need no grain-boundary strengtheners, and therefore can be solutionized at higher temperatures, development of high-temperature nickel-base monocrystal alloys began in earnest (Ref 2, 11, 12). These alloys have better high-temperature properties than conventionally cast or directionally solidified alloys because they can precipitate a higher percentage of the γ' strengthening phase (Fig. 6). In addition, because they have no grain boundaries, monocrystal alloys have improved corrosion resistance (Fig. 7).

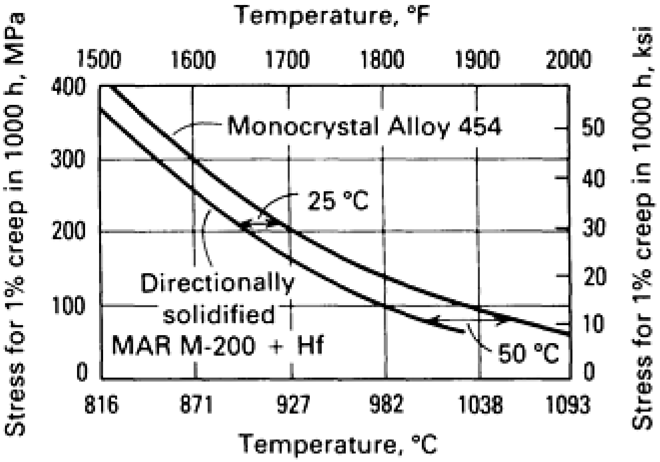

Fig. 6 Creep strength of monocrystal Alloy 454 compared with that of directionally solidified MAR M-200 + Hf. Source: Ref 2

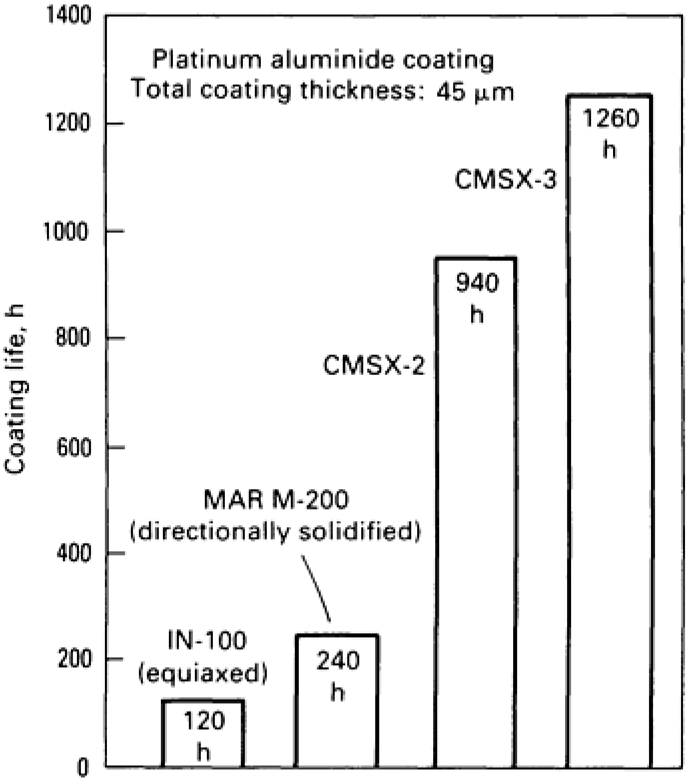

Fig. 7 Effect of grain structure on coating life in hot corrosion testing. Test consisted of exposure to hot salt at 850 °C (1562 °F) and oxidizing atmosphere at 1000 °C (1832 °F). Source: Ref 11

Applications of monocrystal castings must take into consideration the fact that many alloy systems are anisotropic; that is, their properties vary with crystallographic orientation, as shown in Fig. 8. This means that designers must design with this

in mind and that castings must be produced with specific orientations (a tolerance of ±5° of the required orientation is often specified). Further, orientation control may be required in more than one crystallographic direction.

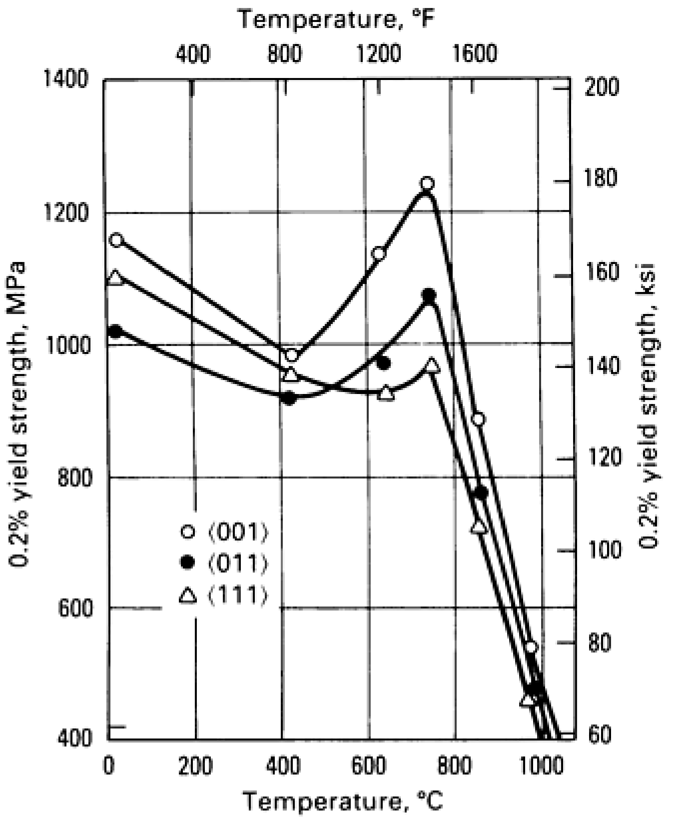

Fig. 8 Yield strength of monocrystal PWA 1480 alloy as a function of temperature and orientation. Source: Ref 13

Monocrystal Casting Processing

Monocrystal castings are produced using techniques similar to those used for directionally solidified castings, with one important difference: A method of selecting a single, properly oriented grain is required. Three methods are most commonly used, as shown in Fig. 9.

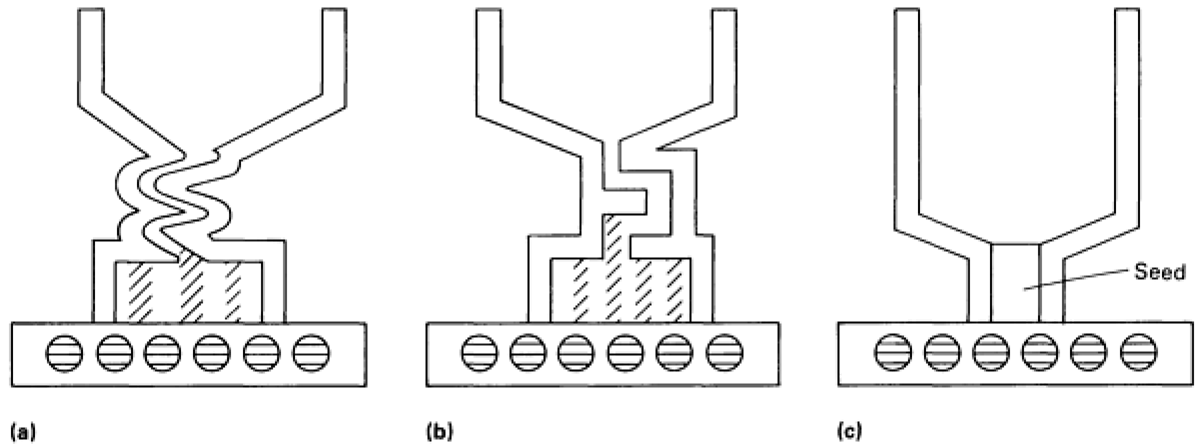

Fig. 9 Three methods of producing monocrystal castings. (a) Use of a helical mold section. (b) Use of a right-angle mold section. (c) Seeding. Source: Ref 14

Helical Mold Sections. In the first method, a helical section of mold is placed between the chill and the casting. Only the most favorably oriented grains are able to grow through this helix because all others are intercepted by the helix wall. Eventually, only one grain is left to emerge from the helix to form the casting. In this method, only the primary orientation of growth can be controlled, and it will be the preferred growth direction (<001>) for nickel-base alloys.

Right-Angle Mold Sections. The second method uses a series of right-angle bends in the helix. Because growth takes place along the preferred growth direction in each of the arms of the selector, the grain that emerges tends to be doubly oriented. If an orientation other than the preferred growth direction is desired, the casting can be tilted on the selector.

Seeding, the third method, is particularly useful for an orientation other than the preferred growth direction. Use of seeding requires that the seeds be prepared and placed in the mold before the casting is poured.

Molds. Because monocrystal alloys have higher incipient melting temperatures than conventional alloys, mold preheat temperatures will normally be higher for their manufacture than for columnar-grain castings. Therefore, mold composition control is of particular importance in the production of these castings.

Testing and Inspection. In addition to surface etching, monocrystal castings are inspected by using back reflection Laué techniques to determine crystallographic orientation. Defects in monocrystal castings are usually the same as those found in columnar castings, and remedial actions are also generally the same. Some monocrystal alloys are susceptible to local recrystallization from rough handling or solidification-induced strains and must be given a stress-relief heat treatment before solution heat treatment.

Squeeze Casting

J.L. Dorcic and S.K. Verma, IIT Research Institute

Introduction

Squeeze casting, also known as liquid-metal forging, is a process by which molten metal solidifies under pressure within closed dies positioned between the plates of a hydraulic press. The applied pressure and the instant contact of the molten metal with the die surface produce a rapid heat transfer condition that yields a pore-free fine-grain casting with mechanical properties approaching those of a wrought product.

The squeeze casting process is easily automated to produce near-net to net shape high-quality components. The process was introduced in the United States in 1960 and has since gained widespread acceptance within the nonferrous casting industry. Aluminum, magnesium, and copper alloy components are readily manufactured using this process. Several ferrous components with relatively simple geometry--for example, nickel hard-crusher wheel inserts--have also been manufactured by the squeeze casting process. Despite the shorter die life for complex ferrous castings requiring sharp corners within the die or punch (tooling), the process can be adopted for products where better properties and/or savings in labor or material costs are desired.

Squeeze Casting

J.L. Dorcic and S.K. Verma, IIT Research Institute

Advantages of Squeeze Casting (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11)

With the current emphasis on reducing materials consumption through virtually net shape processing and the demand for higher-strength parts for weight savings, the emergence of squeeze casting as a production process has given materials and process engineers a new alternative to the traditional approaches of casting and forging. By pressurizing liquid metals while they solidify, near-net shapes can be achieved in sound, fully dense castings.

The near-net and net shape capabilities of this manufacturing process are key advantages. Tolerances of ±0.05 mm (±0.002 in.) are not uncommon for nonferrous castings, with yields of 100% in a number of applications. Improved mechanical properties are additional advantages of squeeze cast parts.

Squeeze casting has been successfully applied to a variety of ferrous and nonferrous alloys in traditionally cast and wrought compositions. Applications include aluminum alloy pistons for engines and disk brakes; automotive wheels, truck hubs, barrel heads, and hubbed flanges; brass and bronze bushings and gears; steel missile components and differential pinion gears; and a number of parts in cast iron, including ductile iron mortar shells.

Squeeze casting is simple and economical, efficient in its use of raw material, and has excellent potential for automated operation at high rates of production. The process generates the highest mechanical properties attainable in a cast product. The microstructural refinement and integrity of squeeze cast products are desirable for many critical applications.

Squeeze Casting

J.L. Dorcic and S.K. Verma, IIT Research Institute

Process Description (Ref 1, 2, 3)

As shown in Fig. 1, squeeze casting consists of metering liquid metal into a preheated, lubricated die and forging the metal while it solidifies. The load is applied shortly after the metal begins to freeze and is maintained until the entire casting has solidified. Casting ejection and handling are done in much the same way as in closed die forging.

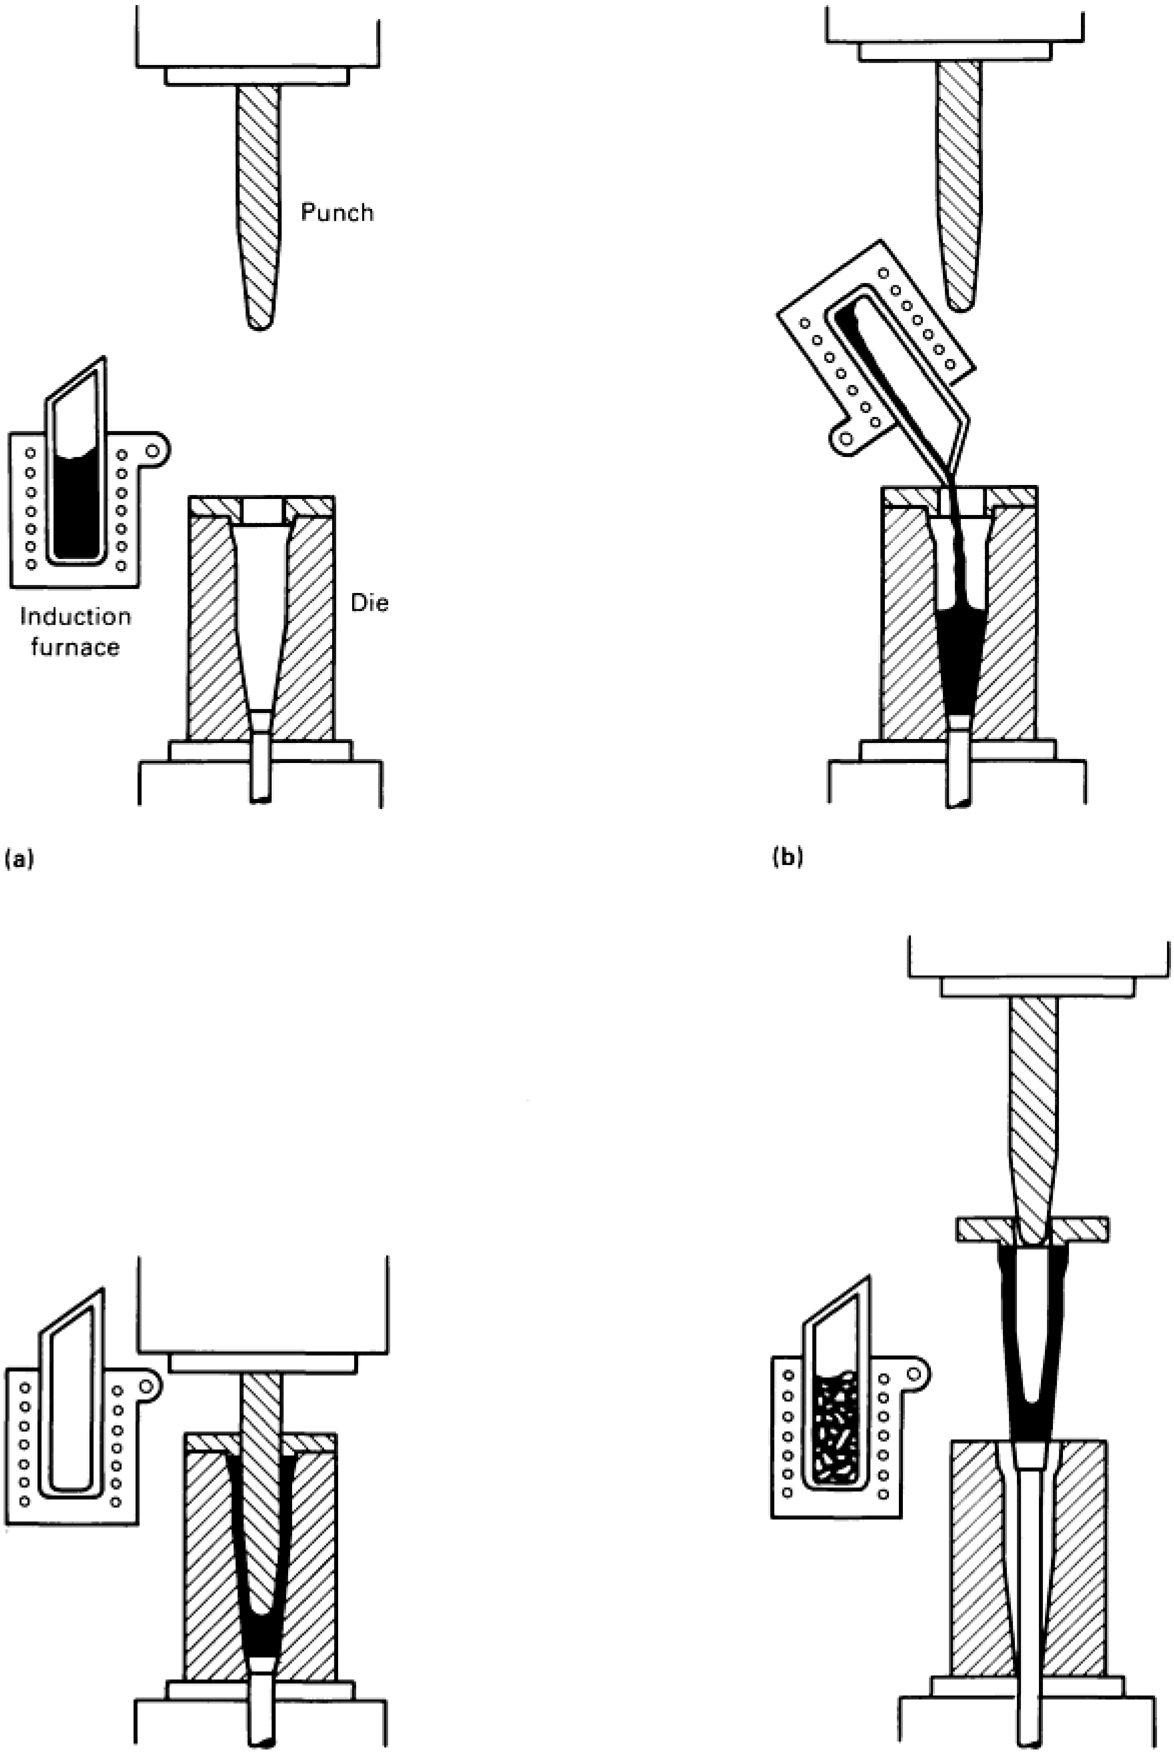

Fig. 1 Schematic illustrating squeeze casting process operations. (a) Melt charge, preheat, and lubricate

tooling. (b) Transfer melt into die cavity. (c) Close tooling, solidify melt under pressure. (d) Eject casting, clean dies, charge melt stock

The high pressure applied (typically 55 to 100 MPa, or 8 to 15 ksi) is enough to suppress gas porosity except in extreme cases, for which standard degassing treatments are used. The tendency toward shrinkage porosity is limited by using a bare minimum of superheat in the melt during pouring. This is possible in squeeze casting because melt fluidity, which requires high pouring temperatures, is not necessary for die fill, the latter being readily achieved by the high pressure applied. In heavy sections of the casting, which are particularly prone to the incidence of shrinkage porosity, the applied pressure squirts liquid or semiliquid metal from hot spots into incipient shrinkage pores to prevent pores from forming. Alloys with wide freezing ranges accommodate this form of melt movement very well, resulting in sound castings with a minimum of applied pressure.

The squeeze casting cycle starts with the transfer of a metered quantity of molten metal into the bottom half of a preheated die set mounted in a hydraulic press (Fig. 1). The dies are then closed, and this fills the die cavity with molten metal and applies pressures of up to 140 MPa (20 ksi) on the solidifying casting.

Process Variables

There are a number of variables that are generally controlled for the soundness and quality of the castings. The variable ranges discussed in the following sections vary with the alloy system and part geometry being squeeze cast.

Melt Volume. Precision control of the metal volume is required when filling the die cavity. This ensures dimensional control.

Casting temperatures depend on the alloy and the part geometry. The starting point is normally 6 to 55 °C (10 to 100 °F) above the liquidus temperature.

Tooling temperatures ranging from 190 to 315 °C (375 to 600 °F) are normally used. The lower range is more suitable for thick-section casting. The punch temperature is kept 15 to 30 °C (25 to 50 °F) below the lower die temperature to maintain sufficient clearance between them for adequate venting. Excess punch-to-die clearance allows molten metal to be extruded between them, eroding the surface.

Time delay is the duration between the actual pouring of the metal and the instant the punch contacts the molten pool and starts the pressurization of thin webs that are incorporated into the die cavity. Because increased pouring temperatures may be required to fill these sections adequately upon pouring, a time delay will allow for cooling of the molten pool before closing of the dies to avoid shrink porosity.

Pressure levels of 50 to 140 MPa (7.5 to 20 ksi) are normally used; 70 MPa (10 ksi) is generally applied, depending on part geometry and the required mechanical properties. There is an optimum pressure for each of the systems after which no added advantages in mechanical properties are obtained.

Pressure duration varying from 30 to 120 s has been found to be satisfactory for castings weighing 9 kg (20 lb). However, the pressure duration is again dependent on part geometry. Applied pressure after composite solidification and temperature equalization will not contribute any property enhancements and will only increase cycle times.

Lubrication. For aluminum, magnesium, and copper alloys, a good grade of colloidal graphite spray lubricant has proved satisfactory when sprayed on the warm dies prior to casting. Care should be taken to avoid excess buildup on narrow webs and fin areas where vent holes or slots are used. Care must also be taken to prevent plugging of these vents. For ferrous castings, ceramic-type coatings are required to prevent welding between the casting and the metal die surfaces.

Squeeze Casting

J.L. Dorcic and S.K. Verma, IIT Research Institute

Quality Control

In general, the process parameters are optimized for each component geometry to be squeeze cast. Maintaining established optimized parameters is critical to the quality and reproducibility of the squeeze cast components. Failure to do so can result in one or more of the following defects.

- Oxide inclusions
- Porosity
- Extrusion segregation
- Centerline segregation
- Blistering
- Cold laps
- Hot tearing
- Sticking
- Case debonding
- Extrusion debonding

The root causes of these defects, as well as methods for their control, are described below.

Oxide inclusions result from the failure to maintain clean melt-handling and melt-transfer systems. To minimize the likelihood of introducing metallic inclusions, filters should be included within the melt-transfer system, or molten metal turbulence should be minimized when filling the die cavity. Preventing foreign objects from entering open dies is also helpful.

Porosity and voids can occur when insufficient pressure is applied during squeeze casting operations. A general rule of thumb is to apply a pressure of 70 MPa (10 ksi), although sound castings have been produced with pressures as low as 50 MPa (7.5 ksi). Porosity and/or voids are usually eliminated by increasing the casting pressure when the other variables are optimized.

Extrusion Segregation. The relative microsegregation that occurs in squeeze cast components is much less than that in other cast components. However, the regions filled by back extrusion are rich in solute; these areas are the last to solidify within a casting. The extrusion segregation can lead to local variations in mechanical and corrosion properties. Such defects can be avoided by designing dies properly, by using a multiple gate system, by increasing die temperature, or by decreasing delay time before die closure.

Centerline segregation is a defect that is normally encountered with high-alloy wrought aluminum alloys at lower solute temperatures. As solidification begins on the die walls, the liquid phase becomes more concentrated with the lower-melting solute, which is trapped within the center areas of the extruded projections or more massive areas of the casting.

Such defects are avoided by increasing die temperature, by minimizing die closure time, or by selecting an alternative alloy.

Blistering. Air or gas from the melt that is trapped below the surface during turbulent die filling forms blisters on the cast surface upon the release of pressure or during subsequent solution heat treatments. Methods of avoiding such defects include degassing the melt and preheating the handling transfer equipment, using a slower die closing speed, increasing the die and punch venting, and reducing the pouring temperature.

Cold laps are caused by molten metal overlapping previously solidified layers, with incomplete bonding between the two. To alleviate cold laps, it is necessary to increase the pouring temperature or the die temperature. Reducing the die closure time has also been found to be beneficial.

Hot tearing takes place in alloys that have an extended freezing range (for example, off eutectic composition). When solid and liquid coexist over a wide range of temperatures, contraction of the solid around the rigid mold surface can initiate rupture in partially solidified regions. The methods used to avoid hot tearing in squeeze cast products include reducing the pouring temperature, reducing the die temperature, increasing the pressurization time, and increasing the draft angles on the casting.

Sticking. A thin layer of casting skin adheres to the die surface because of rapid cycling of the process without sufficient die/punch cooling and lubrication. To avoid sticking, it is recommended to decrease die temperature or pouring temperature.

Case debonding is found only in high-silicon alloys when an extremely fine-grain case 0.51 to 2.0 mm (0.020 to 0.080 in.) thick is formed on the surface and peels off during subsequent machining or cleaning operations. It is caused by extreme chilling of the outer skin of the casting against a cold punch or die. This problem can be overcome by increasing the tooling temperature or the pouring temperature. Decreasing the die closure time may also help eliminate case bonding.

Extrusion debonding takes place when the casting has deeply extruded details and the metal remains in the open die for a long period of time before it is extruded to fill the die cavity. The oxide present on the partially solidified crust in the die remains there after the melt has been extruded around it, resulting in the absence of a metal-to-metal bond at oxide stringer locations. Extrusion debonding can be prevented by increasing the tooling temperature or the pouring temperature. Decreasing the die closure time can reduce the oxide formation on the semi-liquid metal present in the die.

Squeeze Casting

J.L. Dorcic and S.K. Verma, IIT Research Institute

Microstructure (Ref 1, 2, 3, 4, 5, 6)

In addition to the densification achieved, there are several reasons why squeeze casting produces castings with superior properties. Even moderately applied pressure causes intimate contact between the solidifying casting and the die for a tenfold increase in heat transfer rate over permanent mold casting. This results in relatively fine grains in the casting. Fine grain size is also promoted by the large number of nuclei formed because of the low casting temperature and the elevated pressure. Furthermore, because die filling in squeeze casting does not require high melt fluidity, a number of wrought alloys can be squeeze cast. Again, pressurized solidification with rapid heat transfer tends to minimize the segregation that wrought alloys are usually prone to. As indicated in Table 1, the tensile properties of ferrous and nonferrous materials produced by squeeze casting are generally comparable to those of forgings.

Table 1 Comparative properties of commercial wrought and cast alloys

(a) Added as additional reference information only.

In a recent investigation, a side-by-side comparison was made between squeeze casting and permanent mold casting for E-132 aluminum components. As seen in Fig. 2, the squeeze casting is sounder and has a pore-free, fine-grain, nearly equiaxed microstructure as compared to that of the permanent mold casting. In particular, a thin case, which is characterized by an unusually fine cast structure, forms to 2.0 mm (0.080 in.) below the punch. This is caused by a combination of high pressure (resulting in undercooling and a greater number of nucleation sites) and rapid heat extraction into the punch. In practice, squeeze castings made with a ±0.76 mm (±0.030 in.) tolerance on the as-cast head location can be machined to the finished tolerances and still retain more than 0.51 mm (0.020 in.) of the ultrafine-grain case.

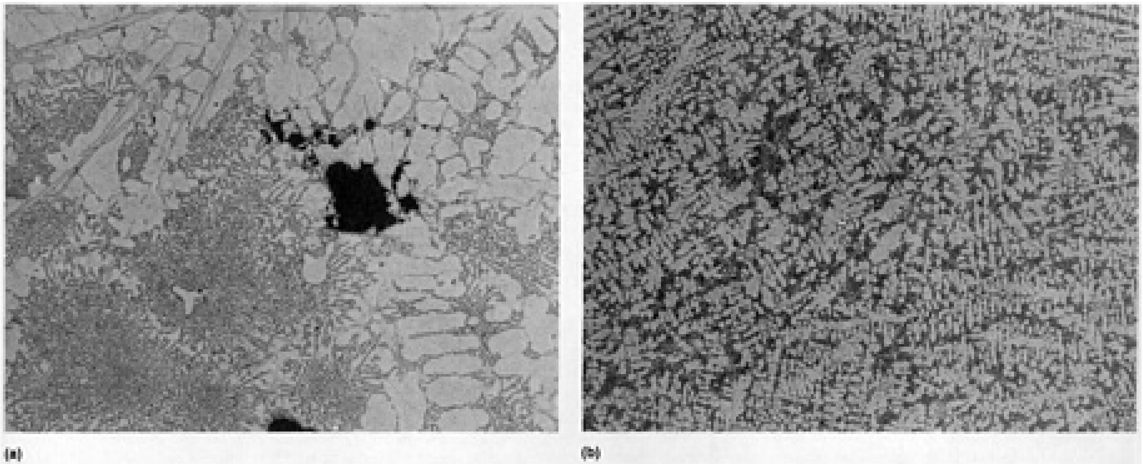

Fig. 2 Comparison of permanent mold cast (a) and squeeze cast (b) E-132 aluminum near the edge in contact with the punch. The microstructure shown in (a) is coarse dendritic; that in (b) is preferred ultrafine dendritic. Both 80×

Product Applications

The squeeze casting process has been explored for a number of applications using various metals and alloys. The parts shown in Fig. 3 include an aluminum dome, a ductile iron mortar shell, and a steel bevel gear. Other parts that have been squeeze cast include stainless steel blades, superalloy disks, aluminum automotive wheels and pistons, and gear blanks made of brass and bronze. Recently, this process has also been adopted to make composite materials at an affordable cost (see the article "Cast Metal-Matrix Composites" in this Volume). A porous ceramic preform is placed in the preheated die, which is later filled with the liquid metal; pressure is then applied. The pressure, in this case, helps the liquid metal infiltrate the porous ceramic preform, giving a sound metal ceramic composite. The technological breakthrough of manufacturing metal-ceramic composites, along with the ability to make complex parts by a near-net shape squeeze casting process, suggests that this process will find application where cost considerations and physical properties of alloys are key factors.

Semisolid Metal Casting and Forging

Malachi P. Kenney, James A. Courtois, Robert D. Evans, Gilbert M. Farrior, Curtis P. Kyonka, and Alan A. Koch, ALUMAX Engineered Metal Processes, Inc.; Kenneth P. Young, AMAX Research & Development Center

Introduction

Semisolid metalworking, also known as semisolid forming, is a hybrid manufacturing method that incorporates elements of both casting and forging. It was based on a discovery made at the Massachusetts Institute of Technology (MIT) in the early 1970s. Processes based on the discovery were identified by MIT as rheocasting, thixocasting, or stir casting (Ref 1). Today it is a two-step process for the near-net shape forming of metal parts using a semisolid raw material that incorporates a unique nondendritic microstructure (Fig. 1).

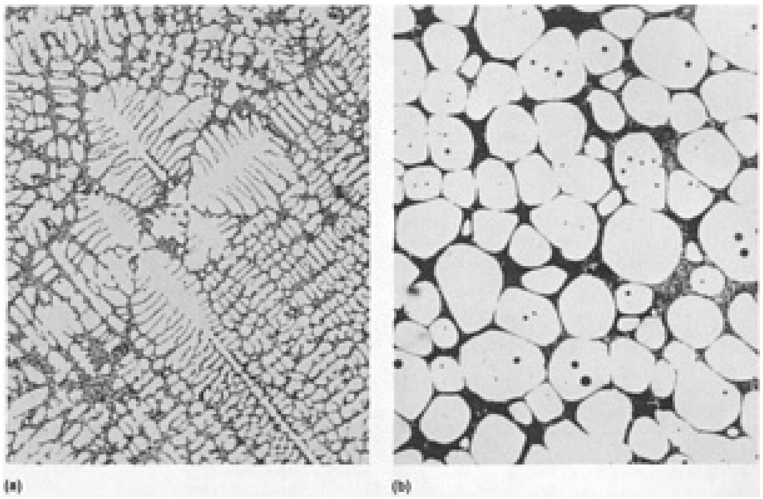

Fig. 1 Comparison of dendritic conventionally cast (a) and nondendritic semisolid formed (b) microstructures of aluminum alloy 357 (Al-7Si-0.5Mg). Both 200×

The key to the process is shown in Fig. 2, in which the semisolid slug has been cut with a spatula while free standing (that is, without containers), thus demonstrating the thixotropic nature of the material. The thixotropic properties permit the material to be handled by robotic devices in the semisolid condition, allowing process automation and precision controls while increasing productivity.

Fig. 2 Semisolid aluminum billet being cut by a spatula

The major commercial semisolid metalworking activity is in the semisolid forging of a variety of aluminum alloy parts for military, aerospace, and automotive applications. In addition, there is moderate copper alloy production for electrical and fluid-handling use. Further, semisolid metalworking technology has been demonstrated to be applicable to most engineering alloy families, including zinc (Ref 2), magnesium (Ref 3), copper (Ref 4), ferrous (Ref 5), titanium (Ref 6), and superalloys (Ref 7).

The unique nondendritic microstructure and the initial processes are protected by a series of patents that began with awards to M.C. Flemings and associates at MIT in the 1970s and has continued with awards to a number of individuals and organizations. A number of corporations have investigated and tested the MIT processes. Universities in Great Britain, Europe, and the United States have also conducted studies in the technology. Along with MIT, these include Delaware and Virginia (USA), Sheffield (Great Britain), and Aachen (West Germany), which have been studying the applications to high-temperature alloys for a number of years. The patent list continues to grow as the technology broadens its application in the emerging field of metal-matrix composites, in which semisolid metalworking has been a key process since the early 1970s (see the article "Cast Metal-Matrix Composites" in this Volume).

Background

Basic Discovery. Semisolid metal forming is based on a discovery made during research on hot tearing undertaken at MIT in the early 1970s. Seeking to understand the magnitude of the forces involved in deforming and fragmenting dendritic growth structures, MIT researchers constructed a high-temperature viscometer. They poured model lead-tin alloys into the annular space created by two concentric cylinders and measured the forces transmitted through the freezing alloy when the outer cylinder was rotated. During the course of these experiments, it was discovered that when the outer cylinder was continuously rotated the semisolid alloy exhibited remarkably low shear strength even at relatively high fractions solidified. This unique property was attributed to a novel nondendritic (that is, spheroidal) microstructure.

The research expanded, and the MIT engineers coined the term rheocasting to describe the process of producing this unique microstructure (a schematic of the rheocast process is shown in Fig. 5 of the article "Classification of Processes and Flow Chart of Foundry Operations" in this Volume) (Ref 5). They showed that sheared and partially solidified alloys could be assigned an apparent viscosity and that they possess many of the characteristics of thixotropy (Fig. 3). Most notably, the semisolid alloys displayed viscosities that depended on shear rate and that rose to several hundred, even thousands, of poise (approaching the consistency of table butter) when at rest and yet decreased to less than 5.0 Pa s or 50 P (poise) (the range of machine oils) upon vigorous agitation or shearing. For the first time, therefore, these results afforded an opportunity to control the viscosity of alloy melts from that of fully liquid to any desired upper limit.

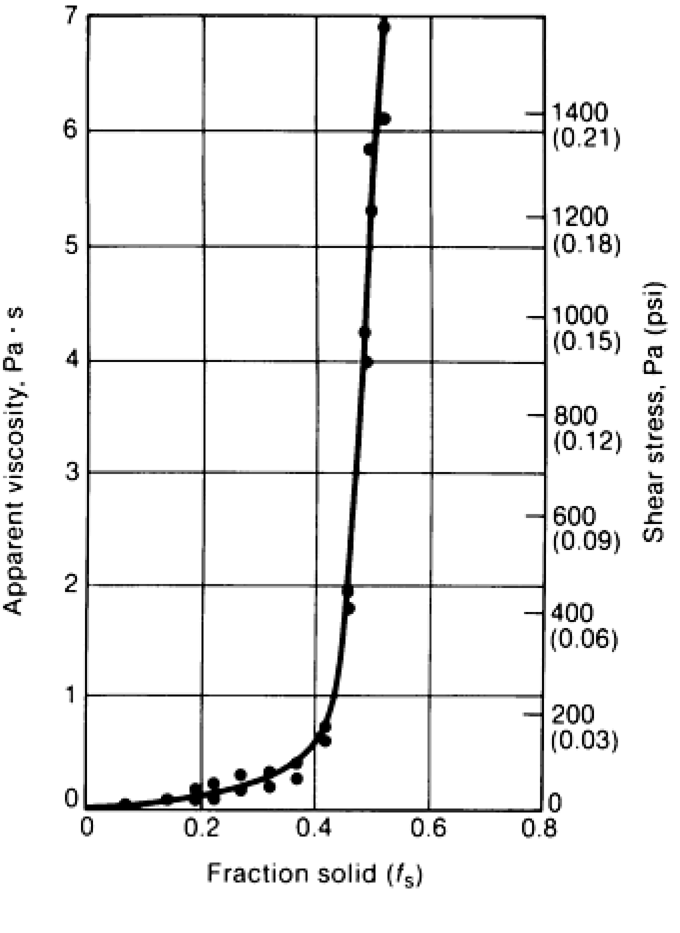

Fig. 3 Apparent viscosity and shear stress of model Sn-15Pb semisolid melts as a function of fraction solid at constant shear rate. Source: Ref 13

Potential Benefits. The MIT researchers were quick to identify several potential benefits that could result from forming processes utilizing semisolid metal and that would differentiate these processes from conventional casting (Ref 8). First, and particularly significant for higher-melting alloys, semisolid metalworking afforded lower operating temperatures and reduced metal heat content (reduced enthalpy of fusion). Second, the viscous flow behavior could provide for a more laminar cavity fill than could generally be achieved with liquid alloys. This could lead to reduced gas entrainment. Third, solidification shrinkage would be reduced in direct proportion to the fraction solidified within the semisolid metalworking alloy, which should reduce both shrinkage porosity and the tendency toward hot tearing.

In addition, the MIT team showed that the viscous nature of semisolid alloys provided a natural environment for the incorporation of third-phase particles in the preparation of particulate-reinforced metal-matrix composites (Ref 9). Here the enhanced viscosity of semisolid metalworking alloys would serve to entrap the reinforcement material physically, allowing time to develop good bonding between the reinforcement and the matrix alloy.

As these ideas unfolded, research into the nature of semisolid alloys progressed, and it became apparent that bars could be cast from semisolid fluids possessing the rheocast nondendritic microstructure. The final freezing of these bars captures this microstructure. The bars then represented a raw material that could be heated at a later time or a remote location to the semisolid temperature range to reclaim the special rheological characteristics.

This process, using semisolid alloys heated from specially cast bars, was termed thixocasting by the MIT inventors (Ref 10). This distinguished it from rheocasting, which has come to be known as the process used for producing semisolid structures and/or forming parts from slurry without an intermediate freezing step.

The efforts at MIT to continue the development of semisolid metalworking were supported by the U.S. government under the Advanced Research Projects Agency and the Defense Advanced Research Projects Agency. This work was directed to a machine casting process for ferrous alloys. Thousands of ferrous components were successfully formed using semisolid metalworking ingots as part of these programs.

Semisolid Metal Casting and Forging

Malachi P. Kenney, James A. Courtois, Robert D. Evans, Gilbert M. Farrior, Curtis P. Kyonka, and Alan A. Koch, ALUMAX Engineered Metal Processes, Inc.; Kenneth P. Young, AMAX Research & Development Center

Background

Basic Discovery. Semisolid metal forming is based on a discovery made during research on hot tearing undertaken at MIT in the early 1970s. Seeking to understand the magnitude of the forces involved in deforming and fragmenting dendritic growth structures, MIT researchers constructed a high-temperature viscometer. They poured model lead-tin alloys into the annular space created by two concentric cylinders and measured the forces transmitted through the freezing alloy when the outer cylinder was rotated. During the course of these experiments, it was discovered that when the outer cylinder was continuously rotated the semisolid alloy exhibited remarkably low shear strength even at relatively high fractions solidified. This unique property was attributed to a novel nondendritic (that is, spheroidal) microstructure.

The research expanded, and the MIT engineers coined the term rheocasting to describe the process of producing this unique microstructure (a schematic of the rheocast process is shown in Fig. 5 of the article "Classification of Processes

and Flow Chart of Foundry Operations" in this Volume) (Ref 5). They showed that sheared and partially solidified alloys could be assigned an apparent viscosity and that they possess many of the characteristics of thixotropy (Fig. 3). Most notably, the semisolid alloys displayed viscosities that depended on shear rate and that rose to several hundred, even thousands, of poise (approaching the consistency of table butter) when at rest and yet decreased to less than 5.0 Pa s or 50 P (poise) (the range of machine oils) upon vigorous agitation or shearing. For the first time, therefore, these results afforded an opportunity to control the viscosity of alloy melts from that of fully liquid to any desired upper limit.

Potential Benefits. The MIT researchers were quick to identify several potential benefits that could result from forming processes utilizing semisolid metal and that would differentiate these processes from conventional casting (Ref 8). First, and particularly significant for higher-melting alloys, semisolid metalworking afforded lower operating temperatures and reduced metal heat content (reduced enthalpy of fusion). Second, the viscous flow behavior could provide for a more laminar cavity fill than could generally be achieved with liquid alloys. This could lead to reduced gas entrainment. Third, solidification shrinkage would be reduced in direct proportion to the fraction solidified within the semisolid metalworking alloy, which should reduce both shrinkage porosity and the tendency toward hot tearing.

In addition, the MIT team showed that the viscous nature of semisolid alloys provided a natural environment for the incorporation of third-phase particles in the preparation of particulate-reinforced metal-matrix composites (Ref 9). Here the enhanced viscosity of semisolid metalworking alloys would serve to entrap the reinforcement material physically, allowing time to develop good bonding between the reinforcement and the matrix alloy.

As these ideas unfolded, research into the nature of semisolid alloys progressed, and it became apparent that bars could be cast from semisolid fluids possessing the rheocast nondendritic microstructure. The final freezing of these bars captures this microstructure. The bars then represented a raw material that could be heated at a later time or a remote location to the semisolid temperature range to reclaim the special rheological characteristics.

This process, using semisolid alloys heated from specially cast bars, was termed thixocasting by the MIT inventors (Ref 10). This distinguished it from rheocasting, which has come to be known as the process used for producing semisolid structures and/or forming parts from slurry without an intermediate freezing step.

The efforts at MIT to continue the development of semisolid metalworking were supported by the U.S. government under the Advanced Research Projects Agency and the Defense Advanced Research Projects Agency. This work was directed to a machine casting process for ferrous alloys. Thousands of ferrous components were successfully formed using semisolid metalworking ingots as part of these programs.

Semisolid Metal Casting and Forging

Malachi P. Kenney, James A. Courtois, Robert D. Evans, Gilbert M. Farrior, Curtis P. Kyonka, and Alan A. Koch, ALUMAX Engineered Metal Processes, Inc.; Kenneth P. Young, AMAX Research & Development Center

Semisolid Forging Applications

The advantages of semisolid forging have enabled it to compete effectively with a variety of conventional processes in a number of different applications. In this section, a number of automotive, aerospace, and industrial applications of semisolid forged parts are outlined with data on alloys, yield, production rates, mechanical properties, and performance requirements. Figure 10 shows a complex high-pressure hydraulic brake valve typical of applications for semisolid forged components.

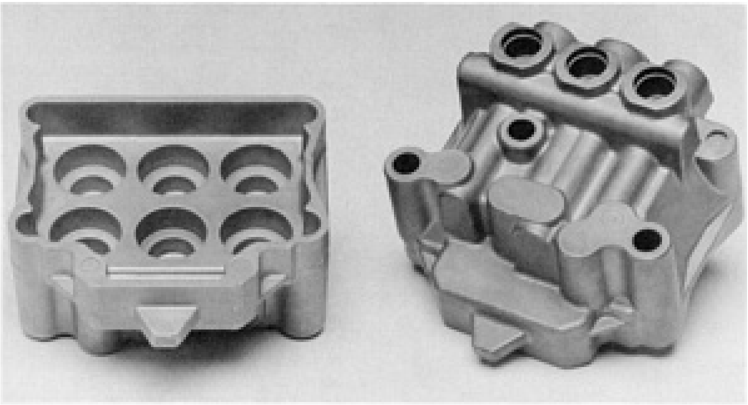

Fig. 10 Semisolid forged hydraulic brake valve

Semisolid forged parts have replaced conventional forgings, permanent mold and investment castings, impact extrusions, machined extrusion profiles, parts produced on screw machines, and, in unusual circumstances, die castings and stampings. Applications include automobile wheels, master brake cylinders, antilock brake valves, disk brake calipers, power steering pump housings, power steering pinion valve housings, engine pistons, compressor housings, steering

column mechanical components, airbag containment housings, power brake proportioning valves, electrical connectors, and various covers and housings that require leak-tight integrity. Table 1 lists mechanical properties of selected aluminum alloys used in these components.

Table 1 Mechanical properties of typical semisolid forged aluminum parts

Aluminum alloy	Mechanical properties						
	Temper	**Ultimate tensile strength**		**Tensile yield strength**		**Elongation, %**	Hardness, HB
		MPa	**ksi**	**MPa**	**ksi**		
206	T7	386	56.0	317	46.0	6.0	**103**
2017	T4	386	56.0	276	40.0	8.8	**89**
2219	T8	352	51.0	310	45.0	5.0	**89**
6061	T6	330	47.8	290	42.1	8.2	**104**
6262	T6	365	52.9	330	47.9	10.0	**82**
7075	T6	496	72.0	421	61.0	7.0	**135**
356	T5	234	34.0	172	25.0	11.0	**89**
356	T6	296	43.0	193	28.0	12.0	**90**
357	T5	296	43.0	207	30.0	11.0	**90**

Reproducible high integrity is a key in this diversity, but this could be offset by the higher cost of the raw material--MHD billets. The near-net shape ability of the process reduces both the weight required and the machining time. When the higher production rate is added to these other advantages, the process becomes cost-effective for many applications.

Example 1: Aluminum Automobile Wheels.

Aluminum automobile wheels (Fig. 11) have been produced by permanent mold casting (gravity and low pressure), squeeze casting, and fabrications of castings or stampings welded to rolled rims. Semisolid forging is a more recent process. Table 2 compares the characteristics of aluminum automobile wheels produced by semisolid forging and permanent mold casting. In addition to an economic advantage, semisolid forging offers other advantages that will be discussed below.

Table 2 Comparison of semisolid forging and permanent mold casting for the production of aluminum automobile wheels

See Example 1.

Process	Characteristic											
	Weight direct from die or mold		**Finished part weight**		**Production rate per die or mold, pieces per hour**	**Aluminum alloy**	**Heat treatment**	**Ultimate tensile strength**		**Yield strength**		Elongation, %
	kg	**lb**	**kg**	**lb**				**MPa**	**ksi**	**MPa**	**ksi**	
Semisolid forging	7.5	16.5	6.1	13.5	90	357	T5	290	42	214	31	**10**
Permanent mold	**11.1**	**24.5**	**8.6**	**19.0**	**12**	**356**	**T6**	**221**	**32**	**152**	**22**	**8**

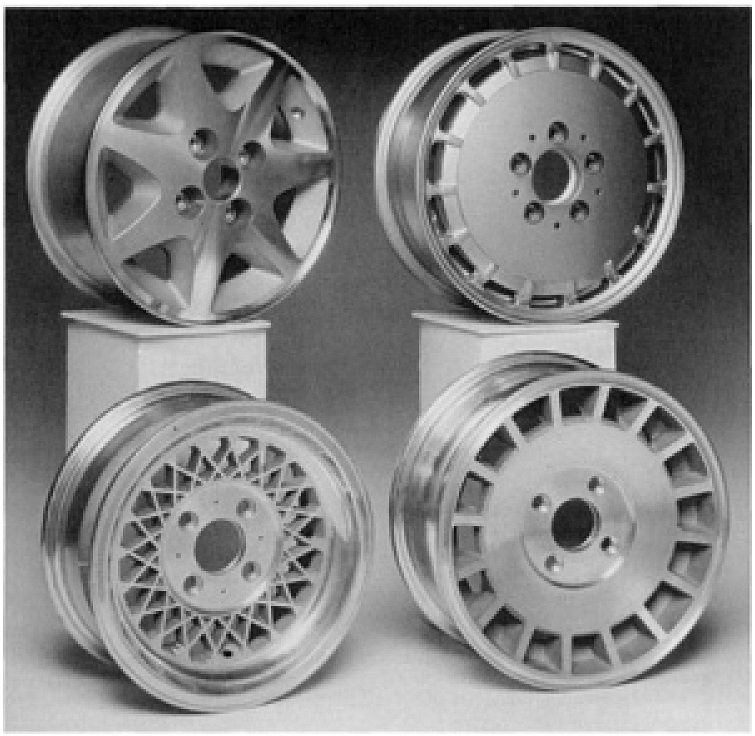

Fig. 11 Semisolid forged aluminum alloy 357 automobile wheels

Lighter Weight. The ability to form thinner sections without heavy ribs to aid in filling the cavity allows a wheel to be semisolid formed nearer to net size with light ribs on the brake side. This results in a finished wheel that is up to 30% lighter than a cast wheel of the same style.

Consistent Quality. The forging process employs a high-quality, specially prepared (MHD) billet with an engineered metallurgical structure, closely controlled chemistry, and consistent casting variables, supplying an extremely consistent raw material with complete traceability. The wheel-forming process is computer controlled and automated with precise control of the heating and forging process variables, making the entire process adaptable to statistical process control.

Structure and Properties. The semisolid forged wheel is fine grained, dense structured, and formed to close tolerances in precision tooling in which the temperature is controlled to provide consistent forging conditions. This provides consistency in part dimensions and metallurgical properties. Forging in the semisolid state avoids the entrapment

of air or mold gas, and the high fraction of solid material, together with the high pressure after forming, reduces the microporosity due to liquid/solid shrinkage. Unlike conventional forgings, the wheel properties are isotropic, reflecting the nondendritic structure of the high-performance aluminum alloy 357 used in the billet.

Design Versatility. The ability to form thin sections (roughly one-quarter to one-half the thickness of casting) permits not only a reduction in the weight of the wheel, but also allows the designer to style the wheel with thinner ribs/spokes and finer detail. Forming in the semisolid state under very high final pressure provides part surfaces and details that reflect the die surfaces. Therefore, the designer has a selection of surface conditions to enhance the style and can obtain exact replication of the fine detail designed in the die.

Example 2: Electrical Connector Multi-conductor.

Military/aerospace electrical connectors (Fig. 12) are highly stressed in service. As a result, the qualification of these parts involves extensive and severe functional testing under various environmental conditions. Production quality control procedures are equally stringent to ensure conformance to specifications and performance under load.

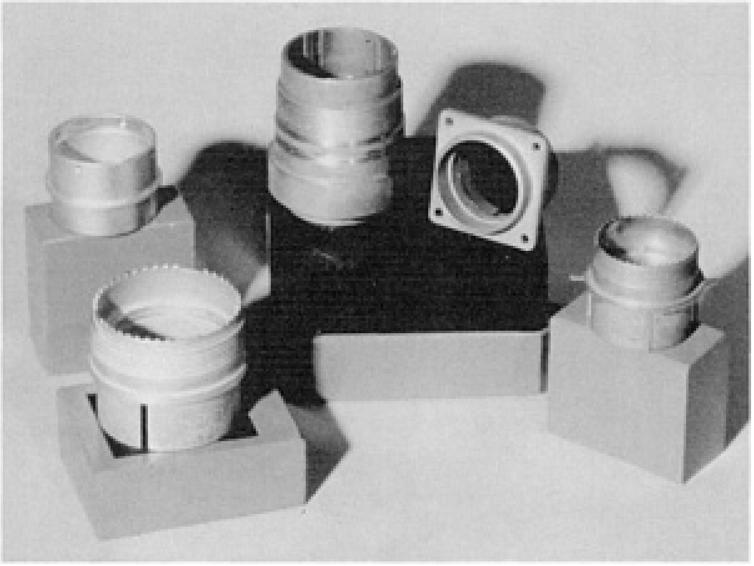

Fig. 12 Aluminum alloy (SIMA 6262) electrical connectors produced by semisolid forging

Before semisolid forging, these parts were machined (on screw machines) from extruded aluminum alloy 6262-T9 bar. Today, a large number of these parts are semisolid forged from SIMA 6262 bar and finish machined after the T6 heat treatment. The characteristics of semisolid forged and machined parts are compared in Table 3.

Table 3 Comparison of the characteristics of semisolid forged and machined electrical parts

See Example 2.

Process	Characteristic														
	Aluminum alloy	**Raw material diameter**		**Raw material weight**		**Finished part weight**		**Material yield, %**	**Production rate (primary operation), pieces per hour**	**Heat treatment**	**Ultimate tensile strength**		**Yield Strength**		Elongation, %
		mm	**in.**	**g**	**oz**	**g**	**oz**				**MPa**	**ksi**	**MPa**	**ksi**	
Semisolid forging	SIMA 6262	19	0.75	25	0.88	23	0.81	92	300	T6	345	50	276	40	**10**

The semisolid forged component possessed all major keyways and locating devices with tolerances at least equivalent to machined parts. The savings in material, plus the higher production rate, makes the semisolid forged part a very economical selection.

After full T6 heat treatment, the parts are finish machined and anodized. The parts are tested per MIL-C-38999 and meet all specified performance criteria. These tests include bending, vibration, durability, thermal shock, and impact.

Example 3: Aluminum Brake Master Cylinder.

Some permanent mold cast brake master cylinders (Fig. 13) are cast essentially solid in order to place solidification shrinkage defects in the center bore, where they are subsequently machined away. The energy crisis motivated the move to lighter automobiles to improve fuel economy. This has caused the conversion of many ferrous automobile components into aluminum. Brake master cylinders have been difficult and expensive to convert, and until the application of semisolid forging, the only acceptable production methods were low-pressure or gravity permanent mold casting. Table 4 compares a permanent mold cast aluminum part, cored as indicated above, with a semisolid forged replacement.

Table 4 Comparison of a permanent mold cast aluminum part with a semisolid forged replacement

See Example 3.

Process	Characteristic											
	Weight (as forged or cast)		**Weight (finish machined)**		**Production rate, pieces per hour**	**Aluminum alloy**	**Heat treatment**	**Ultimate tensile strength**		**Yield strength**		Elongation, %
	kg	**lb**	**kg**	**lb**				**MPa**	**ksi**	**MPa**	**ksi**	
Semisolid forging	0.45	1.0	0.39	0.85	150	357	T5	303	44	228	33	**8**
Permanent mold	**0.76**	**1.67**	**0.45**	**1.0**	**24**	**356**	**T6**	**290**	**42**	**214**	**31**	**8**

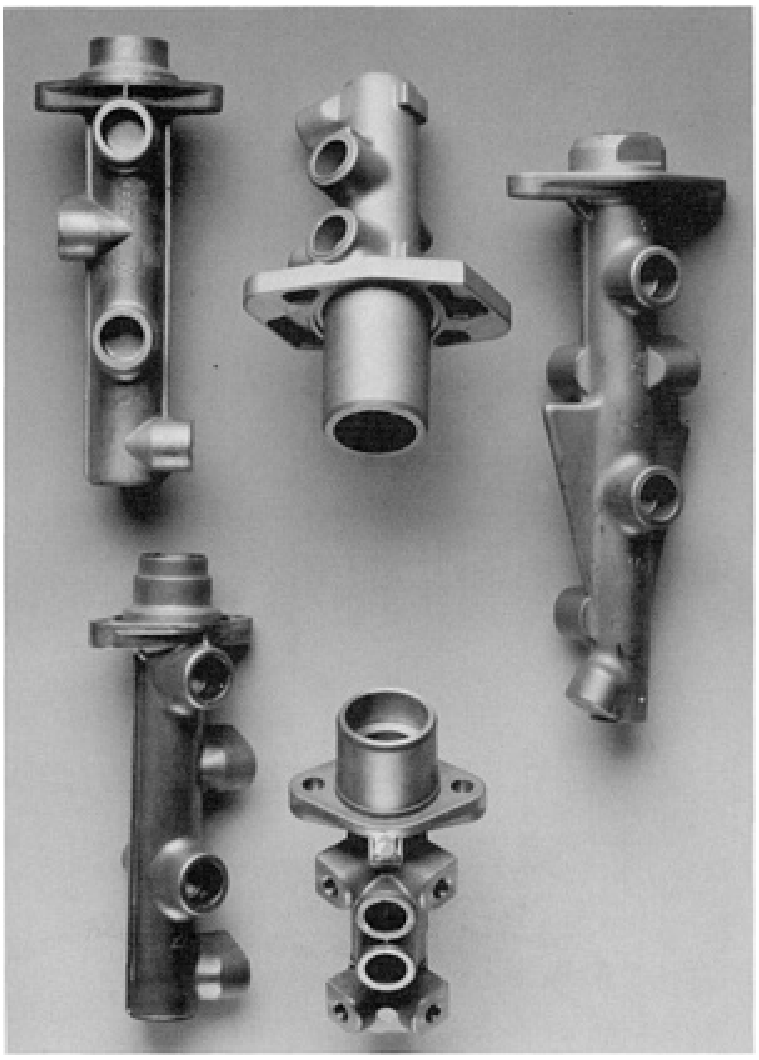

Fig. 13 Aluminum alloy 357 automotive brake master cylinders produced by semisolid forging

Semisolid forging utilizes a two-cavity indirect forming approach and MHD cast alloy 357 slugs cut from 76 mm (3 in.) diameter bar. All major holes are sufficiently cored for tapping or other finishing operations. After semisolid forging, T5 heat treatment, and final machining, parts are subjected to a 9.7 MPa (1400 psi) nitrogen leak test and extensive endurance testing, which includes 300,000 to 1 million hydraulic cycles that must be endured without a sign of wear.

Example 4: Valve Bodies.

Automotive, aerospace, refrigeration, and industrial valves are frequently manufactured by machining, drilling, and tapping the hydraulic passages and valve seats in a section cut from an extruded aluminum profile. Valves typical of such production are shown in Fig. 14.

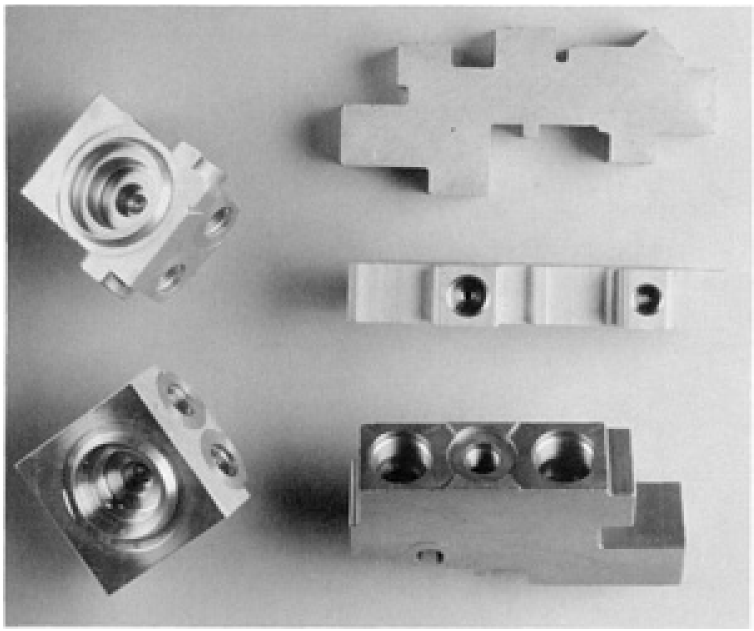

Fig. 14 Aluminum alloy valve bodies machined from extruded profiles

Semisolid forging production can be competitive with this efficient manufacturing method by the substitution of semisolid forging for extrusion, cutoff, milling, and drilling. The semisolid forged valve body is cored and sculpted to minimize metal weight. Finishing requires tapping and drilling the smallest holes, requiring less than one-half the time needed to machine the extruded valve. A typical comparison of weights is given in Table 5.

Table 5 Comparison of weights for semisolid forged and extruded parts

See Example 4.

Process	**Weight (as forged or cut off, including kerf)**		**Relative raw material cost per pound (foundry ingot = 1)**	Weight of finished valve	
	kg	**lb**		**kg**	lb
Semisolid forging	0.32	0.7	1.2	0.27	**0.6**

Example 5: Brass Plumbing Parts.

Brass plumbing components (Fig. 15) were semisolid forged using a closed die to produce a net shape part complete with threads. Strain-induced melt-activated processed Alloy C36000 (free-cutting brass) is heated to the semisolid condition before direct forging. After forging, the part is unscrewed and tumbled to remove minor flash and the die lubricant. Die life of 40,000 pieces is typical for this type of application. Total weight reduction of 50% is frequent when replacing conventional forgings, and 60% weight reduction is common when replacing castings. This weight reduction is an important part of the cost improvement.

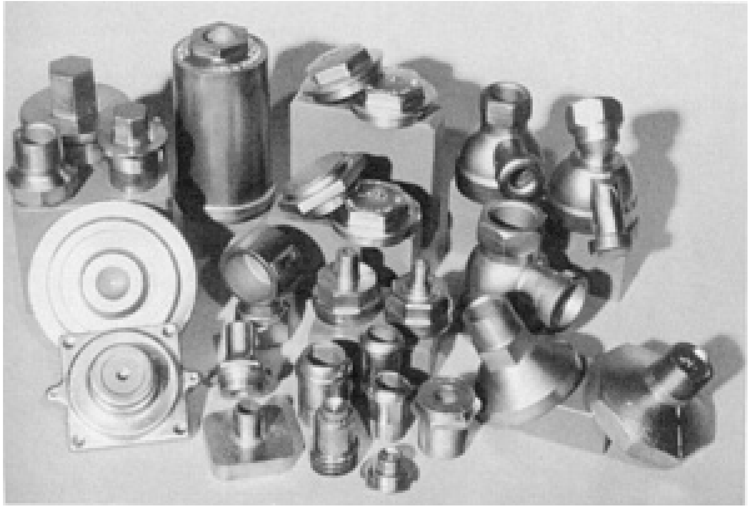

Fig. 15 Copper alloy C36000 (free-cutting brass) plumbing fittings produced by semisolid forging

Quality Factors

As with all processes, it is possible to form parts when all variables are not controlled within specified limits and when discontinuities result. Some discontinuities that may be observed in semisolid forging are outlined below and are shown in Fig. 16.

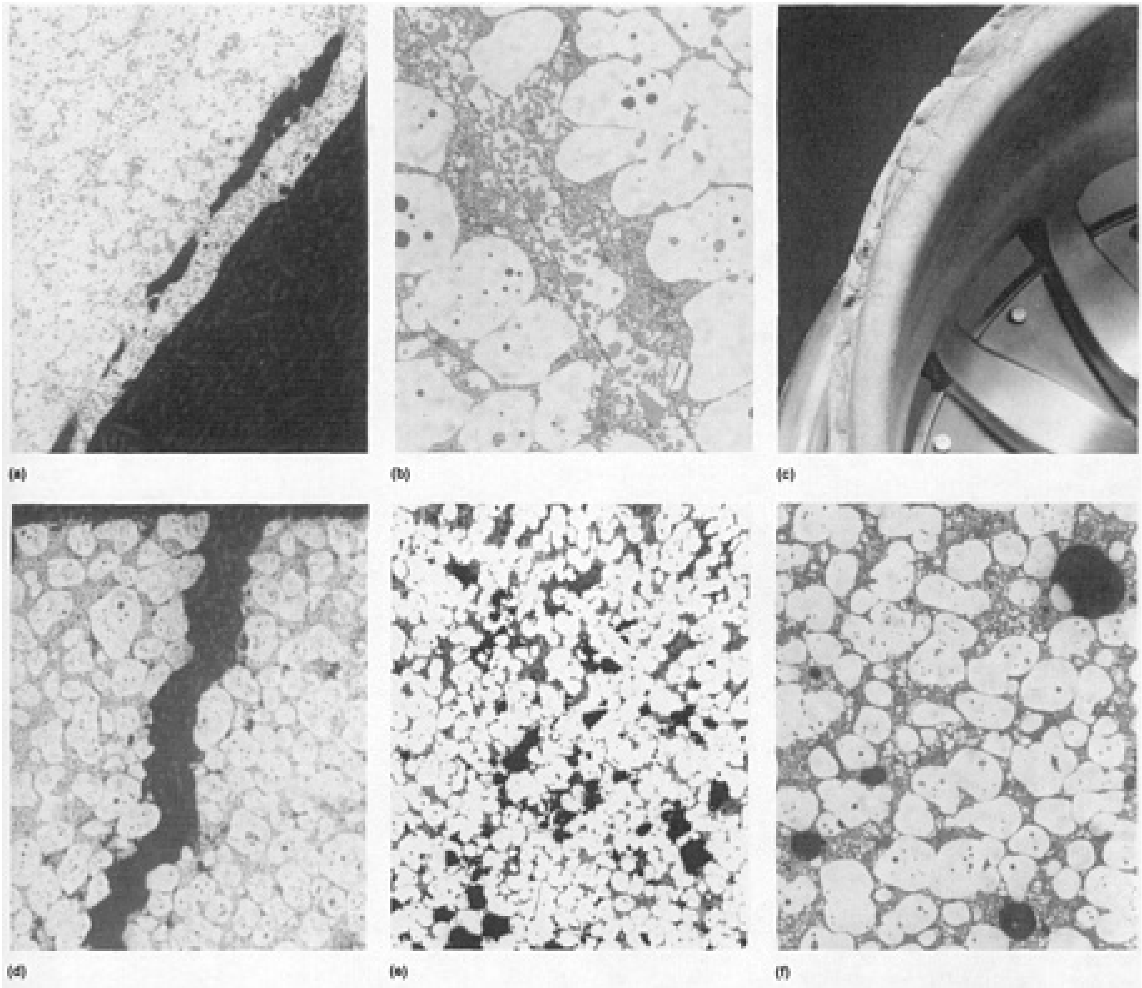

Fig. 16 Defects that may be encountered in semisolid forging. (a) Surface blisters. 75×. (b) Cold shuts. 225×. (c) Non-fill. 0.5×. (d) Hot tears. 75×. (e) Shrinkage porosity. 40×. (f) Gas porosity. 100×

Blisters (Fig. 16a) are occasionally observed on the surfaces of aluminum parts that are subjected to the 540 °C (1000 °F) solution heat treatment. They may result from one of several causes, the most frequent of which is an excessively high metal flow rate where metal is sprayed ahead of the main mass flow. It coats die surfaces, and the following mass entraps minute amounts of mold gas between the skin and the bulk of the mass.

Another cause may be the contamination of die surfaces by substances that are contained in various lubricants and hydraulic fluids. These become contained in the part surface. Later, when the temperature rises, the yield strength drops, and the pressure of the contained gas deforms the surface. The blister usually originates in a zone that is 0.5 to 2.0 mm (0.020 to 0.080 in.) below the surface. Blisters can be avoided by ensuring that all die surfaces are free of contamination and by slowing metal velocities, increasing gate areas, and reducing ram velocities.

Cold shuts, folds, and laps (Fig. 16b) are infrequent. These defects occur when two metal surfaces meet but fusion is incomplete. This may be caused when an oxide film is entrapped or when the flow of metal in two approaching surfaces is slowed by entrapped air, allowing solidification to proceed before the surfaces have fully fused. Such problems can be avoided by changing the metal flow pattern and/or increasing localized venting.

Non-fill (Fig. 16c) occurs infrequently when cold semisolid metal, premature freezing, low pressure or metal velocity, or entrapped mold atmosphere prevents the complete filling of the die cavity. It can be corrected by increasing the liquid fraction in slug, raising die temperatures, increasing venting, and adjusting hydraulics for higher pressure or velocity.

Surface blow occurs occasionally when moisture (lubricant, hydraulic fluid) trapped on the die surface by the semisolid metal generates gas pressure, forcing the semisolid metal surface away from the die. Surface blow is identified by a shiny surface area or an indentation in the part. It can be corrected by ensuring that all die surfaces are clean and dry.

Hot tears (Fig. 16d) are infrequent in casting alloys, but are more frequent in wrought alloys. They occur when the solidified part is constrained by the die while solid-state shrinkage induces strains that exceed the hot ductility. Hot tears may be internal or external. They can be avoided by part/die redesign, higher metal pressure in the die, reduced dwell time, or changing alloys.

Shrinkage porosity (Fig. 16e) can occur when heavy and/or thicker sections solidify after their feeding sections. It can be prevented by adjusting die temperatures and feeding sections and by higher time and pressure during dwell after forging.

Gas porosity (Fig. 16f) is very infrequent. It can be caused by excessively high gate velocities, resulting in excessive turbulence in the metal flow and entrapping mold atmosphere. Gas porosity can be avoided by reducing velocity or opening the gates.

Flow lines occur occasionally where metal flows through a heavy section or past a filled region. They can be observed visually unaided on polished sections of a part, but are difficult to resolve at higher magnifications. The zone between a stationary surface and the moving material evidences slightly higher eutectic concentration.

Metal-Matrix Composites (MMC)

As discussed earlier in this section, the viscous behavior of semisolid alloys allows for substantial benefits in particle incorporation processes. This was recognized by the early MIT inventors, who coined the term compocast to describe the application of rheocasting techniques to the inclusion of fibers and particulate in metal alloy matrices (Ref 9).

In 1981, one company began a program in which tons of MMCs were mixed and formed into housings for lighting fixtures. These composites, mixtures of about 20% by volume of SiO_2 (silica sand) and aluminum, were produced with a continuous process in an effort to substitute an inexpensive filler (that is, foundry sand) for the increasingly expensive aluminum (Ref 23). The process was successful and, the product met all expectations, including cost. However, the price of aluminum decreased and so did the need for this early MMC.

A number of organizations are currently engaged in developing methods for the creation of MMCs, but regardless of the preparation techniques, semisolid forging offers a unique advantage for forming near-net shape parts from MMCs. Therefore, semisolid forging represents a viable process for shaping these difficult-to-cast MMC materials and can achieve a high degree of accuracy. This is particularly beneficial when the MMC material presents difficulties in machining. A number of prototype applications of semisolid formed MMCs are currently under evaluation. Detailed information on other foundry production methods for MMCs is available in the article "Cast Metal-Matrix Composites" in this Volume.

Safety

The potential hazards of semisolid forging are similar to those encountered in other high-speed forging operations. These include mechanical and electrical hazards.

Mechanical Hazards. Semisolid forming equipment typically operates at high speed and is capable of exerting high forces. Therefore, pinch points and personnel access should be shielded, and the equipment is quite capable of automatic operation.

Electrical Hazards. Induction heating coils typically operate at high voltage (>1000 V) and frequency. Coils and leads should be well protected and shielded from personnel contact. Induction coils should also be shielded from inadvertent contact with the workpiece, particularly in the last stages of heating when the possibility exists for workpiece slumping or collapse in extreme circumstances. This could cause coil arcing.

Green Sand Molding Equipment and Processing

Roger B. Brown, Disamatic, Inc.

GREEN SAND MOLDING is one of many methods available to the foundryman for making a mold into which molten metal can be poured. Green sand molding and chemically bonded sand molding are considered to be the most basic and widely used moldmaking processes. The molding media for the two methods are prepared quite differently. Chemically bonded media are prepared by coating grains of sand with a binder that is later cured by some type of chemical reaction. Green sand media are prepared by coating the grains of sand with binder that is later shaped into a rigid mass by the application of force.

Green sand molding is the least expensive, fastest, and most common of all the currently available molding methods. The mixture of sand and binder can be used immediately after the mixing process that coats the sand grains. Although the time taken to shape the mold is of importance in some cases, for the purposes of this article, the forming process can be considered to be almost instantaneous. This section will cover the preparation, mulling, delivery, fabrication, and handling of green sand molds.

Materials

Green sand as a molding medium consists of a number of different materials that must be present in varying amounts and grades in order to produce the desired results for a specific type of casting. The increased demands for casting accuracy and integrity have caused an increase in the use of high-pressure, high-density molding machines. Except for relatively few applications (such as thin-section castings), fireclay (kaolin) is unsuitable for this type of molding (Ref 1). The montmorillonite, or bentonite, clays are used primarily because of their increased durability when heated, higher bonding strength, and plasticity.

Bentonite Clays. The bentonites can be classified as two distinct types: sodium (western) bentonite and calcium (southern) bentonite. The properties derived from the use of each vary widely. The use of one in preference to the other depends on the castings to be made, the system being run, and the economics of the total situation. Fortunately, these bentonites are compatible and can be blended in any ratio to tailor sand properties to the specific requirements of a system (casting condition).

Molding Methods

Green Sand Molds

Green sand molds can be made in a number of ways. The optimum method depends on the type of casting, its size, and the required production. When only a few castings are required, it may be more economical to have a loose pattern made and to have the mold made by hand. Hand ramming is the oldest and slowest method of making a mold. Unfortunately, it is becoming increasingly difficult to locate a foundry with hand molding skills. In most cases, the pattern will at least be mounted on some kind of board to facilitate fabrication of the molds. There are two basic types of green sand molds: flask and flaskless.

Flask Molds. A flask can be defined as the container that is positioned on the pattern (or platen in some cases) and into which the prepared sand is placed before the molding operation. Although there are flasks termed slip flasks, which are slid up the mold as the depth of compacted sand becomes deeper, the most common types of flasks are snap flasks and tight flasks.

Snap flasks are usually square or rectangular. Diagonal corners are held together with cam-action clamps. The clamps are moved to the open position after the mold is made, the cores have been set, and the cope (the upper half of a mold) has been placed on the drag (the lower half of a mold); this allows for easy removal of the finished mold.

Tight flasks are designed as one-piece units that have no clamps. This type of flask remains with the mold during the pouring operation and, normally, until the shakeout operation.

Regardless of the type used, the flask must become more rigid as molding pressure increases. Flexing or movement in the sidewall of the flask will adversely affect the accuracy of mold dimensions, flask-to-pattern alignment, and flask-to-flask alignment during closing of the mold halves.

Flaskless Molds. During the last few years, flaskless molding equipment has become increasingly popular, especially when molds of less than 160 kg (350 lb) are being considered. As the name implies, the flaskless molding machine has no flask. Rather, the flask is replaced with a box or molding chamber that is an integral part of the molding machine.

Flaskless molding gives the foundryman additional versatility in the molding operation. With flaskless molding, a number of things are simplified. Until the advent of flaskless molding, most molds were filled with sand by gravity. With the tighter and more repeatable tolerances that result from the molding chamber being an integral part of the molding machine, other filling methods become more practical. In addition, the parting line of the mold need not be horizontal, but can then be easily placed in the vertical orientation.

First-Generation Machines

This section will discuss jolt-type, jolt squeeze, and sand slinger molding machines.

Jolt-type molding machines (Fig. 1) operate with the pattern mounted on a pattern plate (or plates), which in turn is fastened to the machine table. The table is fastened to the top of an operating air piston. A flask is placed on the pattern and is positively located by pins relative to the pattern. The flask is filled with sand, and the machine starts the jolt operation. This is usually accomplished by alternately applying and releasing air pressure to the jolt piston, which causes the flask, sand, and pattern to lift a few inches and then fall to a stop, producing a sharp jolt. This process is repeated a predetermined number of times, depending on sand conditions and pattern configuration. Because the sand is compacted by its own weight, mold density will be substantially less at the top of a tall pattern. The packing that results from the jolting action will normally be augmented by some type of supplemental compaction, usually hand or pneumatic ramming. When ramming is complete, push-off pins, bearing against the bottom edges of the flask, lift the flask and completed mold half off the pattern. Various mechanisms are used to lift the mold from the pattern and turn it over (in the case of the drag mold) or turn it for finishing operations (in the case of the cope mold).

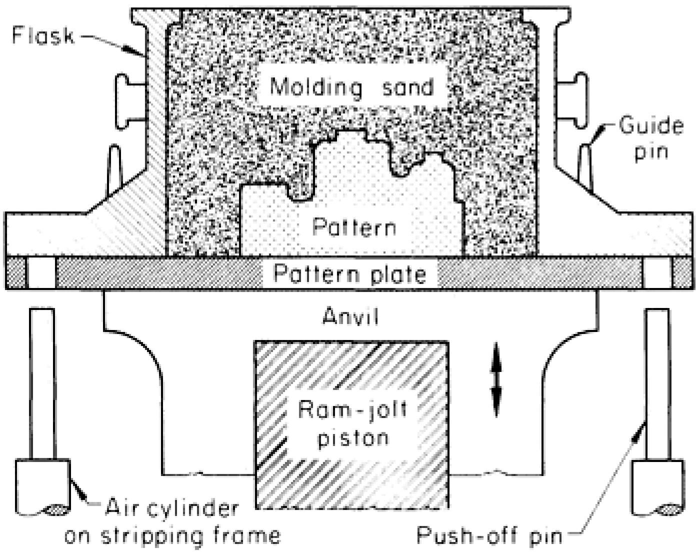

Fig. 1 Primary components of a jolt-type molding machine

Jolt squeeze molding machines operate in much the same manner as jolt-type molding machines. The main difference is that the supplemental compaction takes place as the result of a squeeze head being forced into the molding flask, thus compacting the loose sand at the top. The required pressure can be applied pneumatically or hydraulically. In many cases, the squeeze head will be one piece (Fig. 2) and may even have built-up areas to provide more compaction in deep areas that are hard to ram. In other cases, the squeeze head may be of the compensating type, which consists of a number of individual cylinders, each exerting a specified force on the rear mold face (Fig. 3). Some machines exert the same force on all areas of the mold, while other machines allow the operator to adjust squeezing pressure in zones. Jolt squeeze machines are available in many sizes and are suitable for many different purposes and production levels. They can be operated manually or automatically. The operator has the option of independently adjusting the number of jolts from zero to any number and adjusting the squeeze pressure from zero up to pressure that is considered excessive. Hand or pneumatic ramming is often combined with this process; supplemental ramming normally takes place after jolting but before squeezing.

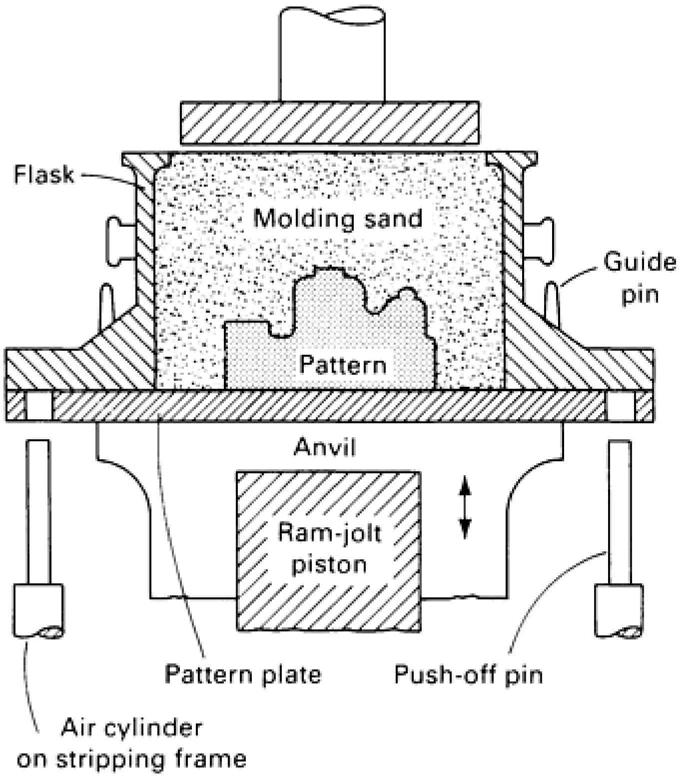

Fig. 2 Jolt squeeze molding machine with solid squeeze heads

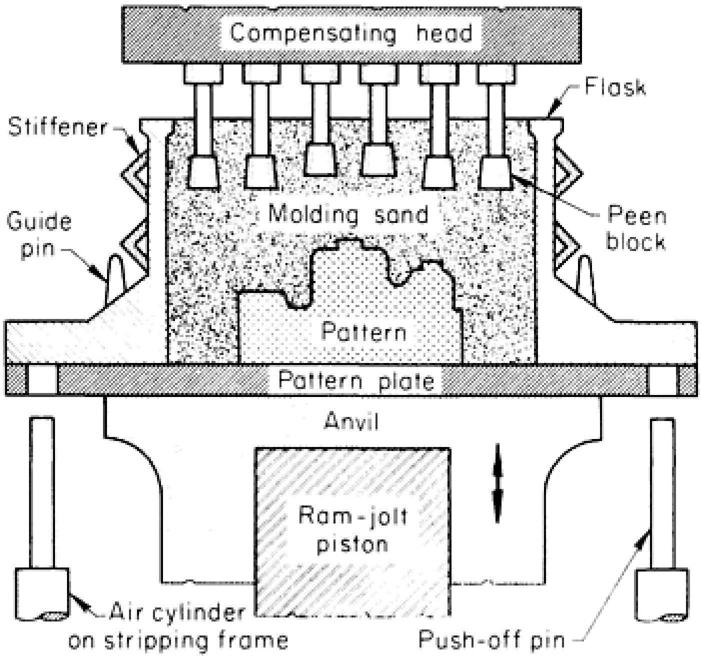

Fig. 3 Jolt squeeze molding machine with compensating heads

Sand slinger molding machines deliver the sand into the mold at high velocity from a rotating impeller. Molds made by this method can have very high strengths because a very dense mold can be made. Density is a function of sand velocity and the thickness through which the high-velocity sand must compact previously placed sand. Sand stingers may or may not be portable. Some ride on rails to the mold, while others have the molds brought to the slinger. Generally speaking, larger molds have the slinger brought to the mold, while smaller molds are brought to the molding station.

Although slingers are useful in producing larger molds, it should be noted that the sand entry location and angle are critical to the production of good molds. Entry location is controlled by the operator, while entry angle and, to some extent, location are controlled by internal adjustment. It is extremely important that these adjustments be maintained in accordance with the appropriate maintenance manual. Error can and does lead to soft spots in the mold or to excessive pattern wear. A considerable amount of operator skill is required to achieve consistent results. Additional information on green sand molding can be found in the articles "Aggregate Molding Materials," "Sand Molding," and "Coremaking" in this Volume.

A number of variations are possible in the above methods. Smaller patterns (resulting in smaller molds) can be constructed such that both the cope and drag impressions are mounted on opposite sides of the same plate. These squeezer or matchplate patterns (Fig. 4) are often used to produce molds with any combination of hand ramming, jolting, and squeezing, just as cope and drag patterns are (Fig. 5).

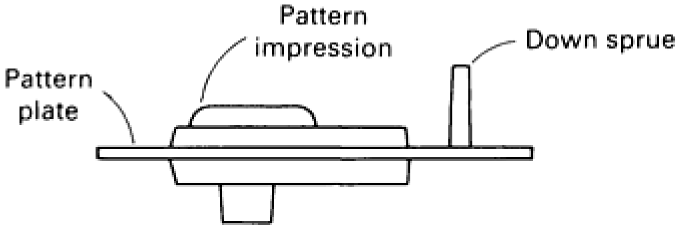

Fig. 4 Primary components of a match plate (squeezer) pattern

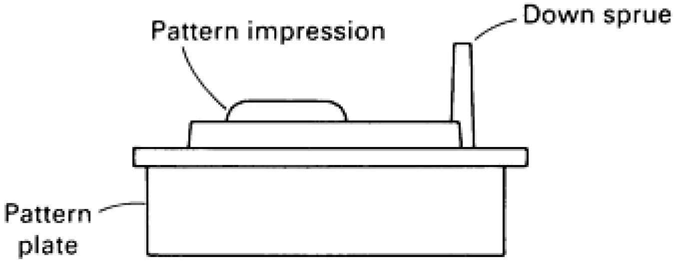

Fig. 5 Drag half of a cope and drag pattern

Second-Generation Machines

Foundry technology has progressed rapidly since the mid-1950s, and molding methods have been a large part of this progression. It was not until the early 1960s that high-pressure molding machines were developed. Depending on design, this new generation of molding machine would accept either match plate or cope and drag patterns and can be of the tight flask or flaskless configuration.

Along with increased levels of foundry technology comes the demand for more accurate and higher-integrity castings (see the article "Casting Design" in this Volume). In any case, modern molding machines, metal technology, sand technology, and support equipment technology assist the foundryman in supplying these demands.

Rap-jolt machines were among the first of the newer high-pressure molding machines. These machines are similar in many respects to jolt squeeze machines. Rap-jolt machines have the option of jolting the mold as described above and/or rapping the mold. Rapping is accomplished by rapidly striking the bottom of the platen on which the pattern is mounted with a weight. The force imparted to the platen/flask/mold combination may not exceed 1 g, or separation between the flask and pattern will occur. Therefore, there is very little if any vertical movement of the pattern and flask. This method allows for the possibility of squeezing and rapping simultaneously. Some machines of this type allow the operator to jolt prior to the rap-jolt operation. Depending on the individual molding machine, any one or any combination of the operations can be used to make the mold. The equipment described thus far has all made use of some type of flask--either the snap or tight flask configuration.

Match Plate Pattern Machines. Automatic molding machines that use match plates have been used in both tight flask and flaskless designs. Because the patterns do not have the strength to withstand the pressure exerted during compaction without flexing, both the cope and drag must be squeezed simultaneously.

Some match plate machines (Fig. 6) fill both the cope and drag by gravity. This type of machine will close up the molding chambers to the pattern and then rotate the assembly so that the drag surface of the pattern is facing up. Sand is then dropped into the drag chamber, and a sealing plate (usually aluminum) is inserted. The molding chamber/pattern assembly is then rotated so that the cope pattern face is up, and the cope chamber is filled with sand. The mold is then compacted by squeezing, the molds are withdrawn from the pattern, and the pattern is removed. The open mold is then available for any finishing work or core setting. The mold is then closed and removed from the molding chambers.

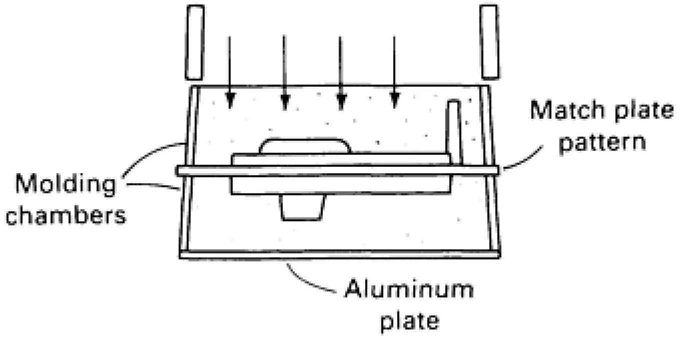

Fig. 6 Gravity-fill pressure squeeze molding machine using match plate patterns

Other match plate machines fill cope and drag molding chambers simultaneously by blowing the sand into the cavity (Fig. 7). After the blowing operation, the mold is compacted by a squeezing operation. After squeezing, the mold halves are withdrawn from the pattern and are available for any necessary finishing or core setting operations. Depending on the design of the machine, it may or may not be necessary to add to the machine cycle time to complete these operations.

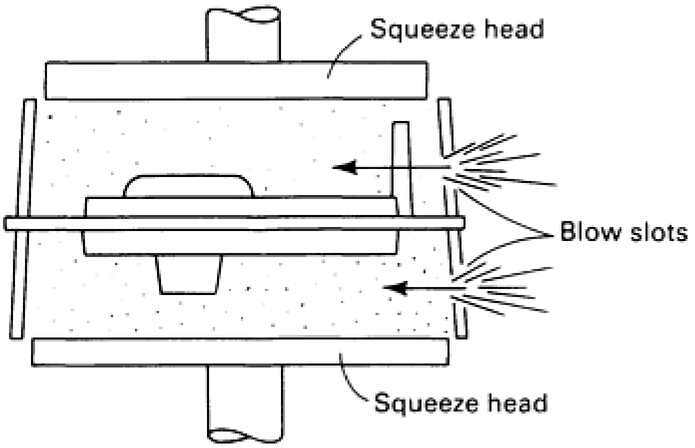

Fig. 7 Blow-fill pressure squeeze molding machine using match plate patterns

Match plate pattern machines are available in tight flask and flaskless designs. These machines normally utilize gravity fill of both cope and drag molds. The cope is filled in much the same manner as for a flaskless machine. The drag is filled by sealing the bottom of the drag flask prior to the gravity-fill operation. The drag flask, still sealed, is then closed to the pattern, and the mold is compacted by squeezing. The squeeze pressure is applied by individual cylinders, each covering a small area of the mold.

Cope and Drag Machines. Automatic molding machines that use cope and drag patterns can also be utilized in tight flask and flaskless designs. Because the patterns normally do not have the strength to withstand the pressure exerted during compaction without flexing, the pattern plates are usually mounted against a platen or grid. In most cases, the cope and drag mold halves are filled and compacted with the pattern facing up. Except in the case of special finishing operations to the cope half of the mold, it is not necessary to rotate either the patterns or the cope half of the mold. However, it is necessary to turn the drag half of the mold over to allow for setting of cores, close up, and pouring.

Most of the first automatic molding machines were automated versions of the rapjolt machine mentioned earlier. The automation of rollover, transportation, and in some cases core setting has greatly increased the rate at which these machines produce molds.

A relatively common method of compaction in tight flask machines utilizes pressure from one or several compensating squeeze heads, as shown in Fig. 3. This pressure is normally adjustable in order to optimize the molding conditions. The mold halves can be filled by gravity or the sand blown in using air pressure.

Pressure Wave Method. More recent designs utilize pressure wave technology as the compaction method. These designs normally fill the flasks with sand by gravity. The top of the mold is sealed by a chamber. The chamber then emits a pressure wave, either by rapid release of air pressure or by an explosion of a combustible gas mixture (Fig. 8). As the pressure wave hits the back side of the mold, the sand grains are accelerated toward the pattern. The pattern immediately stops the downward movement of the sand grains, causing the kinetic energy of the mass to compact the sand. Molds made using this method are most dense at the pattern face and progressively less dense as distance increases from the pattern face. There is no need for additional compaction by the application of squeeze pressure.

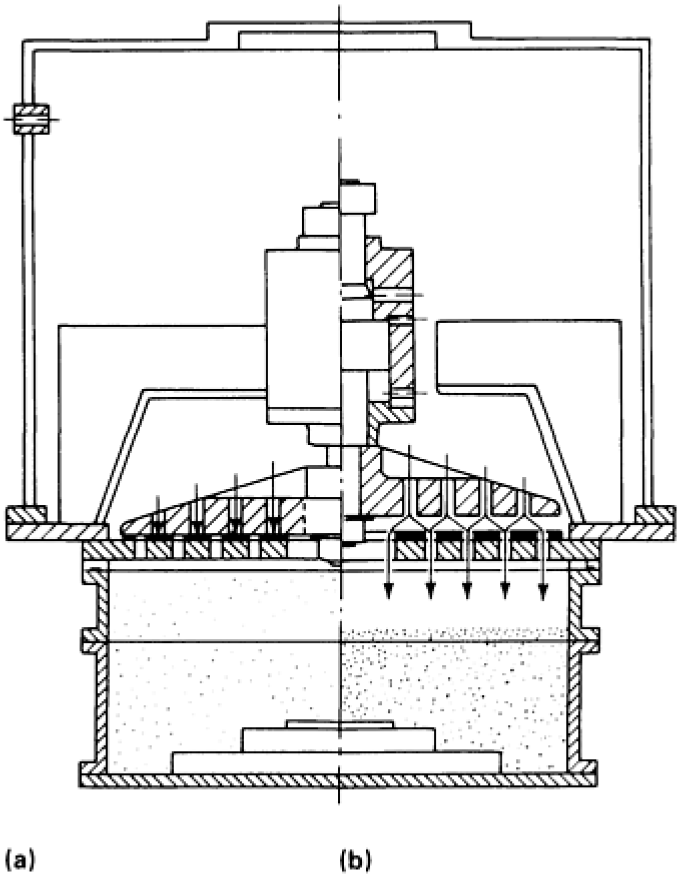

Fig. 8 Pressure wave molding machine that compacts sand by the rapid release of air pressure or an explosive combustible gas mixture. Part (a) shows the mold filled by gravity prior to being compacted by the pressure wave at (b).

Horizontal flaskless molding machines are a relatively recent design. The patterns are mounted in these machines on a hollow pattern carrier (Fig. 9). A grid supports the underside of the pattern to avoid flexing during compaction. The molding chambers are formed by the pattern, the four sides of the molding chamber, and a plate with a sand injection slot. Vacuum is used to evacuate the chamber formed by the pattern carrier and the pattern plates. Vents in the pattern carrier and pattern plates allow the vacuum into the molding chambers, which causes sand to flow into the molding chambers. Upon completion of the filling sequence, the mold is compacted by squeeze pressure and the molds are withdrawn from the pattern. The pattern carrier retracts as the drag half of the mold swings out for blow out and/or core setting while another mold is being produced. Because the molds are produced in the same attitude as they will be used, there is no need to turn either half of the mold over.

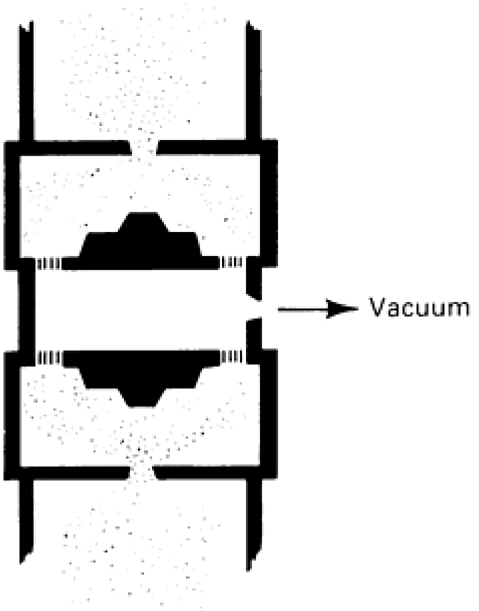

Fig. 9 Vacuum-fill pressure squeeze machine that uses cope and drag patterns

Vertically parted molding machines have been commercially available since the mid 1960s. Like their horizontal counterparts, vertical machines have undergone a number of design changes as electronic technology has improved. Molds are made in these machines by closing the ends of a four-sided chamber with the patterns, which in turn are mounted on platens. The top chamber wall has a slot through which molding sand is blown. After the molding chamber is filled with sand, it is subsequently compacted by squeeze pressure (Fig. 10). Blow and squeeze pressure are both adjustable to optimize molding conditions. After compaction, one of the platens with its mounted pattern swings out of the way, allowing the other platen and pattern to push out the newly made mold to join with previously made molds. At this position, the mold is available for core setting. Blow off is accomplished automatically. Some models are capable of porting vacuum to the back side of the pattern to assist in the filling of deep pockets.

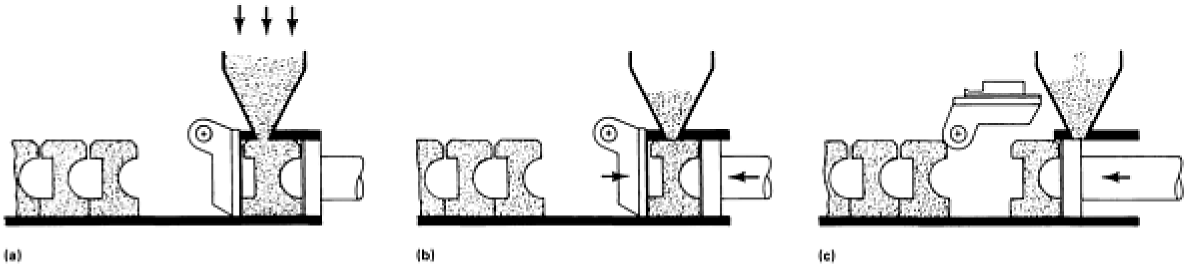

Fig. 10 Blow-fill pressure squeeze molding machine making vertically parted molds. (a) Molding chamber filled with sand. (b) Sand compacted by squeeze pressure. (c) Finished sand mold pushed out of molding chamber

The vertically parted molding machines that are available are flaskless by nature. However, many deliver the mold to a device that will provide added physical support for the mold sides, thus increasing their flexibility.

Molding Media Preparation

The sand in the metal casting process forms a continuous loop, as shown in Fig. 11 (see also the article "Classification of Processes and Flow Charts of Foundry Operations" in this Volume). It is therefore difficult to determine exactly where it

begins. For the purposes of this article, sand preparation will be discussed first. Sand, clay, water, and carbonaceous materials are charged into the mixing device. The length of time these ingredients are left in the mixing device is best determined by the type of device used and the desired sand properties. These devices are called either mullers or mixers. As with molding equipment, different types of mixing equipment can be used. Most foundries use either a continuous or a batch-type muller.

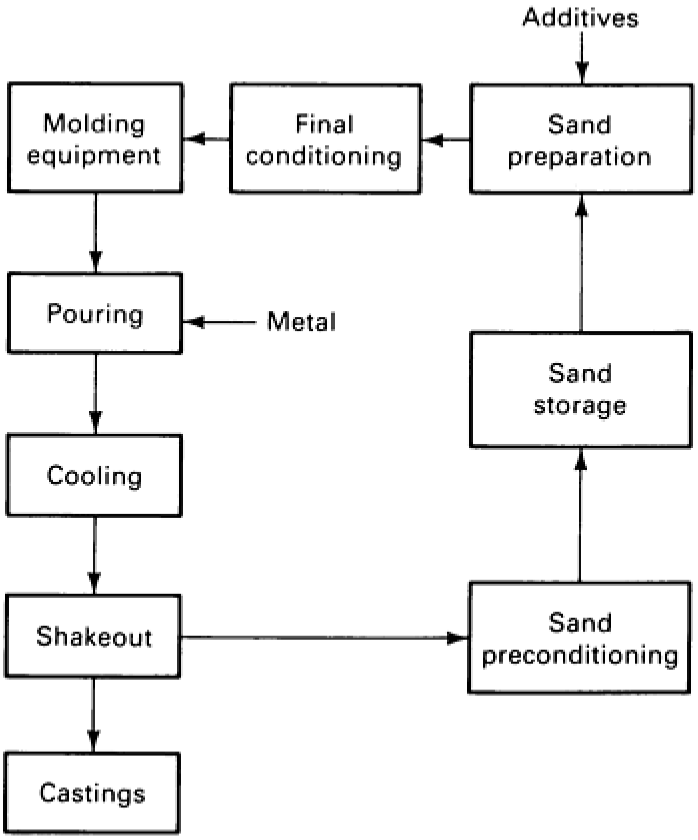

Fig. 11 Flow chart of a metal casting system

Continuous Muller. In a continuous muller (Fig. 12), the sand is fed to the muller into one bowl, and it exits through a door in the other bowl. In most cases, sand is fed into the muller in a regulated, continuous stream, and discharge is controlled based on the power draw of the muller motor. As power draw reaches a predetermined level, the discharge door opens for a short period, allowing some of the sand to leave the muller. On average, sand will pass through both bowls twice before it is ejected. It is possible, however, that a small percentage of sand will pass directly from the input to the exit in one pass. This type of muller is designed to produce large quantities of sand continuously.

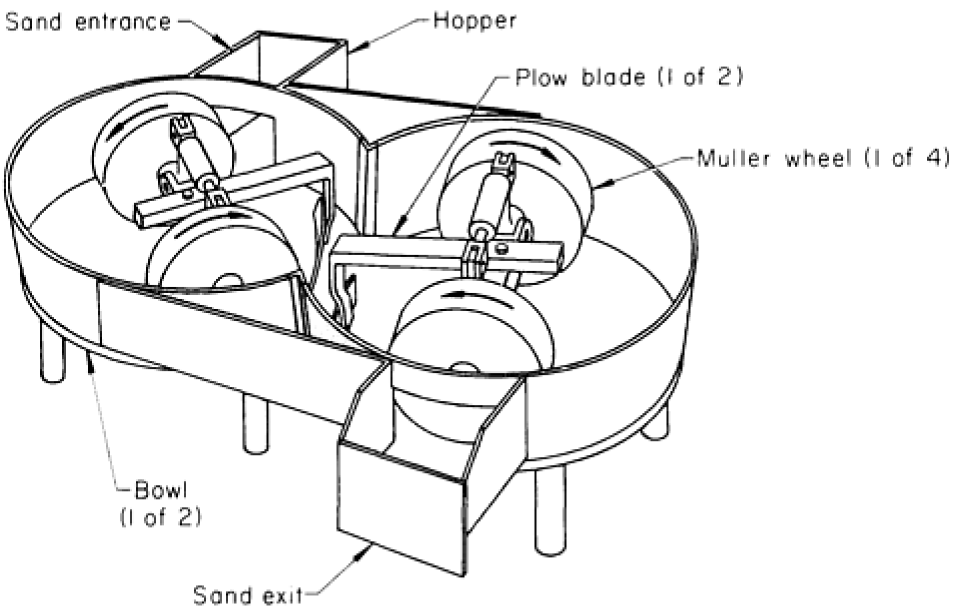

Fig. 12 Primary components of a continuous muller

Batch-Type Muller. Although not a new design, the batch-type muller (Fig. 13) can produce high-quality molding sand. It is equipped with plows to move the sand mass under the large, weighted rolling wheels, which are vertically oriented. This kneading action provides the capability of consistent control but not short cycle times.

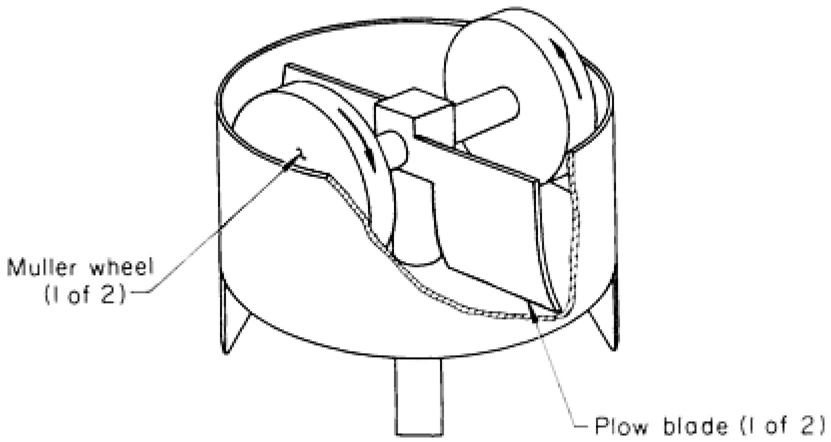

Fig. 13 Essential components of a conventional vertical wheel batch-type muller

The high-speed batch muller shown in Fig. 14 has been adapted to meet the requirements of both high-production molding lines and jobbing foundries. Sand is plowed from the floor of the muller up to the position where the rubber-tired wheels knead the sand against the rubber-lined sidewall. However, not all of the mulling action takes place as a result of the wheels; much of the mulling action takes place as a result of the amount of sand in the muller. For maximum mulling efficiency, the weight of sand charged into this type of muller should not be too small. The manufacturer should be able to provide the necessary information. This type of muller also offers the possibility of cooling the aggregate. A blower can be installed that will force air into the bottom of the unit. As the air flows through the aggregate, it picks up moisture and is exhausted through the top of the muller. By adding sufficient amounts of water, the sand can be evaporatively cooled.

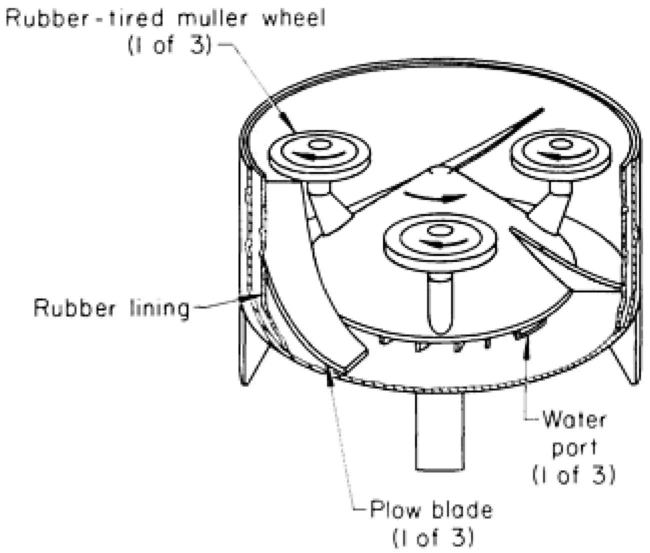

Fig. 14 High-speed batch-type muller with horizontal wheels

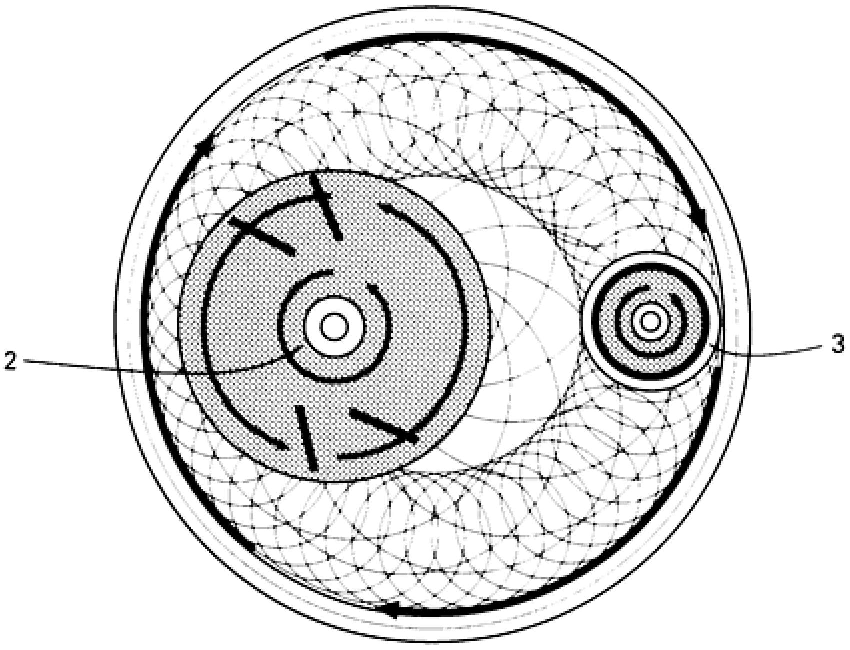
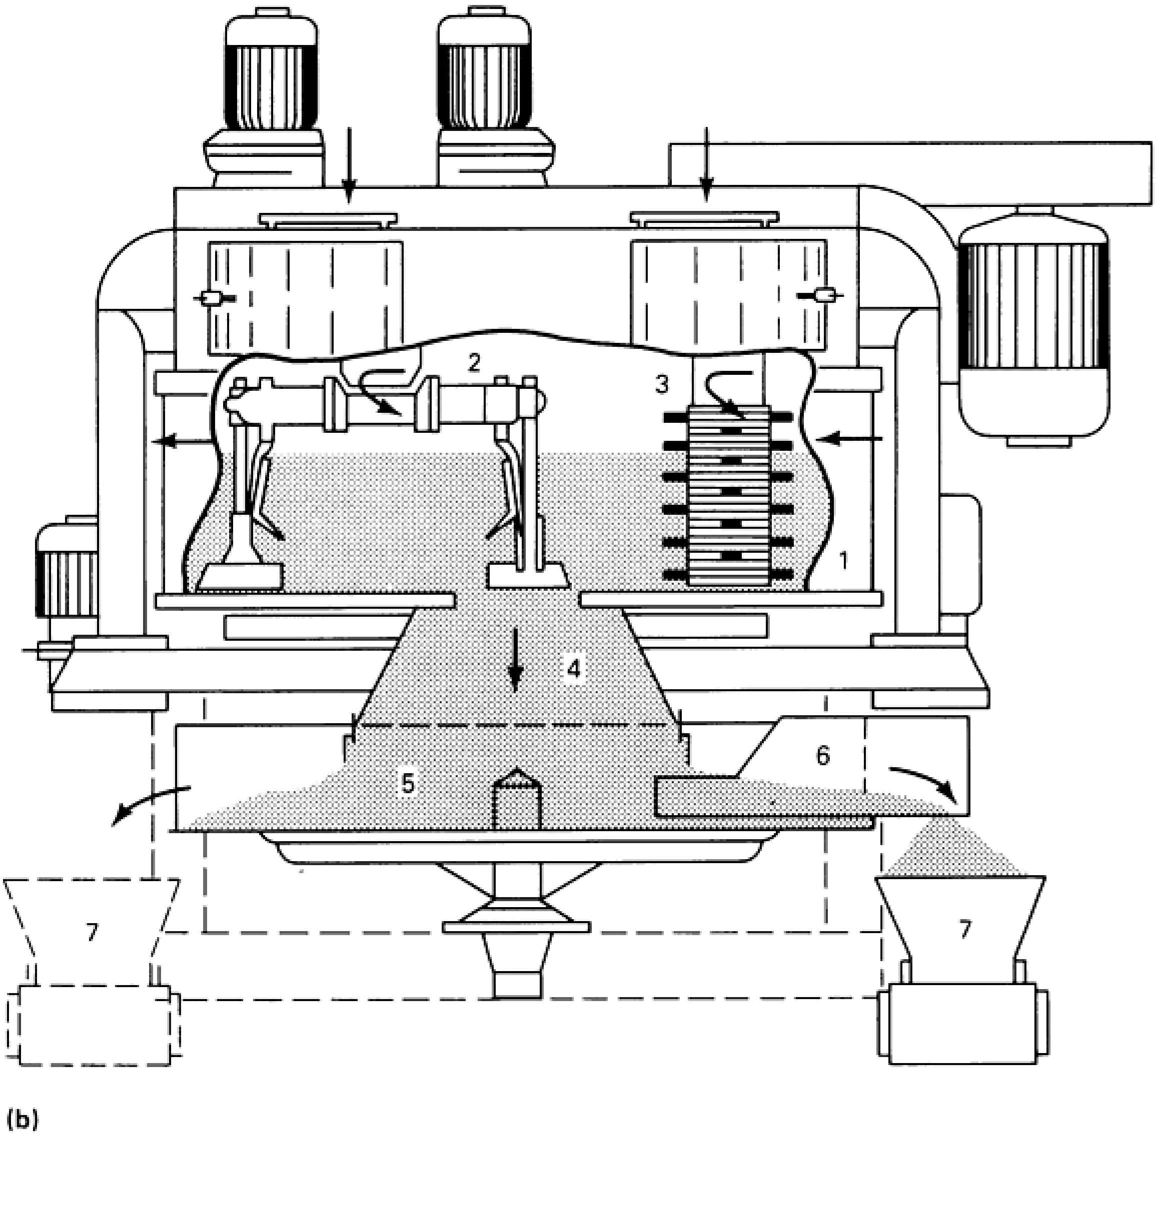
Intensive Mixer. Another type of mixer that is increasing in use is the intensive mixer (Fig. 15). The intensive mixer utilizes a rotating bowl into which the sand is charged. Inside the rotating bowl are one or two driven rotors that are available with different designs, depending on requirements. To avoid internal buildup, the unit is equipped with a scraper that directs sand away from the sidewalls and back toward the center of the mixer. This type of mixer is available in either batch or continuous configurations.



(a)



(b)

Fig. 15 Top (a) and side (b) views of an intensive mixer. The top view illustrates the loop pattern created by the mixing pan (1) rotating clockwise and the rotating mixing tools [movable mixing star (2) and stationary wall scraper] rotating either clockwise or counterclockwise while mounted eccentrically inside the mixing pan. The optional high-energy rotor (3) intensifies the mixing action. Other components include the discharge opening (4), rotary discharge table (5), discharge plough (6), and either one or two discharge chutes (7).

Mixing Variables. Regardless of the type of mixing/mulling equipment chosen, muller input and output must be closely controlled. Clay, combustible material, return sand, and new sand must all be added consistently and in amounts indicated by sand test results. Some sand systems are run on a volumetric basis, while others are run on a weight basis. The preferred method is to add return sand and additives by weight, thus affording closer control. Water additions are controlled in a number of different ways. Some equipment samples the sand going into the muller and bases water additions on testing those samples for heat and moisture content. Other water addition equipment samples the sand inside the muller and adds additional amounts of water as needed. Still other systems use a combination of these. Regardless of the type of equipment used, a minimum of 80% of the total added water should go into the muller immediately before the sand or at least with the sand to allow the maximum amount of time for cooling (if applicable) and/or clay activation and to provide the maximum control Ref 2.

Most mulling equipment does not discharge prepared sand in its most flowable condition. Even if it did, prepared sand will normally be routed through at least one hopper (probably two or more) and will be transferred from one belt conveyor to another. Each time the sand is dropped into a hopper or onto another belt, some prepacking takes place. To provide a more flowable sand at the pattern face, operators of manual molding machines may, at the expense of time, riddle the first sand that enters the flask. In addition, again at the expense of time, an operator may even hand tuck the deeper pockets. Automatic molding equipment affords little or no opportunity for this special treatment. For these reasons, each molding station should be equipped with a good aerator to perform the final conditioning of the prepared sand. The aerator should be located on the last belt feeding the molding equipment in order to avoid any subsequent prepacking of the aggregate.

It is suggested that prepared sand always be conveyed to the molding equipment by belt conveyors. Other methods of conveying sand have been known to introduce unwanted moisture into the aggregate or to scrub clay from the coated sand grains. Prepared sand systems should always be designed with the receiving hoppers large enough to accept the total amount of sand from the feeding equipment. For example, the prepared sand hopper at the molding machine should always have enough capacity to receive all the sand from the muller (or another hopper). Thus, belts can be kept running, minimizing the drying time of the prepared sand on the belt. In no case should sand that will be used for molding be allowed to dry on a delivery belt. At best, this drying will be intermittent and will lead to inconsistent results at the molding station.

The requirements of dimensional stability and casting integrity do not tolerate poor or inconsistent control of molding sand. The old hand squeeze method of testing is not capable of controlling sand within the necessary specifications. Manual operation of the muller can and does lead to incorrect assumptions and corrections. For example, a sand that feels as though it does not have enough body indicates a system that is beginning to run low on clay. The operator is then likely to add additional water. When this additional water is added, the sand may seem to have the correct body, but in fact, it will have an excessive amount of moisture. Defects resulting from oxidation will increase, green sand pockets will be harder to fill, mold wall movement will increase and cause shrinkage defects, casting surfaces will become rougher and shakeout may become more difficult.

Sand test samples should be taken at the point where the sand enters the molding machine. Samples taken from other points, such as at the muller discharge, will provide a false indication of production conditions.

The properties tested often vary from foundry to foundry, as will the necessary frequency of testing. Those properties often include (but are not limited to) moisture content, active clay content, loss on ignition, grain size distribution, compression strength, permeability, and compactability. In some cases, green shear and wet tensile tests are also performed. All these tests provide the operating personnel with useful information.

Although the primary function of this section is not sand testing, it is necessary to mention another sand test that is widely used in Europe and is gaining acceptance in the United States. It is recommended that green tensile tests be conducted along with the other tests. Green tensile strength does not follow the same conditions that apply to green compression and shear strength. Although not documented, tensile strength decreases more rapidly and earlier than the other strength

properties. This, combined with the fact that many molding defects (stickers, drops, and so on) are the result of poor tensile strength, makes the test well worth running. The test has not found widespread use, probably because it is more difficult to conduct and it requires expensive additions to the sand test equipment. Fortunately, another test has been developed whose results have a numerical relationship to green tensile. This test is spalling (splitting) strength. The manufacturers of sand test equipment can supply the necessary information on this test.

Molding Problems

Molding machines have been discussed in the section "Molding Methods" in this article. The use of these machines has been the subject of much discussion and, in some cases, disagreement. There are a number of pitfalls the operator can fall into. The first and most common involves compaction force. Most machines utilize hydraulic pressure to apply the compaction force. This pressure is adjustable, usually over a wide range. In 1970, the Green Sand Molding Committee, 80-M, of the American Foundrymen's Society accepted the definition of high-pressure molding as the pressure exerted on the mold face being equal to or greater than 700 kPa (100 psi). The committee also accepted the definition of high-density molding as a uniformly compacted mold with a mold hardness of 85 or greater as measured with a B-scale mold hardness tester (Ref 3). Unfortunately, it is often mistakenly held that greater pressure means better molds. Although a certain amount of pressure is necessary to compact the mold to arrive at the necessary strength and stability, it can easily be overdone. As pressures on the mold face exceed 1050 kPa (150 psi) and especially as they near 1400 kPa (200 psi), a number of detrimental effects can be noticed.

Springback. As mentioned earlier, the muller is used to coat the sand grains evenly with clay that has been made plastic by water absorption. Ideally, this coating of clay will completely cover each sand grain. The clay, expanded and made plastic by the water, is compacted by the molding machine with enough pressure to cause the clay that coats one grain to cohere to the clay that coats an adjacent grain, thus forming clay bridges. As compaction pressure is increased, these bridges gain more area and become stronger, at least up to a point.

As with most plasticized materials, the clay does have a certain amount of memory. As compaction pressure is released, the clay will attempt to recover some of its former shape. The mold will grow very slightly as pressure is released, even when pressures are quite low. This springback cannot be avoided (Ref 4).

As compaction pressures increase above 1050 kPa (150 psi) and approach 1400 kPa (200 psi), pattern release from the mold can become a serious problem. Not only does the mold swell slightly, causing pockets to become tight in the pattern, but the growth can also reach such a magnitude that the clay bridges are partially broken (Ref 5). When these bridges are fractured, tensile strength suffers drastically as greater compaction pressure is applied. The deeper pockets then become increasingly difficult to draw.

Expansion Defects. Tensile strength is not the only problem with high compaction pressures. As compaction pressure increases, more bentonite is squeezed into the voids that exist between the sand grains. When the grain-to-grain distance becomes too small, there is insufficient bentonite/water to contract as the sand grains expand during the heating by pouring. The result is expansion defects such as rattails, buckles, and scabs.

Similar problems can exist with machines that use some form of the pressure wave principle. The problem of springback may not be quite as great, because the mold becomes progressively less dense as distance away from the pattern face increases. However, if the compaction energy becomes too high, the sand grains may actually be stripped off of the bentonite coating, especially on the pattern face, giving rise not only to expansion defects but also to casting surface finish problems.

Parting Sprays. The tendency of the mold to stick to the pattern is often combatted by spraying the pattern with some kind of parting spray (usually proprietary). This helps draw the pattern from the completed mold and greatly reduces the likelihood of a buildup of bentonite and fines on the pattern surfaces. Unfortunately, there is a tendency to use too much of the spray. Like compaction pressure, the right amount of parting spray is advantageous, but excessive amounts cause a number of problems, including stickers, rough casting finish, penetration, blows, and sand inclusions. Generally, the pattern should be sprayed with a very light coating once every second or third mold. The operating foundryman should experiment with the optimum spray frequency and spray no more than is absolutely necessary.

Pattern Heating. Although the use of a parting spray is effective, a better first step is to heat the patterns to 6 to 11 °C (10 to 20 °F) above the temperature of the molding sand. Cold patterns will cause the moisture in the molding sand to condense on the pattern face, which makes the sand stick to the pattern. Many molding machines do not have any provision for heating the pattern during the production run. Whether the molding machine has the heating capability or not, the pattern should be preheated to the proper temperature prior to the start of the production run to assist in a rapid start-up.

Mold Finishing

After the mold has been compacted and the pattern removed, the mold is ready for the finishing operations. These operations usually consist of blowing out any loose sand, looking for any molding defects, drilling the sprue cup (if applicable), and setting any necessary cores. Once the finishing operations are complete, the cope can be accurately placed on the drag and the mold sent to the pouring station.

Mold blowoff is one of the areas that can cause surface finish problems if not property controlled. Excessive amounts of air blown onto the mold can cause localized drying of the mold surface. On the other hand, if the air contains large amounts of moisture, the mold face can become excessively wet, giving rise to rough finish and burn-in penetration, just as excessive amounts of water in the molding sand or excessive amounts of parting spray will.

Core setting is another part of the process that has undergone tremendous change in the last few years. The increased demand for more accurate castings has affected cores and core setting just as it has molding. With mold hardness in the 85+ range, it is no longer possible to press an oversize core into undersize core prints. From the viewpoint of casting accuracy as well as cleaning room costs, it is equally unacceptable to place undersize cores in an oversize core print. Modern core processes allow the possibility of making the same size core every time, just as the same size mold can be made every time. Thus, it becomes apparent that every cavity in the corebox and every impression on the pattern must be as close as possible to the same dimensions. This obviously places greater demands on the supplier of patterns and coreboxes as well as on the process itself.

Mold closing is the next step in the operation. Some molding machines close the mold inside the machine, while others close the mold just outside the machine. Still others utilize a separate piece of equipment to perform this function totally external to the molding machine. The halves should not be allowed to remain separated any longer than absolutely necessary. Separation of the mold halves for excessive periods of time will allow the mold faces to dry, and this can lead to cuts, washes, and a general degradation of the casting surface.

Transportation of the mold to the closing station is critical. Jarring of the mold can cause green sand pockets to break away from the mold. In some cases, the pocket may not break away until the mold is poured; thus, the mold, the cores, and the metal are wasted. Rough transportation can easily cause heavy cores to shift off location, which can cause errors in casting dimensions, broken cores, and excessive metal around coreprints.

Mold closing is just as critical as mold transportation, and the same basic rules apply. The mold must be treated as smoothly and gently as possible to avoid the same type of defects. The mold guiding mechanism is as important at mold closing as it is during manufacture of the mold. Too often the accuracy and smoothness with which the mold is closed is overlooked. Again, the results can be drops and core movement as well as mold shift, crush, casting dimension problems, and so on.

After the mold is closed, mold transportation again becomes important. The finished mold must be carefully transported to the pouring area, or problems such as those already mentioned will likely occur.

After the mold has been poured, the molten metal must be given time to solidify and coot to the proper temperature before it is removed from the mold. During the solidifying process, the mold halves must be held solidly together. Any movement will introduce the possibility of casting inaccuracies or increased demands for feed metal or both. The loss of casting accuracy has obvious consequences. The requirement for additional feed metal has the consequence that shrinkage cavities may form and will probably not be evident from the casting exterior. Cooling time after solidification is critical for many casting/alloy combinations. Insufficient cooling time can lead not only to dimensional problems due to lack of casting rigidity but also to hardness and internal stress problems, even to the point of cracking the casting.

Shakeout

After the castings have cooled sufficiently, they can be shaken out, that is, separated from the sand mold. Shakeout devices are available in a number of different configurations. Many of the devices available are of the flat deck, vibratory type. They range from normal intensity, frequency, and travel to high-intensity units that utilize a very short travel but high frequency. Some shakeout units are rotary in nature and, depending on design, can also provide the added function of cooling the sand. Another type is the vibratory barrel.

Deck-type shakeouts (Fig. 16) are available in a number of different configurations for various applications. The first is the stationary type. Stationary refers to the casting and sprue, not the shakeout itself. This type of shakeout is normally used by bringing the mold to the shakeout device; therefore, its primary application is for larger molds and low-to-medium production lines. The deck-type shakeout is also available as a unit that provides the function of conveying the castings from one end of the unit to the other. As mentioned earlier, either type is available in a variety of strokes, intensities, and frequencies. Selection of the shakeout is a function of casting design. Heavier castings can be quite successfully run using a longer-stroke shakeout, while thin-wall castings may require a short-stroke high-frequency unit to prevent breakage or damage to the casting.

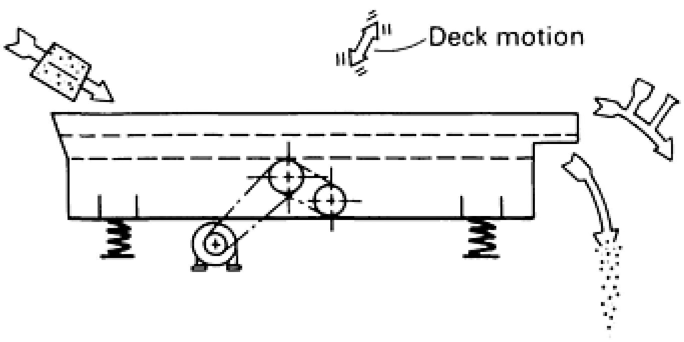

Fig. 16 Flat deck vibratory type shakeout device

Rotary-type shakeouts (Fig. 17) are also available in different configurations. The sand may exit at the same end that the sand and castings enter the unit, or it may exit at the opposite end. This type of shakeout also provides the function of conveying the castings from one end of the unit to the other. Rotational speed is adjustable on most units to allow flexibility in shakeout intensity. In general, as rotational speed decreases, intensity decreases and castings are less likely to be damaged. Light thin-section castings may not be suitable for this type of shakeout. Although the castings themselves may not damage each other, the sprue is sometimes heavy enough that it can damage the castings.

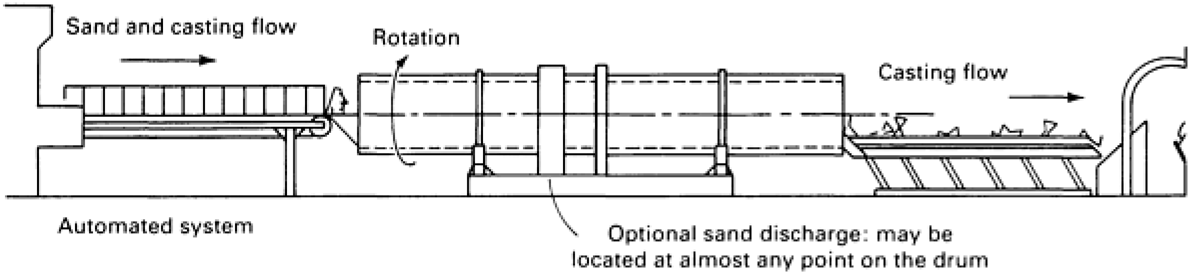

Fig. 17 Rotary-type shakeout system

Rotary plus cooling type shakeouts are also available in a configuration that not only holds the sand and castings together for an extended period but also affords the opportunity to cool the molding aggregate. This type of device is designed such that the castings and sand are held together throughout the length of the drum (Fig. 18). The castings and sprue aid in the breakdown of lumps. Sand temperature samples are normally taken somewhere along the length of the

drum to determine the amount of water necessary for cooling the sand. The cool sand in turn cools the castings, often down to a temperature that can be comfortably handled at the exit of the drum. Sand and castings are separated at the exit of the drum. As with rotary sh akeouts, sprue can damage certain types of castings, especially as wall sections become thinner. In-mold cooling time can become more critical when the castings and sand are kept together in the cooling device. When castings are too hot, hardness problems can result. In some cases, stresses can also be introduced into the castings because of the rapid quenching of the casting in the molding sand.

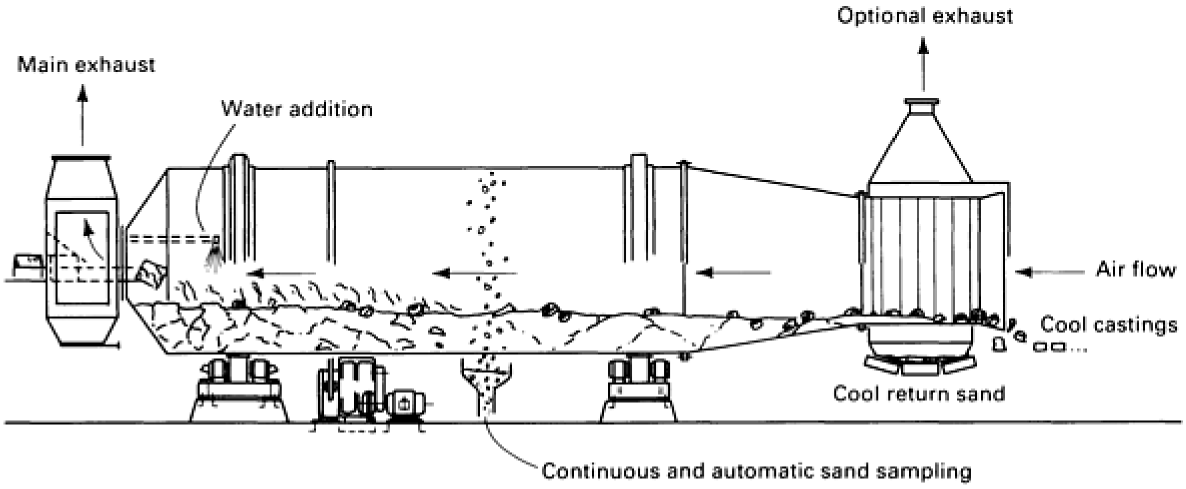

Fig. 18 Rotary plus cooling type shakeout system in which the castings and water-cooled mold sand are separated at the drum exit

Vibrating drum type shakeouts (Fig. 19) combine the operating principles of rotating drum and vibrating deck units. The vibrating section is round in cross section, but it does not rotate. Instead, a rotating action is imparted to the sand and castings by the vibratory action. As the drum vibrates, material is constantly agitated to produce particle migration in both axial and transverse directions. The drum can be designed to provide a very rapid blending action or a gentle folding action, depending on process requirements. Because air can be forcibly exhausted from the drum and because the surface of the sand within the drum is constantly changing, a limited amount of cooling is possible. Additional information on shakeout is available in the article "Shakeout and Core Knockout" in this Volume.

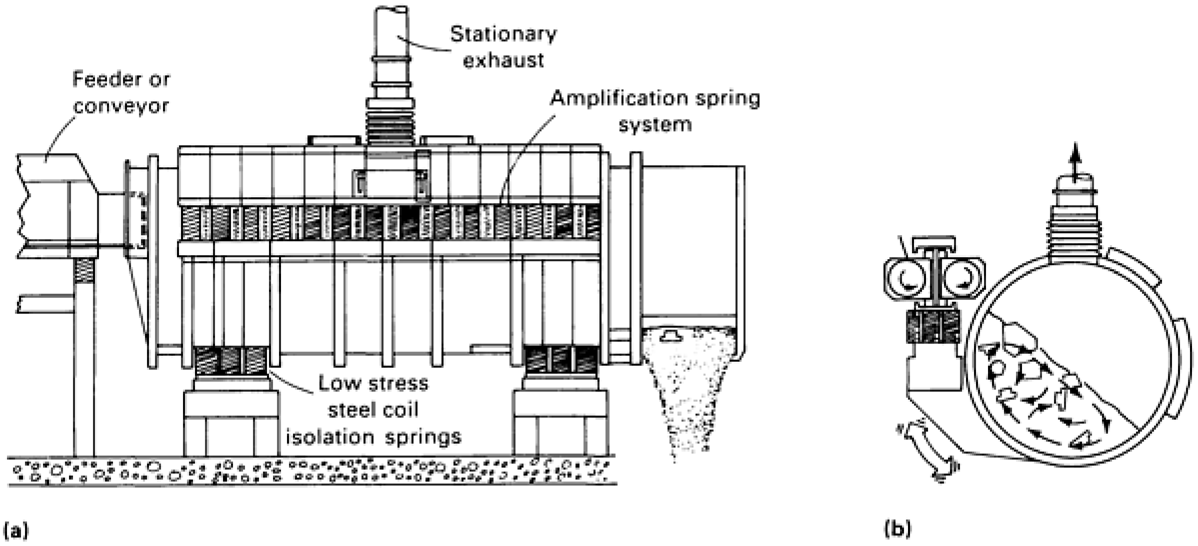

Fig. 19 Front (a) and side (b) views of a vibratory drum type shakeout system

Sand / Casting Recovery

What happens to the sand after shakeout is of great importance to the design and operation of the system (see the section "Sand Reclamation" in this article). Historically, the sand is returned from the shakeout to a storage bin, where it is kept until the next time it is mixed with additional clay, water, and carbonaceous materials. Unfortunately, sand-to-metal ratios of 3:1 to 6:1 are quite common. Sand-to-metal ratios in this range, combined with cooling times that allow the castings to become cool enough to separate from the sand, can easily create return sand temperatures of 120 °C (250 °F) and above (Ref 6).

High sand temperatures cause innumerable problems not only with regard to molding and surface finish but also for the system itself. Bentonite does not absorb water and become plastic to develop the necessary cohesive and adhesive strengths when sand is above 45 to 50 °C (115 to 120 °F). Therefore, the molding sand must be below these temperatures long enough for the muller to provide the necessary input of energy to coat the sand grains properly. Hot sand, usually above 50 °C (120 °F), is difficult to temper and bond, and when above 70 °C (160 °F), hot sands are impossible to rebond (Ref 7).

Unfortunately, sand is not easily cooled, especially in the quantity necessary to keep a molding line running. Molding sand is a relatively good insulator and therefore tends to hold heat for long periods of time. Storage quantity is therefore not the answer. Not only does sand stored in a bin hold its heat for long periods of time but it also cools from the outside toward the center. As it cools in this manner, moisture tends to migrate toward the cooler sand, which causes it to cake on the outside walls. As time goes on, the caking on the outside wall becomes thicker until only a small portion of the sand is actually being circulated through the system. Vibrators and bin poppers have been designed and can be of some help in combatting this rat holing tendency of return sand bins, but the ideal situation would be to cool the sand prior to storage.

Evaporative cooling is the only practical method of cooling the amount of sand needed in green sand systems. Hot sands must therefore have water added in amounts that exceed those required for tempering if both cooling and tempering are to take place. In addition, an ample supply of air must be present to carry away the heated water vapor.

The cooling of molding sand may be regarded as a two-stage process, although no sharp line separates the stages. At temperatures in excess of approximately 70 °C (160 °F), added water causes a flash evaporation cooling effect (Ref 6). Temperature will continue to decrease fairly rapidly to about 60 °C (140 °F), but more slowly after that. As sand temperature approaches ambient temperature, further cooling becomes more difficult and time consuming. Conditions of high ambient temperature, especially when combined with high ambient humidity, can substantially reduce the effectiveness of cooling devices. Therefore, ambient conditions should be considered carefully when sand systems are being designed or modified.

Some mullers have the capability of blowing air through the sand mixture and will cool the sand very effectively. However, there are some disadvantages to this method. It must be kept in mind that mulling (coating sand grains with bentonite) does not take place until the mixture is cool enough to be tempered and bonded (Ref 6). Cooling time must therefore be added to the mulling time. Although western bentonite provides the mold stability needed by most foundries, it does require more time and energy to absorb water and develop the necessary properties (Ref 8). Thus, the job of the muller or mixer becomes even more difficult and time consuming. The storage bin will still have the tendency to rat hole, thus returning sand more quickly and hotter to the muller and further aggravating the situation. Control of solid additives and water becomes more difficult as the molding sand becomes hotter. However, this is not an impossible situation; this method is used quite effectively in a number of foundries.

A few steps can be taken to provide some amount of cooling to the return sand in an existing system and to keep equipment costs as low as possible. For example, water can be fogged on the return sand, preferably as early as possible. Chains can then be dragged through the aggregate and/or plows can be used to turn the mixture over. Additional air can be introduced by fans or other sources to enhance cooling. Elevators can be vented to enhance air flow, but this provides little help because the sand is being conveyed in solid buckets. The only assistance realized will be at the transfer points. Although these and similar methods do help to reduce return sand temperature, they are generally of only marginal value. An effective job of cooling return sand normally requires the addition of water, along with forced air being blown or pulled through the aggregate by some type of auxiliary cooling device.

A number of auxiliary cooling devices are available that utilize forced air for evaporative cooling. These units should always be placed as close as possible to the casting shakeout. In fact, one type of unit, the shakeout-cooling drum, combines the functions of shakeout and sand cooling. Cooling the sand at or near the shakeout enables tighter control,

reduces the tendency toward rat holing in the return sand bin, and reduces the demand for cooling on the muller. Because many muller designs make no provision for cooling, adequate external cooling is not only desirable but necessary.

Cooling the sand as early as possible reduces the total cycle time of the muller by reducing or eliminating the time necessary for cooling and provides a method for making mulling time more efficient. Southern bentonite can be mulled in very quickly if the aggregate temperature is low enough. As mentioned earlier, western bentonite is not mulled in very quickly, because it must swell by such a large amount (Ref 8). For this reason, it is advisable to keep the bentonite swelled and as active as possible. Many of the auxiliary cooling devices can be controlled to the point where the level of return sand moisture will be such that the western bentonite will remain activated. Normally, a retained moisture level of 1.8 to 2.0% will not only keep bentonites activated but will also reduce the amount of dusting at transfer points, thus reducing the load on dust collection equipment.

Cooling Devices. As mentioned earlier, it is possible to realize some cooling by adding water to a return sand belt and then using some method of turning the sand over at various places along the length of the belt. There are mechanized devices (Fig. 20) that perform similar functions and provide air flow through the sand. The effectiveness of these methods is often somewhat limited because of conveyor belt lengths; as belt lengths become shorter, the method becomes less effective. Difficult sand temperature problems will require more serious measures.

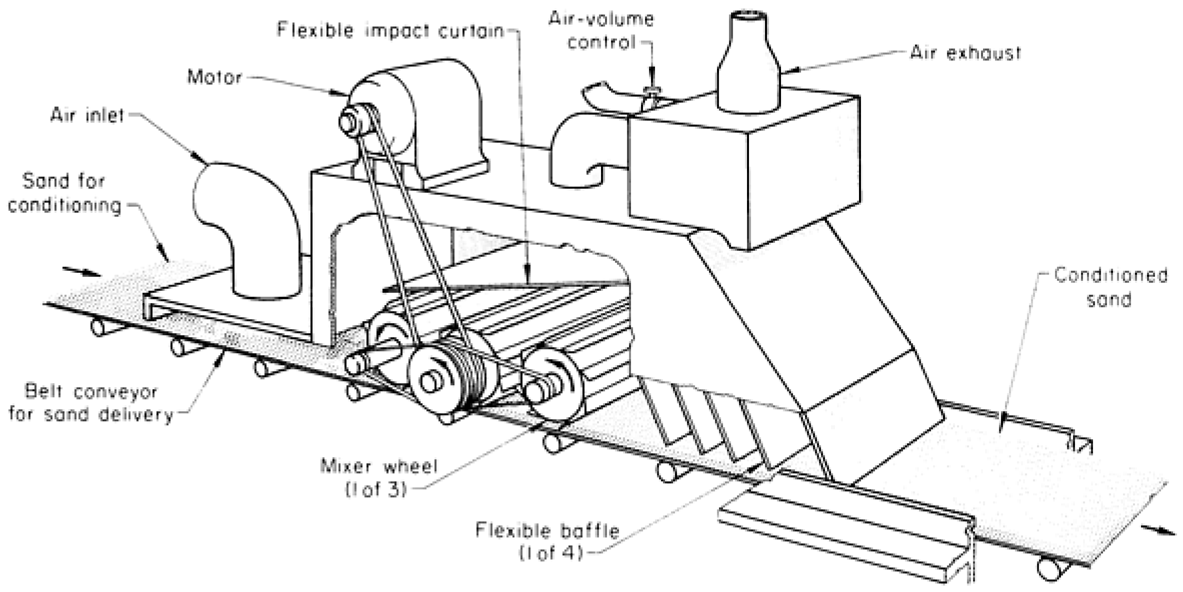

Fig. 20 Mechanized sand cooler used in high-production molding lines

Drums used as cooling units are among the oldest of the effective devices (Fig. 21). A cooling drum does not keep the sand and castings together; instead, this is a separate piece of equipment through which sand from the shakeout flows. As with other cooling devices, water must be added to the molding sand to allow the air moving through the drum to provide the necessary cooling by evaporation.

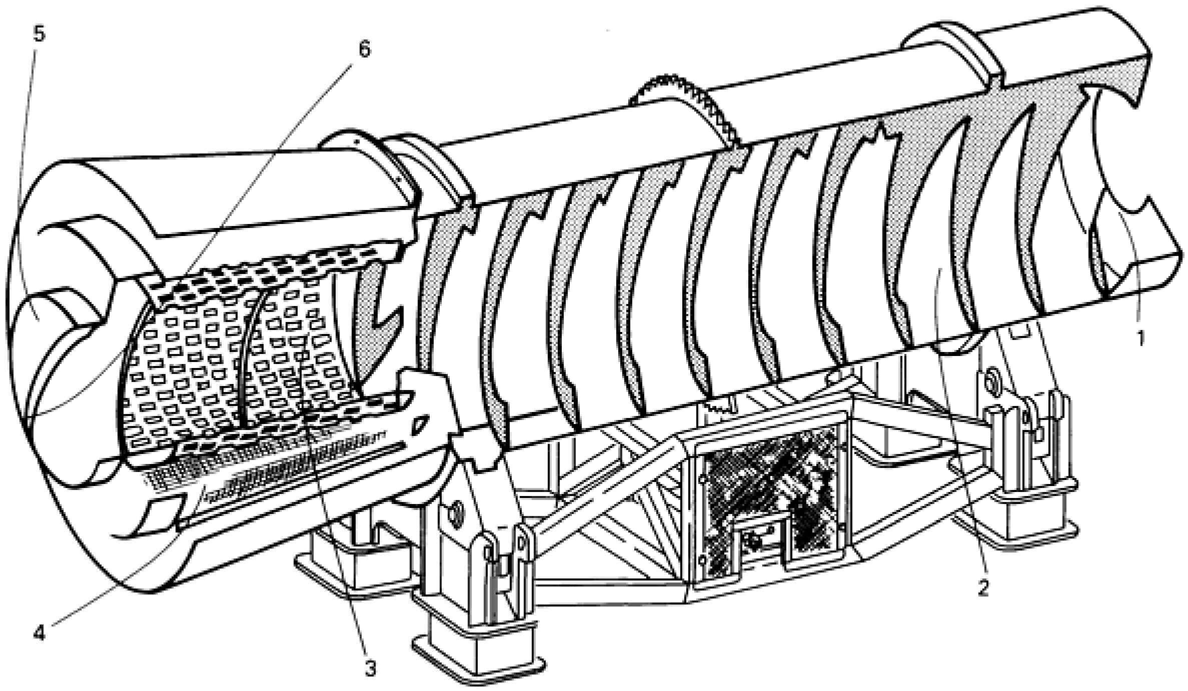

Fig. 21 Cutaway view of a sand cooling drum system. Sequence of operations proceeds from right to left: 1, hot shakeout and spill sand enter, and helical flights convey sand forward to begin blending process; 2, cascading effect provides sand cooling as well as sand homogenization; 3, blended and cooled sand is discharged onto perforated cylinder, which screens off tramp metal and core butts while passing sand; 4, replaceable screen passes sand to discharge onto conveyor; 5, lumps that do not pass final screen carry across to lifter paddles for discharge into overburden chamber

The fluid bed cooler (Fig. 22) is a vibratory type of conveyor through which the sand flows in a more or less continuous but controlled stream. Air is pumped through the sand from underneath, causing the necessary evaporation and cooling.

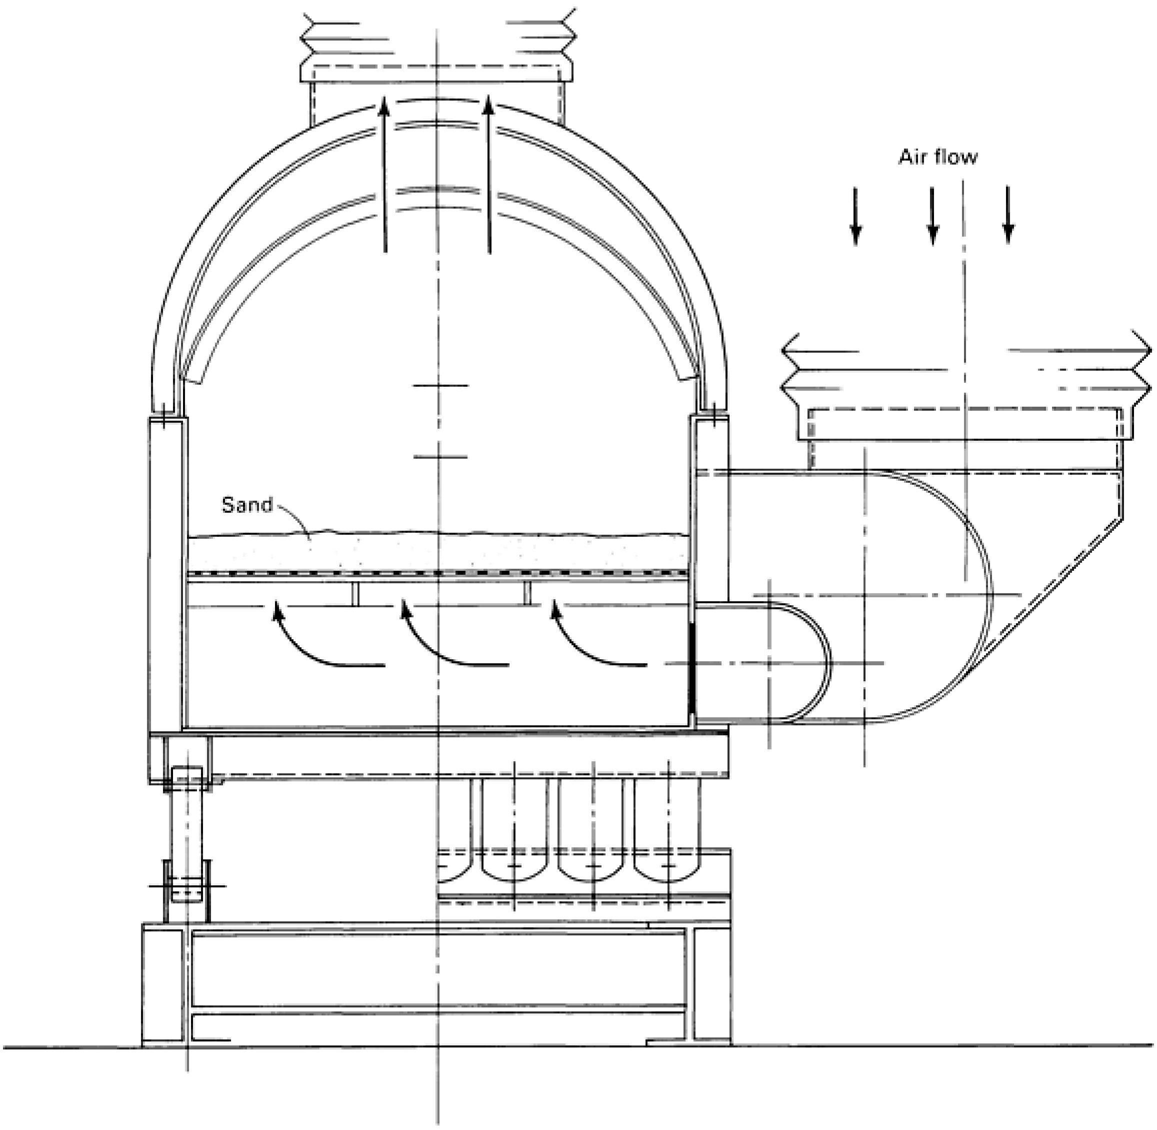

Fig. 22 Schematic of a fluid bed cooler

Figure-Eight Cooler. Similar to the continuous muller shown in Fig. 13, the figure-eight cooler is designed so that air can be pumped through it and provide the necessary cooling. This device has been used directly above the muller, but a more desirable location would be as close to the shakeout as possible for the reasons already mentioned.

Regardless of the equipment used, it is necessary to control the moisture additions so that sufficient moisture is available for cooling and bentonite activation without getting the return sand so wet that problems will be experienced with plugging up of the sand system. The movement of air through the aggregate will almost certainly remove some of the finer material. The higher the velocity of air movement, the better the cooling, but also the greater the loss of that fine material. The loss of a certain amount of that material (such as dead, burnt clay and ash) can be beneficial. Unfortunately, a number of beneficial materials can also be lost, such as the finer grains of sand, coal dust, and bentonite. Any cooling device should be planned with a solids separator on the exhaust air so that these materials can be collected and fed back into the system at a controlled rate. This will improve surface finish, and trapping and using the bentonites and coal dust will provide economic benefits.

Metal Separation and Screening. The shakeout does the primary job of separating the sand from the sprue and castings. Smaller pieces of metal can easily slip through the grating of the shakeout device and be processed along with the sand. This will cause casting defects, and it may damage the equipment. Therefore, it is advisable to remove as much of the tramp metal as possible. When magnetic metals such as most irons and steels are being cast, the job is relatively

easily accomplished with magnets. The suggested practice is to install an over-belt magnet somewhere along the length of a conveyor belt and a pulley magnet at the discharge end of the same belt. Placing both magnets on the same belt allows more complete separation of the magnetic particles.

Nonmagnetic alloys present a different problem. Devices are available that separate the metallic particles based on density differences, but the most common method is to use screens. Multiple screens are often used, and the mesh size from screen to screen becomes progressively finer.

Lumps are found in all sand systems and consist of system sand or core parts that have not been sufficiently heated to break down the binder. For this reason, it is necessary to have a good screen in all systems. The opening size in the screen should be as fine as is practical for the system involved.

Two basic types of screens are in use: flat deck and rotary. The flat deck type is usually vibratory in nature and has the added function of providing further lump reduction as well as the screening function. The rotary type of screen is normally a large barrel that continually rotates. The exterior of the barrel has the desired size of holes in it to provide the screening action. Because of the tumbling action within the screen, lump reduction similar to that obtained with the vibrating flat deck can be expected. In both cases, the size of the screen should be as fine as is practical. After the sand has been cooled, the tramp metal removed, and the core butts and lumps removed, the sand is ready to be returned to the storage hopper to be used again.

Computer-Aided Manufacture

Recent years have seen a rapid advancement in the use of data processing units and data communication. These advancements have made possible almost complete and instantaneous record keeping and, equally important, trend recognition.

The technology is advancing rapidly; there are systems currently in place that record on a continual basis the amounts of return sand, new sand, bentonite (or premix), and water that go into each batch of sand. In many cases, mixing time and maximum current draw of the muller are also recorded. With some systems, compactability can also be recorded. In any case, output data, such as compactability and muller current draw, can be stored for a period of time, and a trend analysis can be done automatically.

Molding machines have also become more sophisticated. With microcomputers and programmable controllers being used to control machine movements, it is possible to read the pattern number automatically when the pattern is installed. Using information that had previously been stored in the memory of the computer or controller, the molding machine can optimize its molding parameters for the individual pattern.

A hypothetical case will illustrate the extent of the available information. During a shift, a new pattern is installed on the molding machine. The operator tells the machine that 1250 molds are needed. Optimum molding parameters, poured weight, necessary cooling time, and so on, have already been determined during earlier runs and stored in the computer. At any point during the run, the operator or someone operating a distant host computer can query the molding machine to find out which mold is going to reach shakeout next, how much cooling time it had, how much metal is required to complete the production run, how much time will be required to complete the production run based on existing molding rates, how many cores will be required to complete the run, how many molds have been made and/or poured, and so on.

These outputs can be used as control signals. More water or less water can be added to the sand cooler when sand from the new molds reaches the cooling device. Molding sand compresses more in the molding chamber/flask as sand becomes wetter (higher compactability), thus trend analysis can be done by recording mold compression during compaction, and the resulting information can be fed back to the sand preparation equipment. The exact position required for an automatic

pouring device can be set by the molding machine. Daily production data reports can be printed out that will give information on each run; this information includes the number of castings, production rate, productivity, number of cored molds, and reasons for downtime (such as waiting for sand or metal).

In the event of machine difficulty, the machine can help troubleshoot itself. It is not only possible but practical to allow the molding machine to exchange data with a remote location (via telephone lines) if assistance in troubleshooting is needed.

The quantity of information that is available and transmittable depends on the mechanical and electronic design of the equipment. Some units are designed to allow one-way communication (output), while others are designed to allow two-way communication (output and input). In the latter case, it is possible for a remote location to control some or all inputs to the production equipment. These remote locations can consist of keyboard inputs from a host computer or even data output from other pieces of equipment.

The type of information available (either as inputs or outputs), the form the information is in, and the communication protocols may vary greatly among manufacturers. It is therefore necessary to research the technical information available from each manufacturer to determine the best way for the various pieces of equipment to communicate and the best way to handle the information obtained. Additional information on the role of computers in the manufacture of green sand molds is available in the Section "Computer Applications in Metal Casting" in this Volume.

Sand Reclamation

Michael Zatkoff, Sandtechnik, Inc.

Reclamation is defined by the American Foundrymen's Society (AFS) Sand Reclamation and Reuse Committee 4-S as the physical, chemical, or thermal treatment of a refractory aggregate to allow its reuse without significantly lowering its original useful properties as required for the application involved. To achieve this objective, one must evaluate the type of sand entering the reclamation system, the binder system used, and the area for its reuse.

This section will provide a brief review of sand reclamation systems for both chemically bonded (resin bonded) sands and clay-bonded sands (green sands). Detailed information on sand molding principles and processes can be found elsewhere in this Volume.

Reclamation of Chemically Bonded Sand

The primary requirement of any reclamation system is to remove the resin coating around the sand grains. This involves abrasion and attrition to break the bond, as well as classification to remove the fines that are generated. The three basic reclamation systems are thermal, dry, and wet. Selection of a system depends greatly on the type of organic binder to be removed from the sand grains. More detailed information on organically bonded sand systems can be found in the article "Resin Binder Processes" in this Volume.

Wet Reclamation Systems

Wet reclamation systems were used for clay-bonded system sands in the 1950s, but are now used for silicate binder systems only. Silicate systems are very difficult to reclaim by dry processes and are impossible to reclaim in thermal systems. This is because silicate is an inorganic system that melts rather than burns in the furnace.

The complete system includes lump-breaking and crushing equipment, an attrition unit, wet scrubber, dewatering system, and dryer. The systems require about one pound of water per pound of sand reclaimed, and in some cases the water can be discharged directly into municipal sewer lines. Most installations allow 100% reuse of the reclaimed sand, with makeup sand as the only new sand addition.

Dry Reclamation Systems

Many factors determine the degree of cleanliness required in a reclaimed sand. These factors include the type of resin system used for rebonding, the sand-to-metal ratio, the type of metal poured, the condition of the reclaimed sand, the type of new sand used, and the ratio of new sand to reclaimed sand.

Attrition reclaimers break down the sand lumps to a smaller grain size. Some fines are removed, but the binder is not removed completely from the surfaces of the sand grains. In most cases, these units produce a sand that requires a higher concentration of new sand when the attritor is coupled with a sand scrubber, as described below.

Additional scrubbing is sometimes required, and there are basically two types of scrubbers: mechanical and pneumatic. Selection between the two types is primarily a question of wear, ease of maintenance, and energy consumption because the units provide comparable performance in terms of scrubbing action.

Pneumatic Scrubbing. Figure 23 shows one cell of a pneumatic scrubber. Sand is introduced by gravity at the top of the unit, and it flows down around the blast tube. High-volume low-pressure air from a turbine blower flows through the nozzle and lifts the sand up through the blast tube to the target plate. The sand grains undergo intense attrition in the tube by impacting on each other; further attrition occurs at the target as binder is removed from the sand grains. These fines and resin husks are then removed from the system by a classification dust collection system. Scrubbed sand falls from the target and is deflected to the next cell or is kept within the same cell for further scrubbing. The degree of cleanliness attained is determined by the retention time in the cells (controlled by the deflector plate) and the number of cells. Sand exiting the final cell should be screened to remove any foreign material that may be present in the refuse sand.

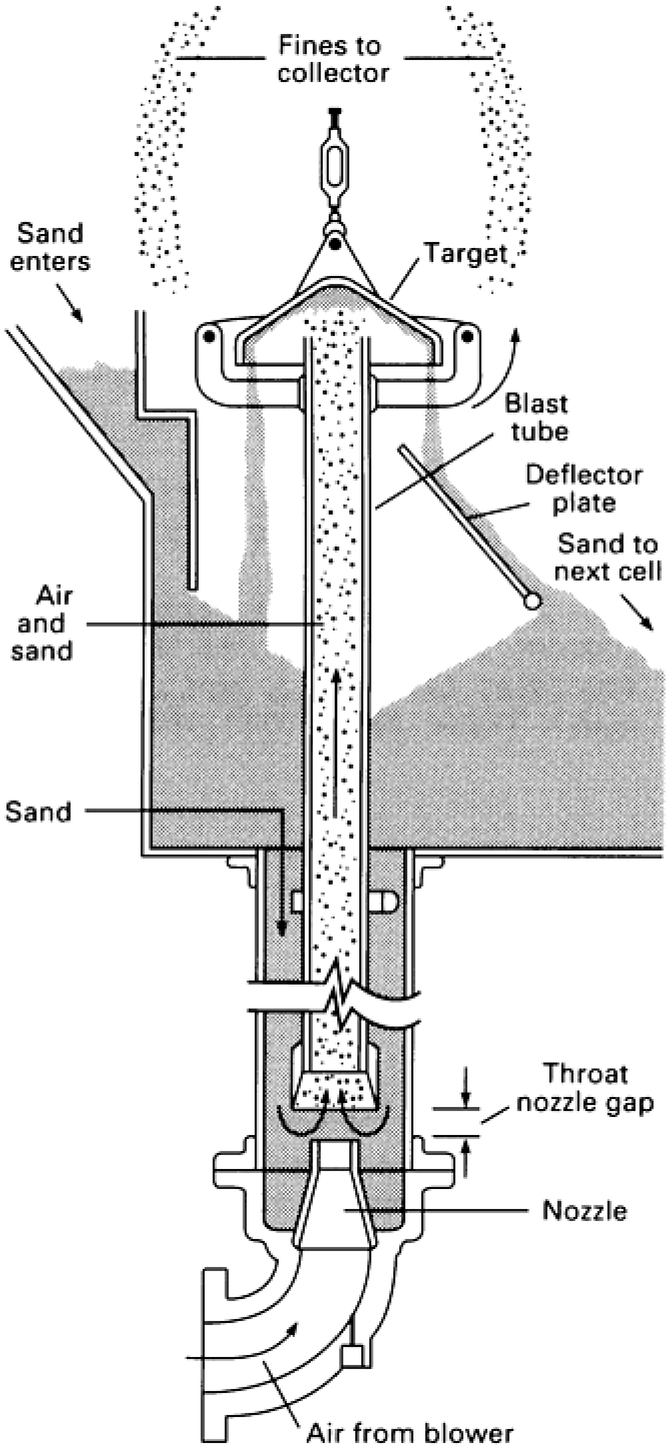

Fig. 23 One cell of a pneumatic scrubber

A conscientious maintenance program must be followed for these scrubbers. High-wear parts are the impellers, targets, and tubes. Improperly maintained units will not yield a consistent reclaimed product. The dust collection system is of equal importance and must also be properly maintained. Excess fines in the sand increase residual binder and decrease sand permeability.

Mechanical Scrubbing. There are two types of mechanical scrubbers: horizontal and vertical. Figure 24 shows a horizontal scrubber. Clean sand (crushed, with metal removed) is fed into the center of the unit and thrown against the target ring at a controlled velocity by the impeller. Some sand-on-sand attrition takes place, but the intense scrubbing

occurs at the target ring. The exhaust plenum surrounds the target ring to remove dust and binder husks. These units can be arranged in sequence for additional scrubbing.

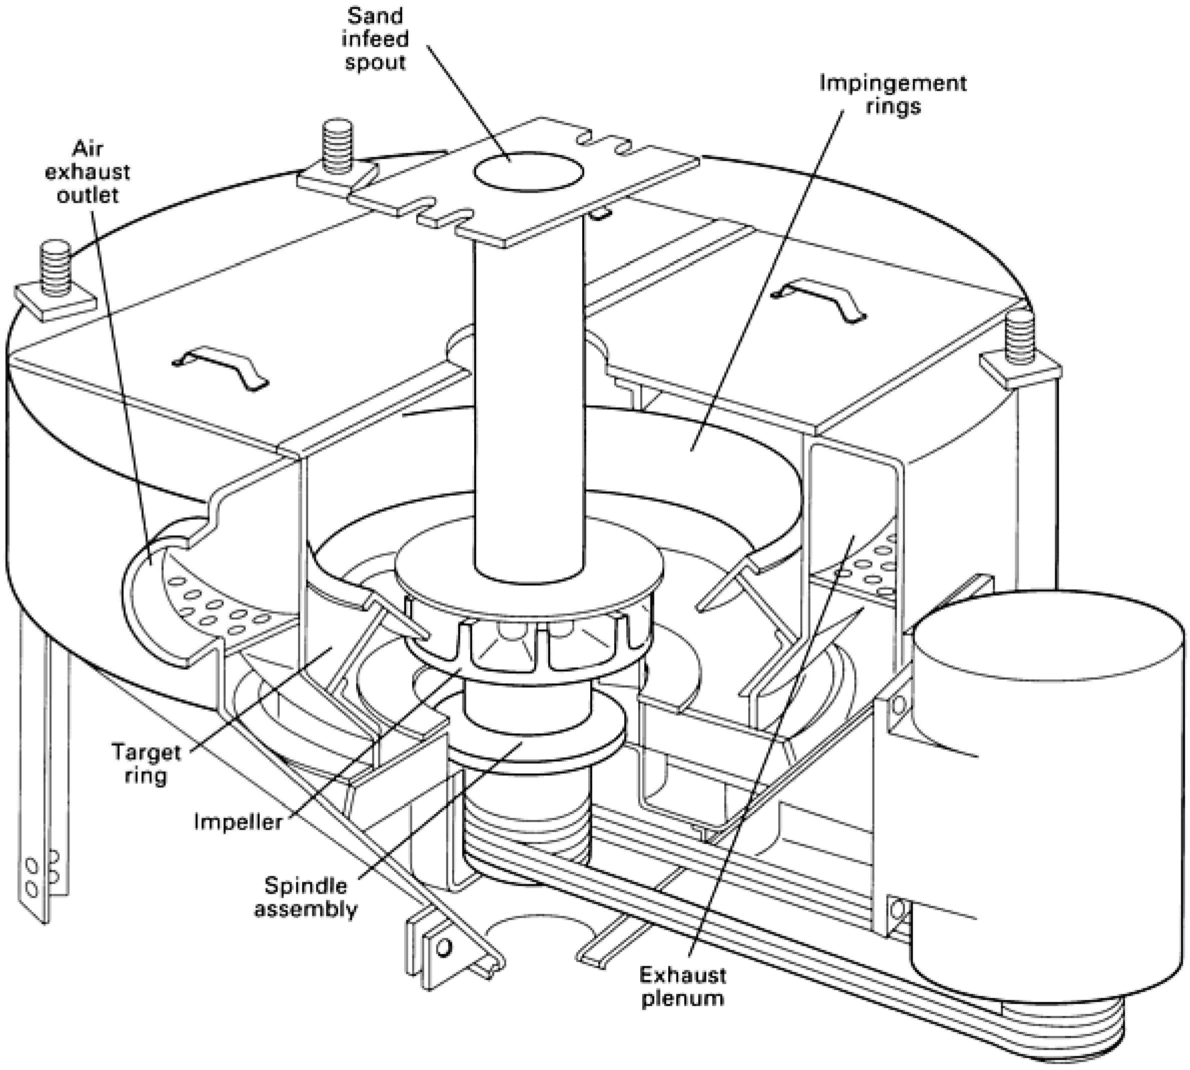

Fig. 24 Horizontal mechanical scrubber

Figure 25 shows a vertical mechanical scrubber. Sand enters the center of the impeller and is thrown upward at a target plate. Attrition takes place as the sand hits the target. The sand falls away and exits into an air wash separator, where the fines are exhausted from the sand. For additional scrubbing; this unit can also be operated in series, as shown in Fig. 25. As with pneumatic scrubbers, the impellers and targets are high-wear parts. The units must be properly maintained to yield a consistent product. The dust collection system must also be properly maintained.

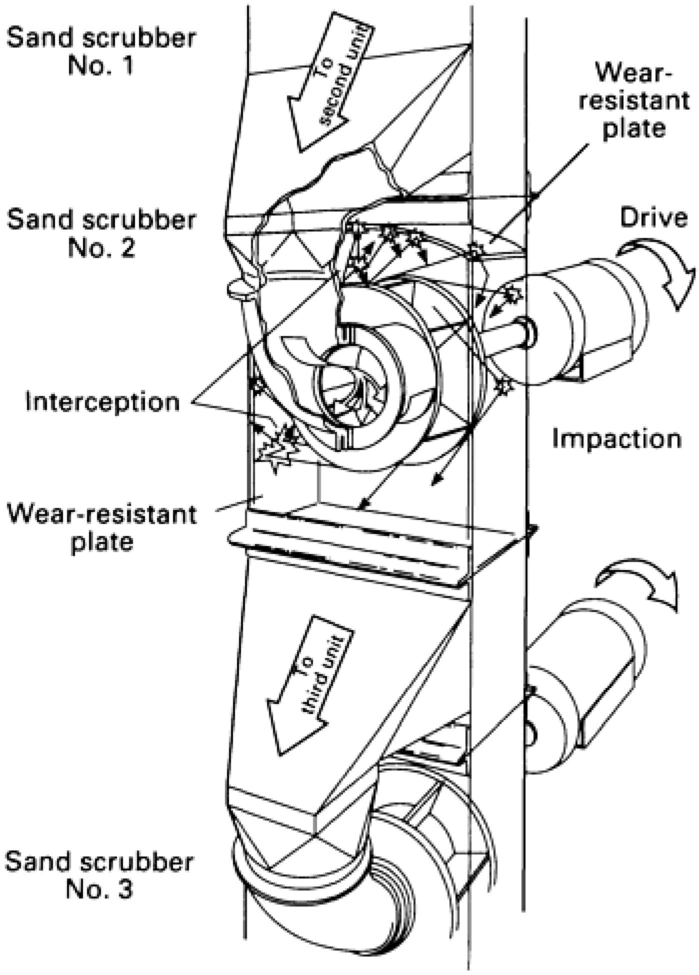

Fig. 25 Vertical mechanical scrubber

Process Controls. There are a number of tests that can be performed on the reclaimed sand from the scrubber. Two of the more important tests are loss on ignition and screen distribution. The loss on ignition test involves firing a 50 g sand sample at approximately 980 °C (1800 °F) to determine the amount of carbonaceous material burned off. These tests are good measures of the operating efficiency of the classifiers. A build-up of sand on the fine screens, such as 200, 270, and 300 mesh, is usually associated with an increase in loss on ignition, which is a problem that is most likely attributable to the classifier. An increase in loss on ignition without the accompanying shift in screen distribution will indicate that binder removal in the scrubber is low and that maintenance may be required on the unit. Most manufacturers supply a troubleshooting guide.

Temperature control is critical when working with chemically bonded sand. The heat of the reclaimed sand at the discharge point is affected by three factors. The first is the temperature of the sand at shakeout. This will vary with the sand-to-metal ratio, the type of metal poured, and the amount of lump reduction from the shakeout. Secondly, heat will be generated within the reclamation system itself. All the components will gradually heat up, thus increasing the temperature of the sand. The third factor that affects the temperature is the season of the year. In the summer, for example, there are more problems with hot sand. Therefore, based on these factors, a sand heater or cooler may be a necessary addition to the total system.

Blending of the sand from the scrubbers with new sand is very important. Blending is done to help replace the sand that is lost in the casting and reclamation processes and to limit the effects of residual binder on the sand grains. The sand should be measured and blended thoroughly to ensure that there are no concentrations that would cause undesirable effects on the castings. Most of the sand reclaimed from these units can be used in blends of 80% reclaimed sand to 20% new sand. Again, the exact ratio will be determined by the metal poured and the type of resin system used.

Thermal Reclamation

Thermal reclamation of chemically bonded sand is achieved by bringing the sand to a sufficiently high temperature over the proper time period to ensure complete combustion of the organic resin and material in the sand. If the proper temperature and atmosphere are not maintained in the unit, the organic resin will volatilize and send volatile organic carbons up the emission stack. This would be a violation of clean air standards. Currently, the two types of thermal units available for sand reclamation are rotary drums and fluidized bed furnaces. For these units to be cost effective, they must be operated 20 to 24 h per day and make maximum use of energy recuperation techniques.

The rotary drum has been in use since the 1950s for the reclamation of shell and chemically bonded sands. The direct-fired rotary drum is a refractory-lined steel drum that is mounted on casters. The feed end is elevated to allow the sand to flow freely through the unit. The burners can be at either end of the unit with direct flame impingement on the cascading sand; flow can be either with the flow of solids or counter to it.

In indirect-fired units, the drum is mounted on casters in the horizontal position and is surrounded by refractory insulation. Burners line the side of the drum, with the flames in direct contact with the metal drum. The feed end is elevated to allow the sand to flow freely through the unit, and in some cases flights (paddles connected by chains) are welded to the inside to assist material flow. The advantage of the rotary drum is its lower capital cost. Its disadvantages are high heat losses, use of moving parts at high temperatures, short refractory life, poor control of material flow, and poor atmospheric control.

Fluidized bed units have been in use for the reclamation of clay and chemically bonded sands since the 1960s. The fluidized bed calciner illustrated in Fig. 26 consists of a cylindrical, brick-lined, vertical combustion chamber. Sand that has been crushed is taken from the surge (feed) hopper by means of an adjustable, closed screw feeder and is fed into the unit. In the bottom, a hot sand bed is kept fluidized by the use of a combustion air blower. This blower controls the output of the unit and ensures the availability of sufficient air for combustion. The fluidized bed uses two sets of burner systems. The start-up burner brings the bed of sand up to operating temperature. After bed temperature is reached, the second system is energized. This system consists of gas lances positioned around the perimeter of the unit and inserted directly into the bed. It maintains the sand bed temperature to within ±8 °C (±15 °F).

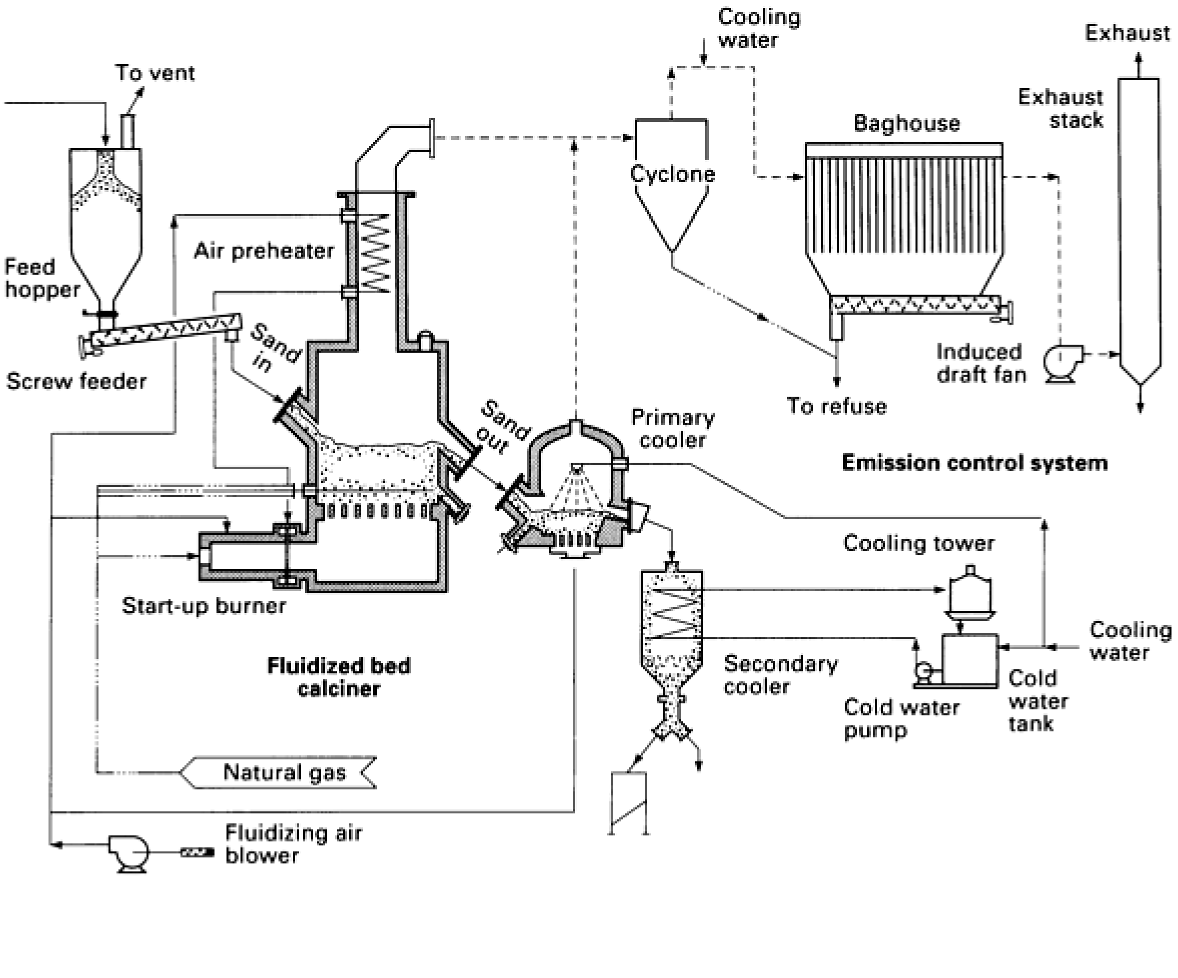

Fig. 26 Fluidized bed reclamation unit

The intense mixing of the sand and the hot gases provides for combustion of the hydrocarbons and residual resin at an appropriate temperature and retention time. The fluidized bed is heated by a postcombustion zone that ensures complete combustion of the waste gases without the use of an afterburner. After the postcombustion zone, an induced-draft fan pulls the dust and hot gases from the unit through the dust collector to ensure constant throughput requirements and efficient emission control. The sand then exits by gravity feed to the cooling and classifying systems. The disadvantage of the unit is its higher capital cost. The advantages are long refractory life, low heat losses (energy consumption), no moving parts at high temperatures, and control of material flow, temperature, and atmosphere.

Reclamation of Clay-Bonded System Sand

The reclamation of clay-bonded molding sand (green sand) allows the reuse of sand in any area of the foundry, including the core room. This practice has been common in Japan for the past 20 years, but has been adopted in the United States only recently. The process combines the different pieces of equipment described above. These reclamation plants must be designed with a total system approach to ensure proper integration of the various pieces of equipment.

After proper crushing and metal removal, the sand is transported to a storage or feed hopper to be metered into the sand calciner. Temperature control in the calciner is very important. If the sand in the unit becomes too hot, the clays in the sand will fuse to the sand grains; this makes clay removal difficult. If the temperature is too low, pollution problems will result.

After calcining, the sand is cooled to an appropriate temperature. Sand exiting the cooler is transported to a scrubber/classifier, as described for chemically bonded sand. In most cases, additional classification is required for proper mineral separation. The final product is then transported to the storage silo. More detailed information on the reclamation of clay-bonded green sand systems can be found in the article "Sand Molding" in this Volume (see the section "Bonded Sand Molds").

Process Controls. The most important tests for clay-bonded reclaimed sand are screen distribution, AFS clay, acid demand value (ADV), and pH.

The screen distribution test indicates the operating efficiency of the scrubber/classifier units.

The AFS clay test indicates the effectiveness of the postprocessing equipment in mineral separation.

The ADV-pH Test. Some take sands contain quantities of calcium carbonate. The carbonate registers in the ADV-pH test because the material is water soluble. After thermal treatment, the calcium carbonate converts to calcium oxide. This will result in a higher pH because the oxide is much more reactive, while the ADV number may decrease or remain the same.

Reclamation Effects on Base Sands (Ref 9)

As described in the article "Aggregate Molding Materials" in this Volume, a wide variety of sands are used in sand molding processes. Each differs in composition, particle size and distribution, purity, shape, and hardness. These properties are not only important to successful moldmaking and coremaking operations but also influence the reclamation process.

To determine the effects of reclamation on the surface area, shape, and yield of sand samples, a number of raw sands, without resin coating, were reclaimed through the use of a pneumatic scrubber (Fig. 23). The entire 135 kg (300 lb) sample was split through a large sand splitter before reclamation to obtain a representative sample. The representative sample of the before-reclamation sand was retained. After reclamation, the sand was weighed to determine the yield, and again the total reclaimed sample was split and the sample retained. The cyclone dust collector material was then weighed, split, and sampled.

The results demonstrated that the reclaimed sand was similar in screen analysis to the before-reclamation sand. Tables 1, 2, and 3 give the screen analyses of the before-reclamation sand, the reclaimed sand, and the cyclone dust collector sample, as well as the yield for silica, olivine, and chromite sands.

Figures 27(a) to (c) show the relationships between the before-reclamation sand weight distribution and the reclaimed sand and dust distribution. The vertical scales in Fig. 27 are not in percent retained on the screen, but in the weight retained on each screen (pounds per screen). The shaded areas show the amount of change in the total distribution. The greater the shaded area, the greater the change in the total sand retained on any individual screen.

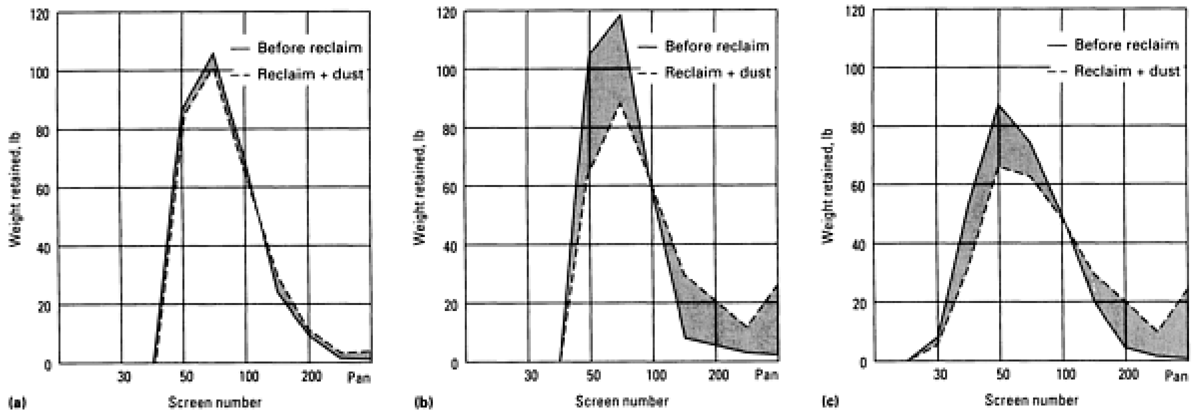

Fig. 27 Relationship between the before-reclamation sand weight distribution and the reclaimed sand/dust distribution for 135 kg (300 lb) silica (a), olivine (b), and chromite (c) sand samples. See Tables 1, 2, and 3, respectively, for screen analyses of these sands. Source: Ref 9

The rounding of angular sands due to reclamation results in a sand with less surface area and a sand that packs to a more dense configuration (less permeable molds). This is clearly the case for reclaimed olivine sands, which are extremely angular and have a higher hardness than silica sands. Olivine and silica sands are compared in Fig. 28. Figure 29 shows chromite sand before and after reclamation.

Melting Furnaces: Electric Arc Furnaces

Nick Wukovich, Foseco, Inc.

Introduction

THE ELECTRIC ARC FURNACE made its appearance as a production tool at the beginning of the 20th century. These early furnaces had capacities of 910 to 14,000 kg (1 to 15 tons). Currently, the electric arc furnace is regarded as one of the primary melting tools used by foundries and steel mills. Electric arc furnaces are used as melters and holders in duplex operations and as melting and refining units. This article will focus on the construction and operation of these furnaces and their auxiliary equipment in the steel metals industry.

Power Supply

The current applied to the electric arc furnace is supplied by a local electric utility company and passes through an electrical substation that is designed specifically for the furnace(s) to be supplied. A simplified diagram is shown in Fig. 1.

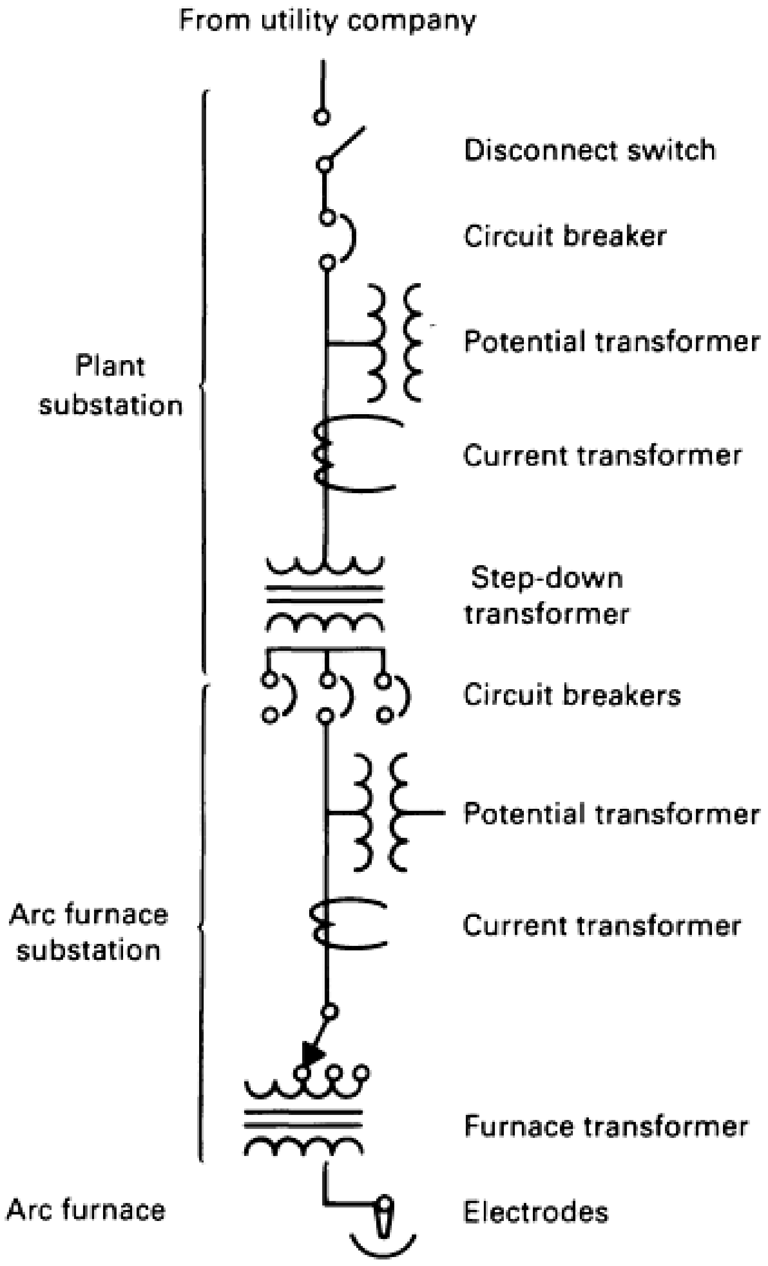

Fig. 1 Schematic of electrical network for the electric arc furnace.

The power supplied to the furnace during melting is provided by an electrical arc established from three carbon or graphite electrodes. During the meltdown portion of the heat, the three arcs or phases act as a single phase. Two arcs can strike the furnace charge and draw current without a current going to the third arc or electrode. Because of the type of scrap used and the arc lengthening and shortening that take place, there is a great fluctuation in the current during meltdown, which causes a significant variation in the electrical supply system. If the same power source is the supply for other plant power, a flickering of lights and voltage fluctuation will be noticed on machinery and electrical equipment. During the refining cycle or after meltdown, the arcs tend to stabilize, partially because of a slag cover on the liquid metal and the flatness of the bath. In addition, the arcs have been shortened to direct their energy in a smaller area.

A great amount of energy is produced during this meltdown and refining of ferrous metals. Controls for harnessing and directing the energy of the arcs are required in order to produce molten iron and steel in the electric furnace without destroying the furnace refractories. The energy requirements for melting various carbon levels in iron or steel are shown in Fig. 2.

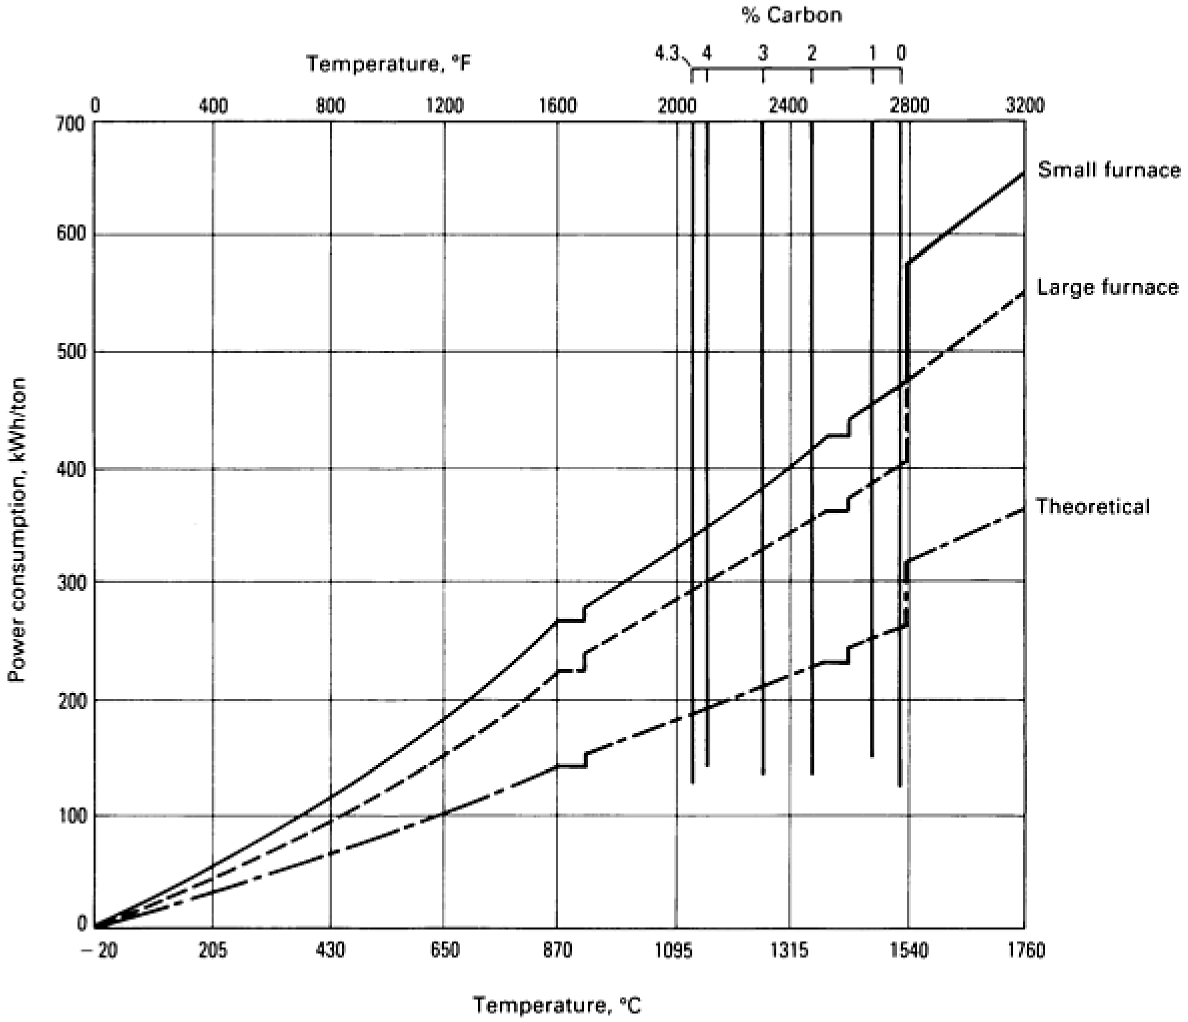

Fig. 2 Power consumed in melting iron and steel in the electric arc furnace. Values will vary depending on scrap, transformer, lining, and so on. The melting point of pure iron (0.0% C) is 1535 °C (2795 °F); of iron containing 4.3% C, 1130 °C (2066 °F).

Power Factor. The efficiency with which power is transferred to the melt is called the power factor. The power factor, PF, is the ratio of watts, W, divided by volt-amperes, VA:

$$PF = \left(\frac{W}{VA}\right).100$$

One method of measuring the average power factor over a period of time requires the use of two separate meters: a watt-hour meter to accumulate the useful power and a var-hour meter to accumulate the reactive power. The var-hours (in a given time) divided by the watt-hours (in the same time) will give the tangent of the power factor angle. The cosine of this angle is the power factor. The local utility company can be contacted for this information and for recommendations on the effect on energy usage.

Arc Furnace Components

The list of equipment associated with an electric arc furnace can be extensive. This list is assembled as if a proposal for the furnace has been made.

The locations for the furnace foundation and pits or elevated platforms are selected. Factors that also must be considered include the location of the furnaces in the plant, flow and access to raw materials, storage of melt materials, ladle construction, ladle preheating, crane runways, water, air, electrical lines, transformers, laboratory, and temperature equipment.

This list is not all-inclusive. Fume and dust collection equipment can be added, as well as used-refractory and slag removal equipment. For the melting portion, a supply of oxygen, hoses, pipe for oxygen blowing, gages, valves, thermocouples, and so on, will be needed.

The furnace itself is the primary concern after the location, cement work, and electrical supply have been chosen. The electrical system for the furnace includes the transformer and the control panel. Very small furnaces (<910 kg, or 1 ton) are not used in current production schedules; heats of these sizes are normally made in induction furnaces. Furnaces are described as supplying so many tons or pounds per heat under normal conditions, but larger heats can be made by modifying the furnace. This is done by stopping off the tap hole and raising the breast on the working and charge door (if the furnace has one).

The furnace is lined with refractories that determine the type of melting practice (acid or basic) that will be used (Fig. 3). Table 1 lists various refractory furnace materials used in acid and basic melting practices. Depending on whether the process is basic or acid, slag color may be sufficient to determine the iron oxide content of the slag, as shown below:

Color	**FeO, %**	**CaO/SiO_2**
Acid slag

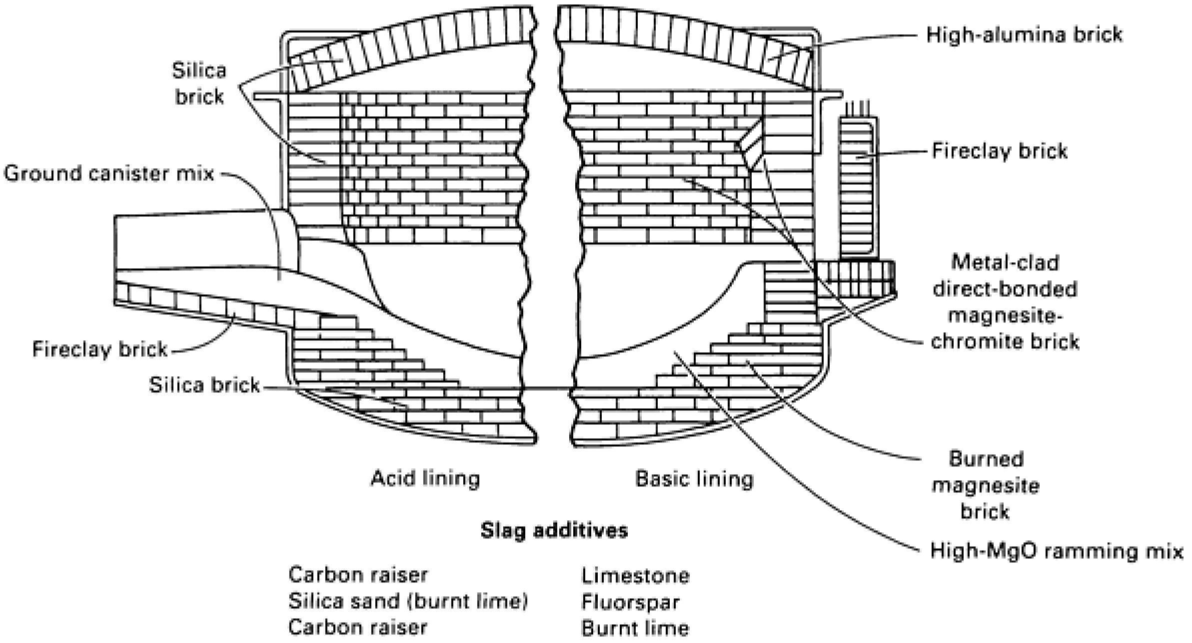

Fig. 3 Cutaway view of electric arc furnace showing the typical refractories used.

The silica content of basic slag can profoundly affect the melt. Silica ties up to two to three times its mole weight of basic slag formers, thus reducing basicity and the ability of the formers to desulfurize the steel. The effect of silica content on basic slag can be summarized as follows:

- SiO_2, P, and S--acid in nature
- Silica more acid than P or S
- CaO and MgO--basic in nature
- Reaction in basic slag when silica is excessive:

$$2CaO + SiO_2 \rightarrow 2CaO{\cdot}SiO_2$$
$$2MgO + SiO_2 \rightarrow 2MgO{\cdot}SiO_2$$
$$2CaO{\cdot}SiO_2 + 2MgO{\cdot}SiO_2 \rightarrow 2(CaO{\cdot}MgO{\cdot}SiO_2)$$

-

The size of the furnace can vary from 450 to 91,000 kg (0.5 to 100 tons) or larger. Typical furnace data are given in Table 2.

The electrode can be graphite or carbon. The graphite electrode has greater current capacity than the carbon unit for the same size electrode. Table 3 lists some data on electrode sizes, weights, and current capacities.

Table 3 Electrode sizes, weights, and current capacities

Diameter × length		**Approximate current capacity, A**	**Approximate weight of electrode and nipple**	
mm	**in.**		**kg**	**lb**
Graphite electrodes				
102 × 1015	4 × 40	1,800-3,300	13.6	30

The electrodes are supported on three separate arms and held to the electrode arm by a spring-clamped, pneumatically released electrode holder. On older furnaces, the electrode holder had a mechanical wedge-type clamp; on newer, larger furnaces, power-operated clamping devices are used. The electrode arms support the electrodes, holders, bus tubes, and transformer power cables. Smaller bus tubes and power cables can be used if they are air or water cooled.

The electrodes are raised and lowered by manual or automatic controls. These controls can be operated manually when the bottoms of the electrodes are raised to the roof or when electrodes are shifted. The electrodes are raised and lowered automatically during the melting and refining process (Fig. 4).

The furnace designer will make the electrode circle as small as possible to increase the speed of melting. This will intensify the heat in the delta section of the roof and can cause excessive refractory wear in this area. The use of water-cooling rings around the electrode ports can help to reduce this wear.

The electrodes should be vertical from all sightings around the furnace. When the electrodes are not vertical, the distance and arc flare on the sidewalls are not uniform, and a hot spot may cause the refractory wear to be greater in the areas closer to the electrodes. In addition, because the arc works between the electrodes and the bath, the current per phase can fluctuate (Fig. 5).

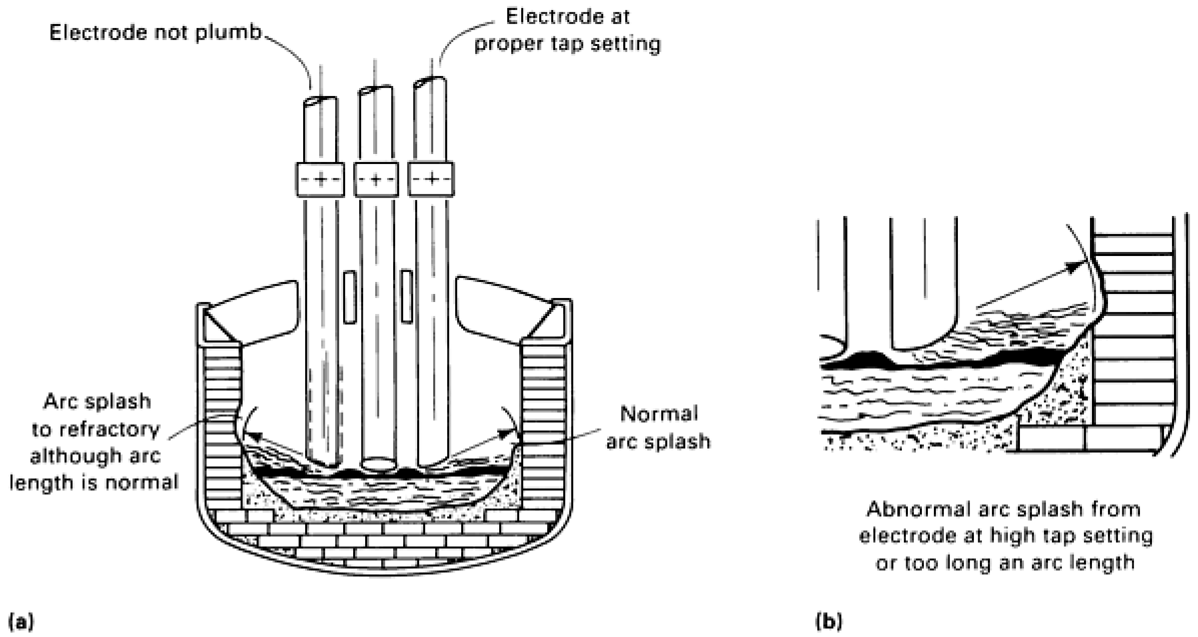

Fig. 5 Effect of arcs on furnace refractories due to electrodes not being vertical (a) on section left of center and (b) running too high a tap after meltdown.

The roof structure is arched to be self-supporting and to keep the greatest distance between the arc action in the delta section. Refractory roofs start with a roof ring that is designed as a channel or an angle beam that is rolled or cast into a ring. The ring generally has a water-cooling chamber on all or a portion of its height (Fig. 6). Newer designs of water-cooled roofs are cast in gray iron except for the delta section and the exhaust and oxygen lance holes on large roofs, and they are cooled by a network of steel pipes running throughout the structure. The delta section and electrode ports are usually constructed of a high-alumina refractory brick, rammed material, or precast shapes.

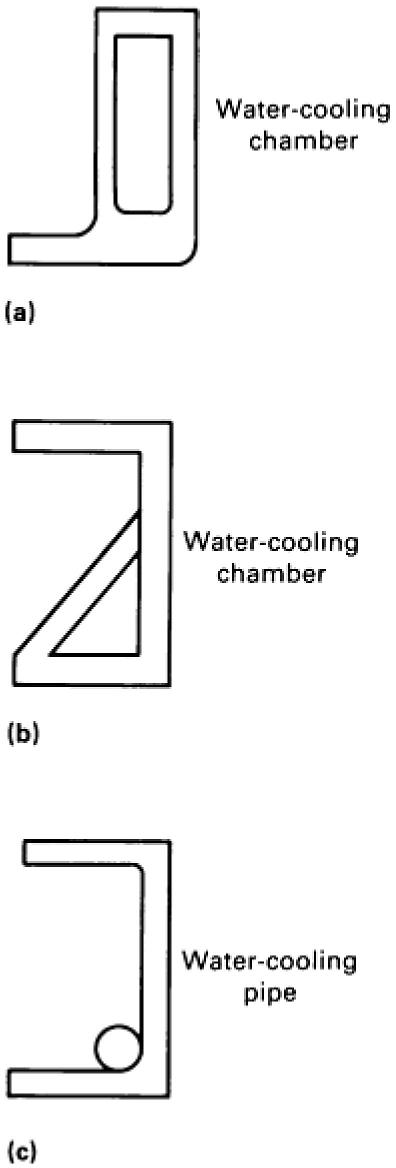

Fig. 6 Typical roof ring with cooling face. (a) Designed for use with special-shaped or cut starter brick. (b) Designed for use with skewback starter brick. (c) Designed for use with special-shaped or cut starter brick.

The roofs of all modern electric furnaces are designed for top charging. The roof and electrodes are raised several inches above the top of the furnace shell and swung to one side. The charge is dropped into the furnace, and the roof is swung back into place. The raising of the roof is raised by electrohydraulic systems. Schematics of roof-lifting devices are shown in Fig. 7.

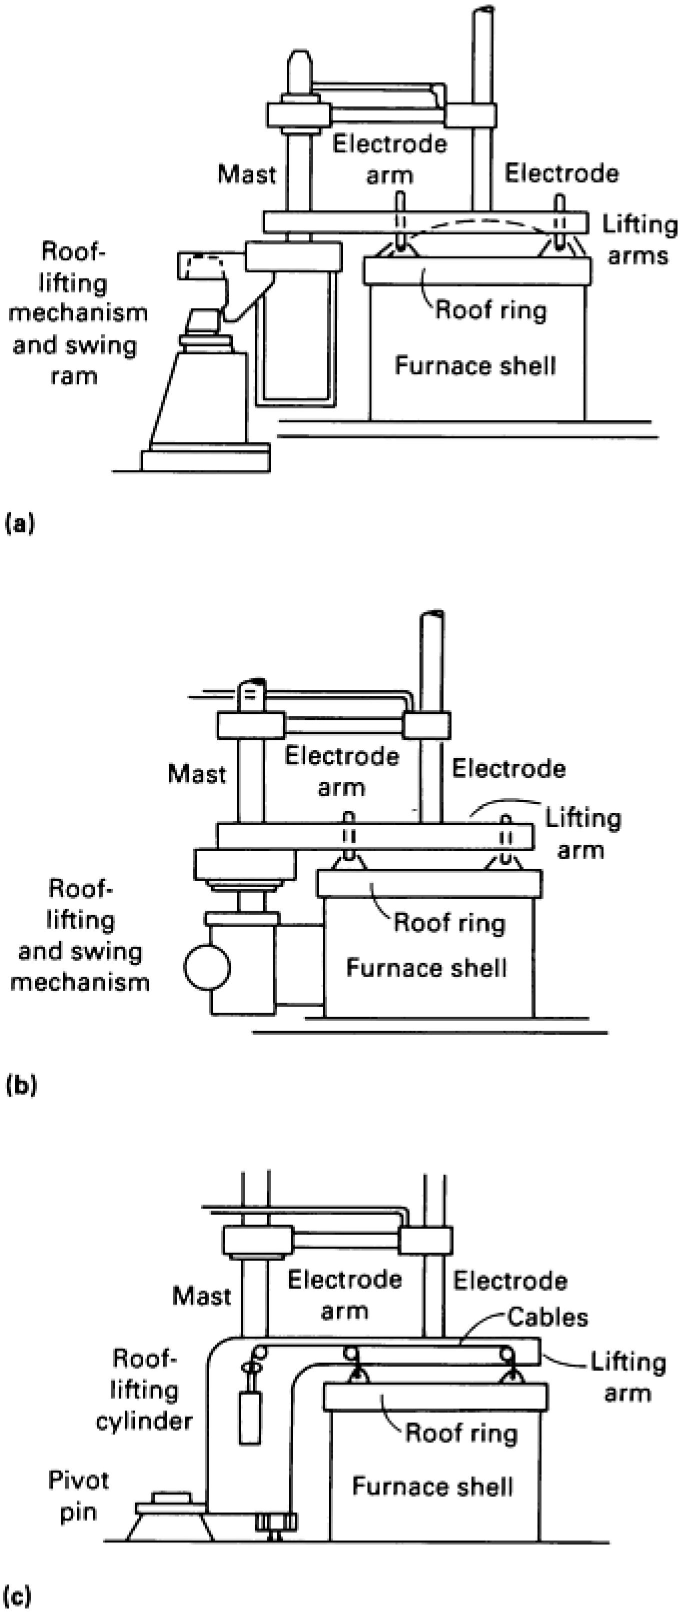

Fig. 7 Roof-lifting devices and swing mechanisms used on top-charging electric furnaces. (a) Roof-lifting device and swing arm mounted separately from furnace. (b) Roof-lifting device and swing mechanism attached to furnace. (c) Roof lifting by cylinder and cable/swing system by rotating roof with a kingpin arrangement.

Tilt Control. The electric furnace is tapped out by tilting the furnace into a position in which the metal and slag will run out of a hole above the slag line in the furnace wall down into a spout and into a ladle. Tapping of the furnace requires

that the roof and electrodes remain attached to the furnace shell; therefore, safety locks or stops are found welded to the shell and roof ring. The tilting mechanism can be mechanical for very small furnaces or can be motor driven (either by a screw pitman or a rack-and-pinion mechanism) or hydraulic, and it has rockers attached to the furnace and rails attached to the foundation. Emergency equipment is usually provided to pour the heat from the furnace in case of a power failure.

The furnace shell is typically made of carbon steel sections that are rolled and welded to the diameters listed in Table 2. The diameter and height define the furnace size. The furnace bottom is formed and welded to complete the pot. The shell will have door openings cut into it and a cooling frame welded around the door. The door-lifting supports will also be welded onto the shell. The furnace rockers and other lifting equipment attachments are welded onto the shell. With the rockers and door aligned, the spout opening is cut out of the shell and the spout frame attachment welded onto the shell. To ensure that the furnace is properly grounded, straps, rods, or mesh is attached to the bottom on the inside and ground on the outside prior to lining of the furnace. The choice of refractories will depend on the melting practice selected (Fig. 3 and Table 1). New furnaces being built in the 1980s have seen the use of water-cooled panels in the furnace sidewalls above the slag line (Fig. 8).

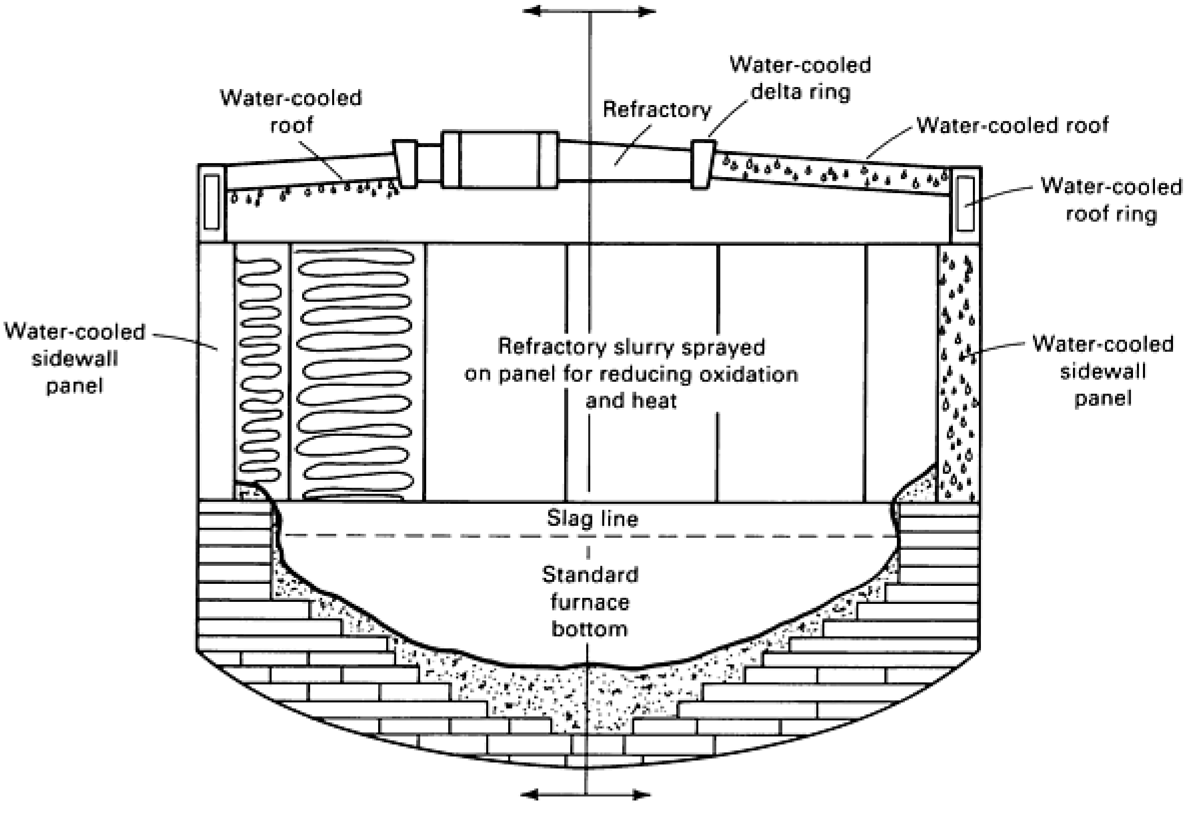

Fig. 8 Furnace design incorporating a water-cooled roof and upper sidewalls. The location of the water-cooling passages depends on manufacturer's suggestions.

Spout and Tap Hole. The length and shape of the furnace spout have been a source of controversy. The melter and metallurgist want the shortest possible spout, while the design engineer is confronted with a network of electrodes, crane cables, pit dimensions, and ladle and tap hole dimensions needed for positioning the ladle in order to obtain a fast and smooth tap from the furnace, using an acceptable spout.

New designs and changing the locations of tap holes may reduce the physical and mechanical problems encountered with the spout. One of these alternatives is the side slide gate spout (Fig. 9), and another is eccentric bottom tapping with the use of a slide gate (Fig. 10).

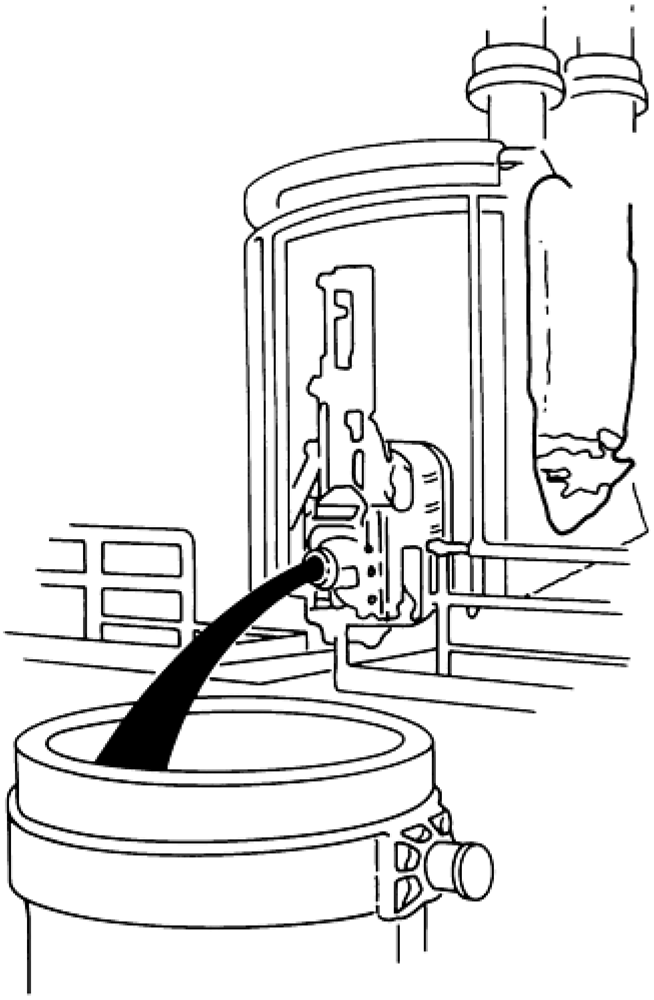

Fig. 9 Furnace slide valve used to hold back slag.

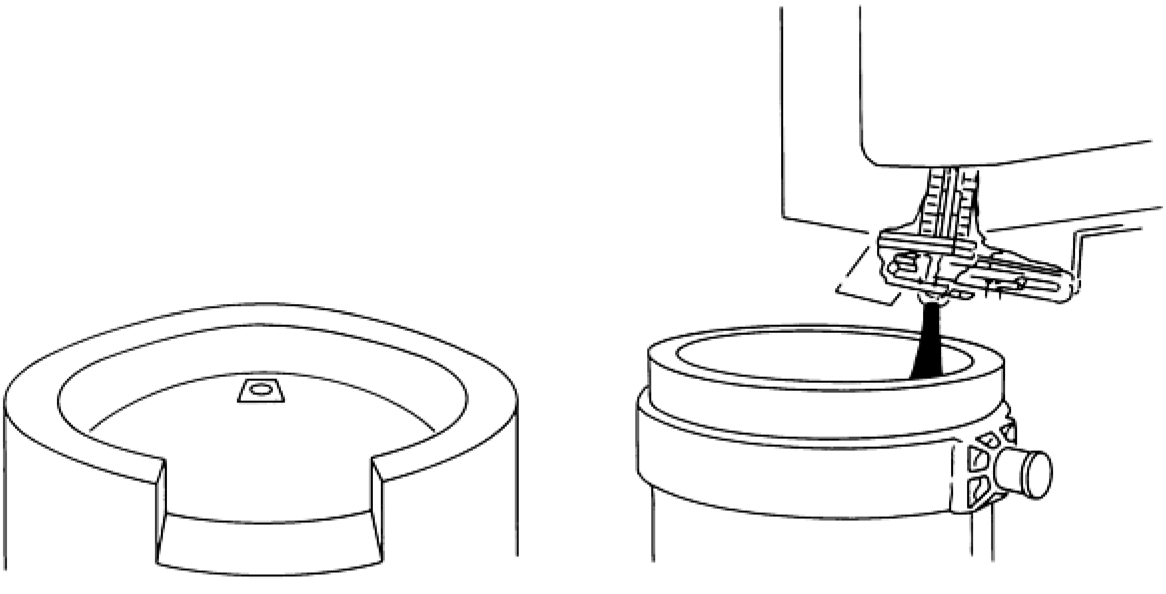

(a) (b)

Fig. 10 Eccentric bottom tap hole furnace (a) with slide gate attached to furnace bottom (b).

Tap-Out and Back-Slagging Pits. The design of the furnace pit should include sufficient depth for the slag boxes, and along with this depth, provision must be made for preventing ground water from entering the pit. Sump pumps are needed to minimize the presence of water and to ensure an environment that is safe from steam explosions. The length and width of the pit should be sufficient to allow movement of the ladle; this is necessary if the furnace slag is to be kept out of the ladle so that ladle metallurgy or secondary refining can be done following tap out.

Water-Cooling System. Water cooling of the furnace is becoming common practice. Before this innovation, water cooling was used on:

- Electrode holders, arms, and clamps
- Roof rings and electrode rings in the delta section
- Around the door
- Cooling panels positioned on the outside of the furnace to cool the furnace wall refractories

Preheat and Furnace Scrap Burners. Preheating scrap with natural gas or flue gases helps reduce the electrical cost of melting a charge. On the electric furnace, this preheating may also help stagger furnace operation to keep electrical demand peaks to a minimum.

Furnace oxygen/natural gas burners can help melt the charge and reduce electrical charges and electrode usage while shortening the melt time from tap to tap. Improper use of these burners can cause excessive oxidation of the heat and the electrodes and can reduce the life of the refractory lining.

Fume and dust collection at the electric furnace has been a required practice in melting during the last 25 to 30 years. The complexity of the fume and dust collection equipment varies from a simple fourth-hole connector to an entire separate room for the melting furnace in which the fumes and dust are collected and where the furnace is tapped into a ladle that is brought to the furnace and then removed through a dust protection door. Figure 11 shows typical dust and fume collectors.

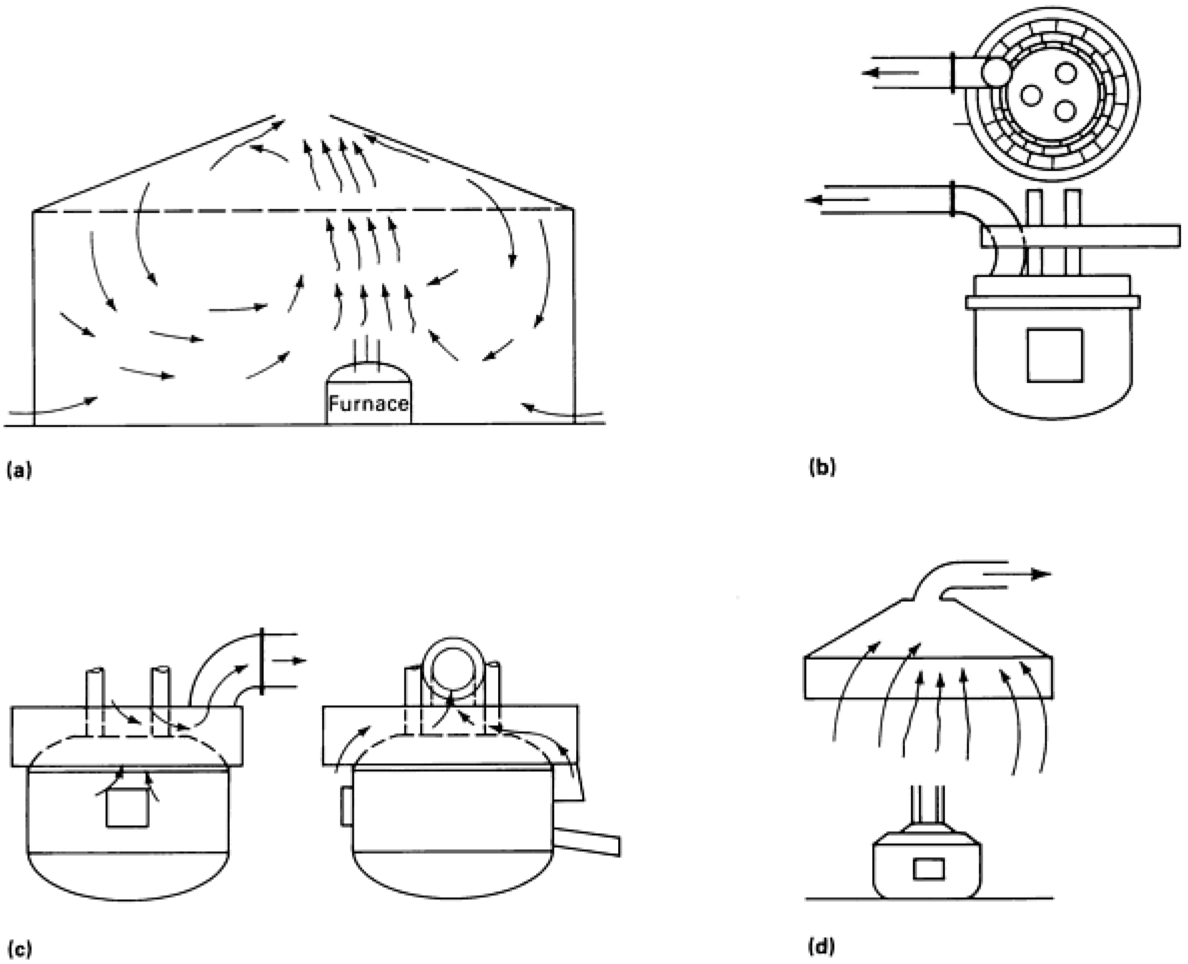

Fig. 11 Four methods of dust and fume control in electric furnaces. (a) Prepollution control ventilation for dust and fume removal. (b) Direct furnace dust and fume collection (both front view and top view are shown). (c) Total furnace hood for fume and dust collection. (d) Canopy hood for fume and dust collection.

The charge bucket is sized to fit within the refractory walls of the furnace, and is open at the top with a lifting bale that folds back or is removable from two trunions. The bottom of the charge bucket can be designed to drop the charge in one of several ways:

- The clam shell bottom is actuated with a trip lever
- The orange peel bottom, which is set in a stand to fold the leaves back and is tied with a rope, burns off when the charge bucket is placed into a hot furnace
- The preheat charge bucket uses a trip lever and after being charged with scrap is preheated to some temperature above 260 °C (500 °F) to up to 815 °C (1500 °F)

Figure 12 shows a typical charge loaded in two different types of charge buckets.

The operations control panel has seen many improvements in the last 20 to 30 years--from electrodes that were hand operated to electrode control motors to the current solid-state computerized technology. The heart of the melting operation of the furnace comes from this panel. The panel is usually set into the wall of the transformer vault next to the furnace where the operator can see his controls and observe the furnace operation. As shown in Fig. 13, the panel will typically have the following connections and instruments:

- A, clock, for time of day and logging actions taken at the furnace during the heat
- B, arc lamps, one for each electrode. The melter observes the intensity of these lamps indicating the arc action; from the lamp intensity and flickering, he can tell if the electrodes have a proper arc or if one or all are dipping into the bath
- C, megawatt meter indicating the total power being used by the three phases during melting
- D, megavar meter indicating total reactive power used during melting
- E, kilowatt-hour meter showing electrical energy consumed during melting
- F, voltmeter that reads actual phase-to-ground and phase-to-phase voltage; a selector switch allows the operator to control phase-to-ground or phase-to-phase voltage
- G, kilowatt-hour register for a readout of data on kilowatt-hour meter, which the operator should reset to zero

after each heat

- H, three ammeters connected to show the secondary current in amperes for each phase
- I, three rheostats for regulating the distance between the electrode tip and the charge material or bath
- J, three switches for the individual electrode raising and lowering control
- K, gang-control switch for raising and lowering the electrodes
- L, voltmeter switch with multiple positions
- M, tap-change switch with four to six positions that connect the wattmeter across the secondary phases to ground; newer panels may have additional features
- N, power circuit breaker that disconnects power to the furnace by remotely stopping the high-voltage furnace power supply; this must be open during off-load tap changing
- O, control switch that cuts all power to the furnace controls; this switch is turned off when the furnace is not in operation or when maintenance is being performed

Ladles may be part of the equipment assigned to the electric furnace, or they may be assigned to the pouring crew or the mold department. Nevertheless, the heat is not finished until the metal is removed from the furnace.

In foundries and steel mills, the ladles are refractory lined--usually with an alumina lining. More than 72% alumina is used if a clean steel low in inclusions due to ladle refractory is desired. In one application, magnesite or olivine is used in situations where the metal and slag will attack the refractory, as in Hadfield manganese steel.

In foundry operations, the type of ladle used varies. For holding ladles, bottom-pour, teapot, and lip-pour ladles are used. For pouring ladles, bottom-pour, teapot shanks, lip-pour shanks, and drum ladles are used. The ladle linings have changed from refractory lining to the one-heat type with insulating linings made of insulating board or of one-piece designs on shank ladles to eliminate preheating. The repeated use of the refractory reduces cast steel cleanliness and quality, but the board ladles have overcome this problem (Fig. 14).

Precision Weighing and Laboratory Testing Equipment

Scales. Charge and alloy scales are required for weighing the charge and alloy additions. The charge scale can be the standard beam scale type or the newer load cell type. These scales should be checked daily or weekly to ensure accurate weighing of the furnace melt. The alloy scale can be a small spring or a large balance beam type capable of measuring in pounds and ounces. These should be periodically checked for accuracy.

Quality Control Testing Equipment. The demands for faster and more accurate chemical analysis methods have spawned advancements in the spectrographic, x-ray defraction, and scanning electron microscope analysis of metals. Carbon, sulfur, alloy, and residual analysis is quick and accurate. Gas analysis, oxygen probes, and nitrogen and hydrogen analysis equipment is within the reach of the average melt shop to assist in quality control. Temperature control immersion thermocouples that are easy to use and recorders that are accurate to within 3 or 6 °C (5 or 10 °F) are available.

Scrap and Alloy Storage

Purchase scrap, shop returns, and alloys should be stored in a covered area. Wet scrap will produce small errors in weight and increase the gas content of the melt. Purchase scrap should be stored by size and the density of its bulk. Scrap should be stored according to specification or alloy content. Alloys and melt additions, that is, slag formers, fluxes, and deoxidizers, should be organized by usage.

Acid Melting Practice

The melting operation from charge to tap out will vary, depending on the type of charge materials and alloy additions used to produce steel in the acid melting practice. The furnace lining will be made from silica or alumina refractories. These refractories determine the type of slag generated during melting, along with the dirt or silica sand included in the charge. The acid practice is a fast oxidizing operation that does not remove phosphorus or sulfur from the melt. Therefore, charge materials with low phosphorus and sulfur levels should be selected in order to meet the final chemical analysis of the steels produced.

The acid melting practice is selected for the following reasons:

- Flexibility in producing small quantities of steel to various chemical compositions
- Lower refractory costs due to the initial cost and the refractory life
- Lower power consumption as compared to a two-slag basic practice
- Greater tonnage per unit of time

Acid Steelmaking

Steelmaking practices can be classified as partial-oxidation or complete-oxidation operations. These practices are differentiated by the amount of carbon removal during oxidation compared to the final desired carbon content of the melt. The advantages of acid melting practices utilizing partial oxidation are:

- Rapid steel production
- Good refractory life due to lower iron oxide content in the slag
- Lower power input
- Lower electrode consumption
- No recarburization required

The disadvantages include:

- Insufficient removal of gases
- Occasional poor fluidity due to oxides

- Occasional poor mechanical properties

The advantages of acid melting practices utilizing complete oxidation are:

- Low gas content
- Good fluidity
- Good mechanical properties
- Elimination of nearly all silicon and most of the manganese to a uniform base metal to which additions can be calculated more closely

The disadvantages are:

- Slower steel production
- Shorter refractory life due to higher iron oxide content in the slag
- Higher production cost

In partial oxidation, the charge carbon content is 0.05 to 0.15% above the finishing carbon content. If the carbon is above this level, a short blow with the oxygen lance is required. No slag-forming materials are added to the bath or the charge, and a fast melting practice is used. The rust and scale in the charge, along with the oxidation of the charge during melting, are sufficient to produce a light boil. When melting is complete, the carbon content will be about 0.25 to 0.35%, and the silicon content will be 0.15 to 0.20%; the actual value depends on the amount of oxidation from the charge and the oxidation during meltdown. By the time the laboratory report on the melted down carbon and manganese is prepared, the carbon content will have dropped another two or three points, and by the time the tap temperature is reached, the carbon will have dropped so that any alloy additions will bring the carbon content to the desired finishing range.

Slag additions are seldom required. The slag will be 3 to 5% of the charge weight because of silica dirt and refractory erosion.

Foundries using partial oxidation have minimal mechanical test properties to meet. They use a good grade of scrap, and their primary concern is the high production of molten steel from their furnace capacity. This practice is losing favor because of quality standards and product liability laws affecting the finished product.

Complete Oxidation. Most steel foundries using an acid melting method employ the complete-oxidation practice. This is because nearly all steel castings must meet minimum mechanical test requirements, along with magnetic-particle, visual, and radiographic inspection.

In this process, rapid melting is necessary to start a boil during meltdown, followed by oxidation with the use of the oxygen lance. Some melters add iron ore or mill scale to the charge to obtain a partial boil during meltdown. This boiling action or oxidation is accomplished with the following reaction:

$$C + FeO \rightarrow CO$$

Slag-forming materials are not added to the charge or the bath. Slag is formed from silica and dirt on the charge and erosion from the furnace refractories. A fluid black slag should be obtained by prudent additions of mill scale to ensure consistent silicon and manganese contents at meltdown.

Meltdown Period. The meltdown carbon content should be 0.20 to 0.40% above the aimed carbon level. The meltdown carbon level will drop 20 to 40 points after oxygen lancing to about 0.20% C. The silicon and manganese contents at meltdown will be about 0.13 to 0.20% and 0.25 to 0.35%, respectively. After oxygen lancing, the silicon content will be 0.02 to 0.10%, and the manganese content will be 0.07 to 0.15%. A vigorous boil (oxygen lancing) will eliminate carbon, most of the hydrogen, and small amounts of nitrogen from the bath; the elimination of oxygen depends on the carbon-iron oxide reaction during this period. The slag should be green when the boil is completed. After the boil, silica sand can be added to increase the slag volume and to reduce its iron oxide content. Lime is sometimes added to the slag to reduce

some of the iron oxide in the slag. Most slag formers are added to the bath during the refining period. Lime is sometimes added to thin the slag.

To minimize the loss of oxidizable elements--silicon and manganese--during melting, the percentages of these elements in the charge should be low. Overoxidizing of the heat should be avoided, and alloying elements should be added immediately before tap out.

The Refining Period. After decarburization, the boil will slow to a gentle roll, and recarburization and slag additions can be made if required. The recarburizers may be low-silicon, low-phosphorus pig iron, sorel pig iron, high-carbon steel, broken electrodes, petroleum coke, and so on, and occasional dipping of the carbon electrodes. The addition of carbon gives a carbon boil:

$$C + FeO \rightarrow CO + Fe$$

This helps keep the gas content down. Small additions of ferrosilicon and ferromanganese or silicomanganese are made to the bath at the end of this boil to hold the bath at the desired carbon level. This is known as a block. The heat should be tapped as soon as possible after this procedure and after the addition of any required alloying elements.

Deoxidation is required for preventing the reaction of dissolved oxygen and carbon in producing gaseous products such as CO or CO_2, into which hydrogen can find a nuclei and into which it can accumulate and form pinholes in the cast product. The first of these additions is silicon in the form of ferrosilicon or silicomanganese and then aluminum, a powerful deoxidizer. Special deoxidizers such as titanium and zirconium help tie up nitrogen, while complex deoxidizers containing silicon, aluminum, calcium, and other elements help modify inclusions.

Melting Heats and Raw Materials

The preceding discussion is a general description of the acid melting process. This section will discuss the heat and the materials used.

The charge will consist of 30 to 50% shop returns (heads, gates, and scrap castings) and 50 to 70% purchase scrap (plate, clean punchings, railroad wheels, and so on). The weight of each group of materials is recorded on the furnace log. The charge distribution into the furnace will normally be heavy scrap and casting on the bottom, followed by light scrap and purchased plate. Nonoxidizable materials such as nickel and molybdenum can also be added with the scrap charge. Carbon raiser additions to the furnace, if desired, are normally done before the charge is placed into the furnace. The roof is swung into place after an inspection of the furnace top to ensure that the scrap does not contact the roof ring and the roof is then locked down.

Melting should proceed as soon as the charge is in the furnace. The No. 1 tap will normally be used for meltdown. To protect the roof from excessive erosion, the No. 2 tap can be used to start the electrodes into the charge, followed by a change back to the No. 1 tap. This procedure will reduce roof wear in the delta section. A pool of metal will form on the bottom of the furnace as the electrodes burrow through the charge. Once the electrodes have reached this pool of metal, the remainder of the charge will be melted by radiation from the pool and the arc splash off of the electrodes. Rust and any iron ore added to the charge will help in forming a watery slag with the sand, eroded refractory, and slag remaining from the previous heat to form an oxidizing slag on the pool of metal produced from the melting portion of the heat. When the charge is completely melted, the tap is changed to No. 2 or lower to reduce arc splash on the furnace walls and roof. A laboratory sample is taken to determine the carbon level of the bath in preparation for the blow-down, or oxygen lancing.

The oxidation following meltdown should not begin until a temperature of at least 1540 °C (2800 °F) is reached. When heats containing chromium are to be made, temperatures of 1595 to 1620 °C (2900 to 2950 °F) should be reached before lancing to minimize the loss of chromium to the slag, from which it cannot be recovered. Depending on the amount of carbon, the bath temperature, and the amount of oxygen present in the bath, a decrease of 0.08 to 0.10% C will occur for each minute of oxygen injection. Generally, a steel pipe is used as the lance (ceramic-coated steel pipes are also available). The pipe must be clean and free of grease and oil. The blow time is recorded on the furnace log. After the oxygen blow, a lab sample is taken, and the heat is prepared for finishing and tap out.

When the lab test is returned to the melter, adjustments to the carbon level will be made by recarburizing or by additional lancing to the required carbon level. A final check on carbon is made, and the heat is blocked with ferrosilicon. This silicon addition will bring the bath silicon content up to about 0.10% or slightly higher to stop any remaining carbon boil. Final additions are made to the furnace to adjust the bath to the final chemistry. These additions may include ferrosilicon, ferromanganese, ferrochromium, ferromolybdenum, silicomanganese, nickel, or other alloys. Following these additions, the bath is heated for a few minutes to ensure that the alloys have melted and that the desired tap temperature has been attained.

The bath is quickly tapped out into a ladle and the refractory is preheated to minimize temperature loss and skulling from the refractories. Any alloy additions required to meet the final chemistry can be added to the ladle before tap out. The furnace should be tapped so as to hold back the furnace slag and to give a clean full metal stream. The furnace spout should be smooth, clean, and dry in order to obtain a full metal stream without a spray into the ladle.

Deoxidation of the steel in the ladle can be accomplished in several ways. One method is to add the aluminum as ingots to the bottom of the ladle just before tap out with other ladle additions. In another method, a steel bar with stars or doughnut ingots attached to it is plunged into the ladle when the ladle is one-half to three-quarters full. Small additions of less than the weight of an ingot are made with aluminum shot or wire clippings weighed into a bag and tossed into the metal stream at tap out. The amount of aluminum used for deoxidation ranges from 1.0 to 1.5 kg/metric ton (2 to 3 lb/ton); the higher carbon heats require less aluminum, while the lower carbon heats require more aluminum because of their higher oxygen levels in the steel. All alloy additions should be recorded on the furnace log with the wattmeter reading, along with any comments on the heat.

Other deoxidizers are often used to provide a complex deoxidation of the steel. These include titanium and zirconium to tie up nitrogen plus calcium and barium to modify inclusions. The type and amounts of these supplemental deoxidizers are determined according to the need and choice of each foundry.

After tap out, the furnace should be inspected for slag line and bottom erosion and should be patched with silica sand or a mixture of low-grade alumina and silica. This prepares the furnace for the next heat.

Loss of Alloys. In the acid melting process, alloying elements that are oxidizable are not completely recoverable, and care must be taken to estimate their loss when the additions are made to the bath and the ladle, as well as the loss while the heat is being melted. This loss of alloying element can be compensated for based on the data given in Table 4.

Table 4 Alloy loss in acid melting practice

Element	Loss from charge after blow, %	Loss when making addition, %	Required element weight to be added as furnace or ladle addition to make up desired weight, %
Manganese	80-85	20-30	125
Silicon	90-95	5	95
Nickel	0.0-2	0.0-2	100
Chromium	35-50	0.0-3	For less than 1% Cr, add 150% to charge; over 1% Cr, add $\frac{1}{3}$ after blow for a total of 120% for >4% Cr alloy.
Molybdenum	0.0-2	0.0-2	100
Niobium	0.0-2	0.0-10	100

Copper	0.0-2	0.0-2	100

Alloy Additions. The typical analysis of alloy additions made to the electric furnace is shown in Table 5. Because this is an incomplete list, alloy manufacturers should be consulted for an expanded list and additional detail with regard to residual elements, material size, and packaging.

Table 5 Analysis of alloy additions for the electric furnace

(a) Aluminum is not included in this list, but it is the primary deoxidizer used in steelmaking. The melter needs to understand that there are various grades of aluminum. For example, primary aluminum in the form of ingots and shot has a purity of 99%, while Grades I, II, III, and IV can contain 86-96% Al plus other nonferrous alloy elements. Care should be taken to purchase and add this deoxidizer on the weight contained and not to buy on lowest cost basis.

Basic Melting Practice

The melting operation from charge to tap out will vary, depending on the type of charge materials and the alloy additions used to produce steel in the basic melting practice. The lining of the furnace bottom and sidewalls is made of basic materials, such as dolomite, magnesite, chrome magnesite, bricks, and/or rammable materials. The roof is generally made of high-alumina brick, and the delta section is made of rammable material. Silica materials or materials high in silica will cause melting and refining problems and will attack the basic lining materials. The slag additions for basic melting are lime and high-lime-containing minerals.

The basic practice can remove phosphorus from the steel if a double-slag practice is employed, but the results and the percentage of removal have been disappointing. Sulfur removal with the basic practice can be very successful if a very high lime-to-silica ratio (2.5 to 3.5) is maintained in the refining slag or if a synthetic desulfurizer is used at tap out in the ladle. Because of the ability of slag to remove phosphorus (by oxidation) and sulfur (by reduction), lower-quality scrap can be used in the charge. A great portion of the oxidizable elements can also be recovered from the lime slag during refining.

For these reasons, the basic melting practice is the preferred method for the production of highly alloyed steels, stainless steels, high-manganese steels, and specialty alloys. However, the basic steelmaking practice will be slower than the acid melting practice when its abilities to reduce the phosphorus and sulfur from the steel and to reduce alloys from the slag are employed to capacity.

Basic Steelmaking

The basic steelmaking practice is divided into two parts: the oxidizing period and the reducing (refining) period. Both periods are important because of the reactions that take place during melting. Of the two, the reducing portion of the melt is of greater importance.

The charge for the foundry practice will consist of 30 to 50% shop returns, such as heads, gates, and casting scrap; the remainder will be 50 to 70% purchase scrap. Along with these materials, a carbon raiser and lime or limestone are added to the charge. The amount of carbon raiser added should be sufficient to increase the meltdown to 0.20 to 0.45% C over the finish carbon level. In addition to the charge to the furnace, a small amount of limestone or lime is normally added to the furnace bottom along with the recarburizer. (It is sometimes considered preferable to add lime to the middle or top of the melt.) Heavy scrap is first placed on the bottom, followed by light scrap and finally medium scrap on the top of the charge. Every effort is made to get the entire charge into the furnace at one time to reduce the time loss caused by delays in back charging the required weight into the furnace. When stainless steels are being produced, a greater portion of the chromium addition is held out of the charge to conserve chromium, to help keep carbon levels down, and to cool the bath after the carbon boil when temperatures may reach 1870 to 1925 °C (3400 to 3500 °F) to achieve concentrations of 0.02 to 0.08% C.

Because of the negative effect of silica in the basic practice, a conscious effort should be made to keep sand out of the charge. Oily and wet scrap should also be avoided in the charge materials to minimize gas pickup.

The oxidizing period will require the addition of lime to form a slag on the bath during melting until about 1.5 to 2.0% CaO is present in the charge. Once the charge has been melted and temperatures of 1540 to 1595 °C (2800 to 2900 °F) have been reached, the oxygen lancing can begin. If phosphorus is to be removed, another approach requiring a double-slag practice should be used.

The following conditions must be met to remove phosphorus from the melt during the oxidation period:

- Temperature below 1540 °C (2800 °F), because the process is reversible with high temperature
- High iron oxide content in the bath and the slag; the use of iron oxide in the early stages of meltdown is required as a source of oxygen to oxidize the phosphorus
- Low silicon and silica in the bath and the slag
- A high lime ratio to negate the effect of the silica in the slag; because this slag must also be fluid, fluorspar additions may be required. High concentrations of manganese oxides also hinder the satisfactory removal of phosphorus

The desired reaction for the phosphorus is:

$$2P + 5FeO + 3CaO \rightarrow 3CaO{\cdot}P_2O_5 + 5Fe$$

Tricalcium phosphate is formed in the slag and the bath; it must be removed to lower the total phosphorus content. This is accomplished by raking off the slag. Limited success is achieved in reducing the phosphorus content, as manifested by the film visible around the sidewalls of the bath following slag removal. This film may contain a major portion of the tricalcium phosphate remaining in the bath, which, if left in the furnace, allows for only minor phosphorus reductions and the reversion of phosphorus to the bath with higher temperatures.

After the oxidizing slag has been removed, a new lime slag must be added to the melt. Any oxidizable element lost to the first slag must also be added back to the bath during the reducing and final tap out.

In the single-slag process, oxygen lancing will remove silicon, carbon, manganese, and chromium from the bath, with manganese and chromium partially reduced from the slag in the reducing period. To minimize chromium loss, a high temperature is required before lancing; therefore, a starting oxygen lancing temperature of 1595 °C (2900 °F) is suggested.

The silicon and manganese contents after oxygen lancing will be between 0.01 to 0.05% and 0.03 to 0.20%, respectively, with carbons in the 0.10 to 0.20% range. An addition of ferrosilicon to bring the melt chemistry to 0.10% Si will stop the boil.

Reducing or refining of the heat follows the oxygen lancing of the bath. At this time, a reduction in sulfur can be made, or the practice can proceed quickly without adjusting the slag to reduce the bath sulfur. With the temperature of the bath increased after lancing, additions of lime or calcium oxide and fluorspar are made to the furnace to prepare for sulfur reduction and alloy recovery. Sulfur reduction depends on:

- A high lime-to-silica ratio in the slag, called the V-ratio
- High temperature
- Low oxygen content in the steel and slag

The reaction can be expressed as follows:

$$CaO + FeS \rightarrow FeO + CaS$$

This reaction is reversible. An increase in silica will reduce the availability of CaO to react and thus retard the reaction, while high FeO will limit the amount of sulfur that can be removed.

The slag in the basic melting practice is the key to the production of quality steel. The reduction of iron oxide by the use of coal, aluminum, graphite, or low-sulfur coke is often done to deoxidize the slag and to reduce the oxide content. With this deoxidation, manganese and chromium in the slag are returned to the bath.

After a check on the melt or bath chemistry, alloy additions are made to adjust the chemistry with ferrosilicon, silicomanganese, and ferromanganese, along with chromium, nickel, molybdenum, and other alloys if required. At tap out, final alloy additions are made to the ladle, and the heat is deoxidized with aluminum as the primary deoxidizer plus special deoxidizers as desired.

Melting Heats and Raw Materials

The following discussion is a brief review of the basic melting practice. A heat and the raw materials used will also be described.

The charge is placed into the furnace with the heavy scrap carbon raiser and limestone on the bottom, the light scrap in the middle, and the medium scrap on the top. Nonoxidizable materials such as nickel and molybdenum can also be charged into the furnace at this time. The roof is swung into place with an inspection of the top of the charge to ensure that the scrap does not contact the roof ring, and it is then locked down.

Melting should proceed as soon as the charge is in the furnace on the No. 2 tap to burrow a hole into the scrap, followed by a change to the No. 1 tap until the charge is melted. The initial use of the No. 2 tap will reduce wear on the furnace delta section.

A pool of metal will form on the bottom of the furnace as the electrodes burrow through the charge. Once the electrodes have reached this pool, the charge will be melted by radiation from the pool and the arc splash off the electrodes. Rust on the scrap, along with oxidizing scrap from the melting charge, will react with the lime and eroded refractories to make a watery slag. When the charge is completely melted, additional limestone or lime is added to the furnace to increase the volume of slag for an estimated $1\frac{1}{2}$ to 2% of the charge weight.

At this point, the melt can be processed as a single-slag heat without phosphorus removal, or it can be processed as a double-slag heat where phosphorus removal is attempted. This procedure is described earlier in this section. If a double-slag practice is chosen, the oxygen content of the slag and the bath must be increased while holding down the bath temperature. The old slag must then be removed and a new slag built on the bath. Oxygen lancing can be done before or

after this stage to lower the carbon content to the required level, or it could have been done to increase the oxygen content of the bath.

Reducing the Heat. The slag must be reduced in iron oxide, and because only a small amount of slag has been added to the furnace up to this point, another $1\frac{1}{2}$ to 3% of charge is added to this slag, along with a measured amount of fluorspar. This additional slag volume will dilute the iron oxide content in the slag to reduce the oxygen content and to improve the ability of the slag to retain sulfur. A deoxidizer such as coke, coal, or aluminum can be added to the slag if desired to speed the reaction. Sulfur removal and alloy recovery are the primary concerns while the bath is being heated in preparation for finishing. If a specific sulfur level is needed, further laboratory testing and lime additions may be required for achieving a higher lime-to-silica ratio, along with fluorspar to thin the slag. If the sulfur level is acceptable, the heat, blocked with ferrosilicon and alloy additions, is finished, and a temperature check is made prior to tap out.

The melt is tapped into a ladle that has been preheated if it is refractory lined, or it is tapped into a cold ladle liner of insulating basic material or boards. Any further alloy additions are made to the ladle prior to tap out. The furnace should be tapped to hold back the slag and to provide a clean full stream. The furnace spout should be clean, smooth, and dry to obtain a full metal stream without a spray into the ladle.

An additional opportunity for sulfur removal presents itself at this point. A desulfurizing agent can be added to the ladle during tap out to reduce the sulfur content by 20 to 50%.

Deoxidation of the steel should be accomplished in the ladle; this can be done in several ways. One method is to add the aluminum as ingots to the bottom of the ladle and tap onto it. Another method is to attach stars or doughnuts of aluminum to a steel rod and plunge the rod into the ladle when the ladle is one-third to three-quarters full. Small additions of aluminum should be in the form of shot or wire clippings weighed and placed in a bag and thrown into the stream while tapping. The amount of aluminum used for deoxidation is about 1.0 to 1.5 kg/metric ton (2 to 3 lb/ton), although higher carbon heats require less and lower carbon heats require more because of the oxygen levels in the steel.

After tap out, the furnace should be inspected for slag line and bottom erosion and then patched with dolomite or other materials. Patching is done by shoveling in or gunning on the patch material. This prepares the furnace for the next heat.

Loss of Alloys. A wide range of melting techniques are used in the basic melting practice by foundries--for example, single slag, double slag, deoxidation of slags, desulfurization, and alloy production. Therefore, the individual foundry and melter will need to adjust the recovery and additions to meet particular needs and final chemical analysis based on experience.

New Technology

The direct current arc furnace has been introduced into steel mills and should be changing the arc melting practices in the future from the three-phase arc furnace to the single-arc direct arc practice (Fig. 15). The direct current arc furnace has not made its appearance in the steel foundry yet, and it has been put into operation in only a few steel mills.

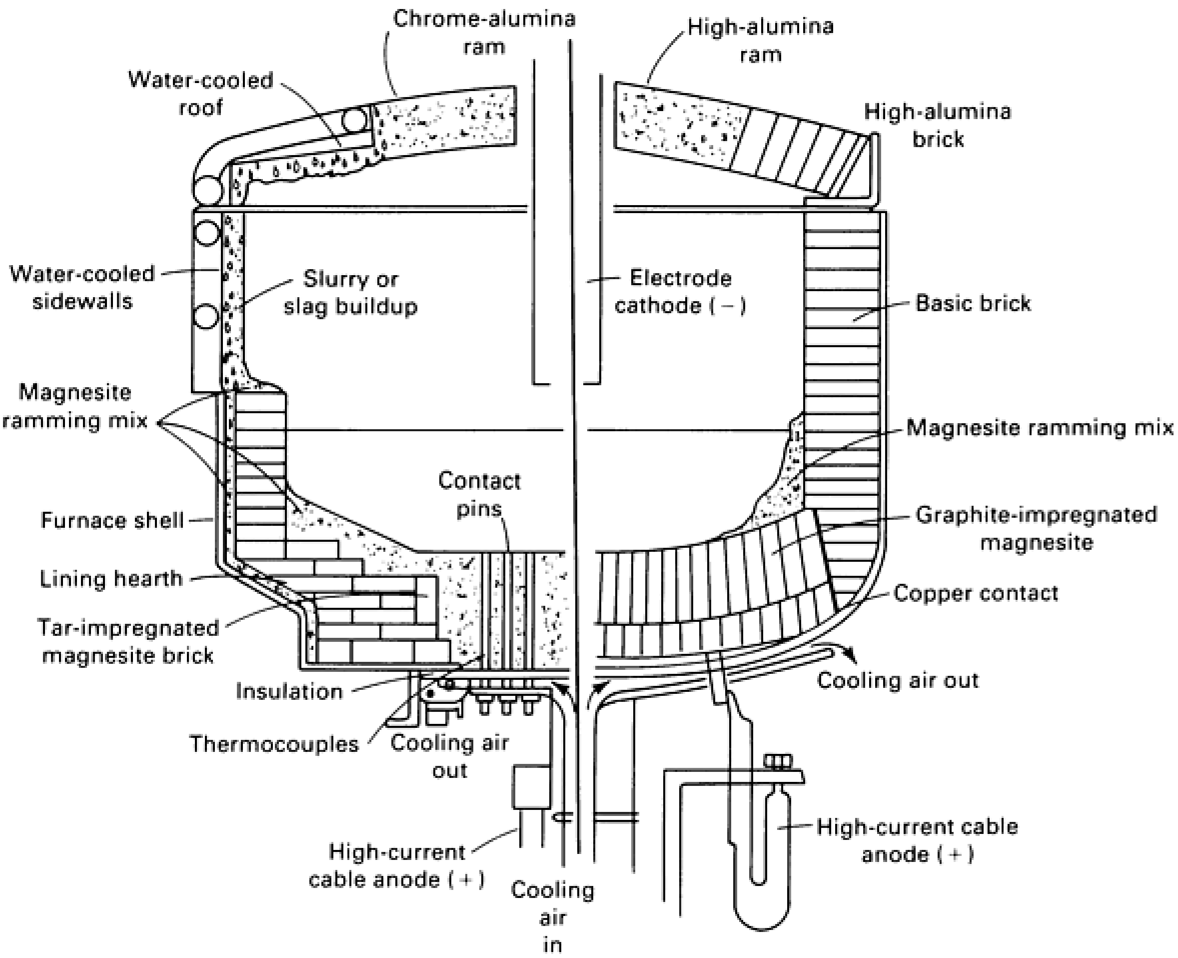

Fig. 15 Cutaway view showing the basic components of a direct current arc furnace.

Those steel mills using the direct current arc furnace have lower electrode consumption and slightly lower operating costs. The direct current arc furnace was developed for two main purposes:

- An alternative to the conventional three-phase ac electric arc
- For the final stage in practices for melting prereduced material for the production of liquid iron

Since its development, this furnace has been used in the production of ferrotungsten, ferrosilicon, carbon, low-alloy steel, and stainless steels.

An existing three-phase furnace can be modified into a direct current arc furnace by the addition of a thyristor converter to its controls and the incorporation of a water-cooling system. Modification of the existing furnace requires the removal of the two outboard electrodes and the positioning of the center electrode to the center of the roof. It has also been shown that a larger electrode will require additional hardware to conduct current and to provide support. The electrode is the cathode in this system. In the three-phase system, current passes from one electrode to another through the charge; in the direct current system, the current passes from the electrode through the charge or bath to the cathode located at the bottom of the furnace.

The current from the bottom of the furnace passes through graphite- or tar-impregnated refractories to a copper base plate to the outside cables, or through pins of steel connected to outside current cables (Fig. 15). The heat distribution in the direct arc is 360°, while in the three-phase furnace, the heat pattern is off the edge of the electrode, causing localized refractory heating and erosion. The electrode usage per ton of steel is reported to be 50 to 60% of a conventional three-phase furnace.

The shell bottom of the furnace needs to be modified to accept the current-carrying loads that will result and should be insulated to protect it from shorting out. Thermocouples and cooling air will be required for monitoring overheating or loss of current-carrying ability in the bottom. The furnace foundation may also require modification to accept power cables and air cooling ducts.

Patching of the refractory is limited to the slag line, sidewalls, and roof. Noncurrent refractories on the bottom will cause poor conduction. Another consideration to be made by the melter is the heat sequence, because direct arc melting requires long start-ups or a heel of metal over the bottom to make electrical contact.

Ladle metallurgy has been introduced for the removal of sulfur and for the micro-alloying of metals.

Argon stirring of heats of steel in ladles as a method to float out some inclusions found in the heat at tap out is becoming more popular. The need for dry gas is very important because argon containing more than 5 ppm of moisture will induce gas pickup.

Calcium wire injection has recently been introduced to modify inclusions in steel along with argon stirring to improve steel cleanliness.

Introduction

INDUCTION FURNACES have gradually become the most widely used means for melting iron and, increasingly, nonferrous alloys as well. The key to the ready acceptance of this type of furnace has been its excellent metallurgical control coupled with its relatively pollution-free operation.

Currently, induction furnaces are available in a wide variety of sizes. Coreless units range in capacity from a few pounds, favored by the precision cast metal producers, to 68 Mg (75 tons) powered at 21,000 kW. Channel-type units have been built with a capacity of over 180 Mg (200 tons) powered at 4000 kW per inductor.

In the past, large, high-powered induction furnaces operated at 60 Hz, the frequency of the incoming power. Thanks to major breakthroughs in electronic, solid-state frequency conversion techniques, it is now possible to build a highly efficient furnace operating at medium frequencies (70 to 5000 Hz). Coreless units of 7000 kW in power for ferrous metals and 4000 kW for nonferrous metals have been built in medium frequencies, and even channel-type units have recently been equipped with solid-state, medium frequency power supplies.

The advantage of medium frequency is that the power density of the furnace system can be increased substantially without increasing its size. Much more melting power can be applied, while maintaining the stirring action at desirable levels. Heat losses, which are a function of furnace size, are reduced, and overall efficiency of the system is improved. The furnace is also easier to operate because a single potentiometer will typically provide efficient and stepless control of the power.

Types of Furnaces

There are two classifications of induction furnaces: coreless and channel. Cross sections of each are shown in Fig. 1 and 2.

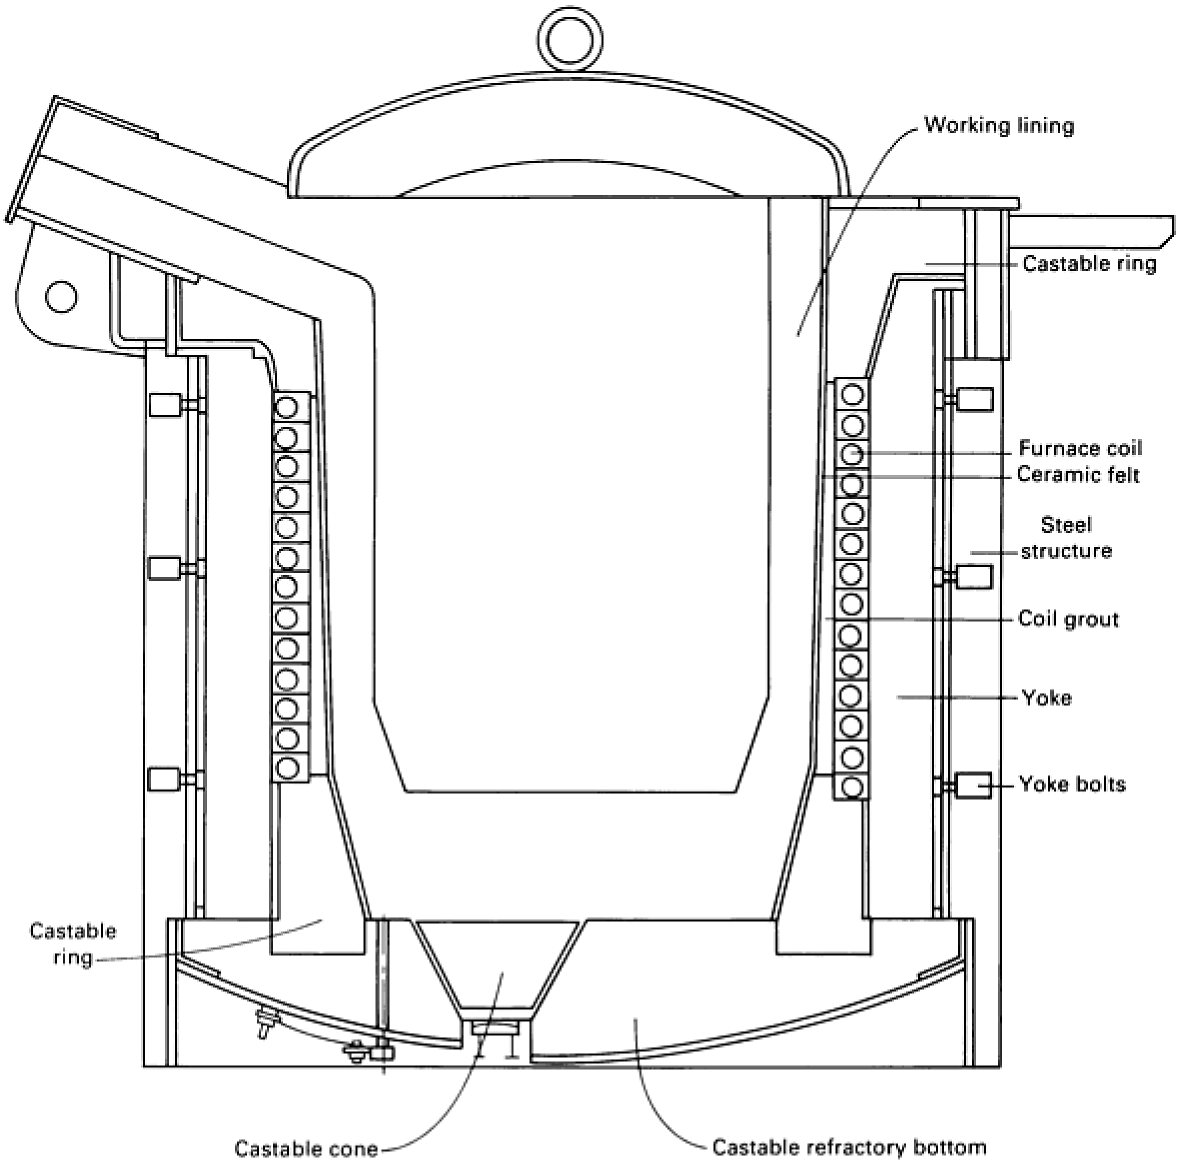

Fig. 1 A cross section of a coreless-type induction furnace showing water-cooled copper induction coil and key structural components. The entire molten metal bath (which serves as the secondary) is surrounded by the coil (the primary) that encircles the working lining.

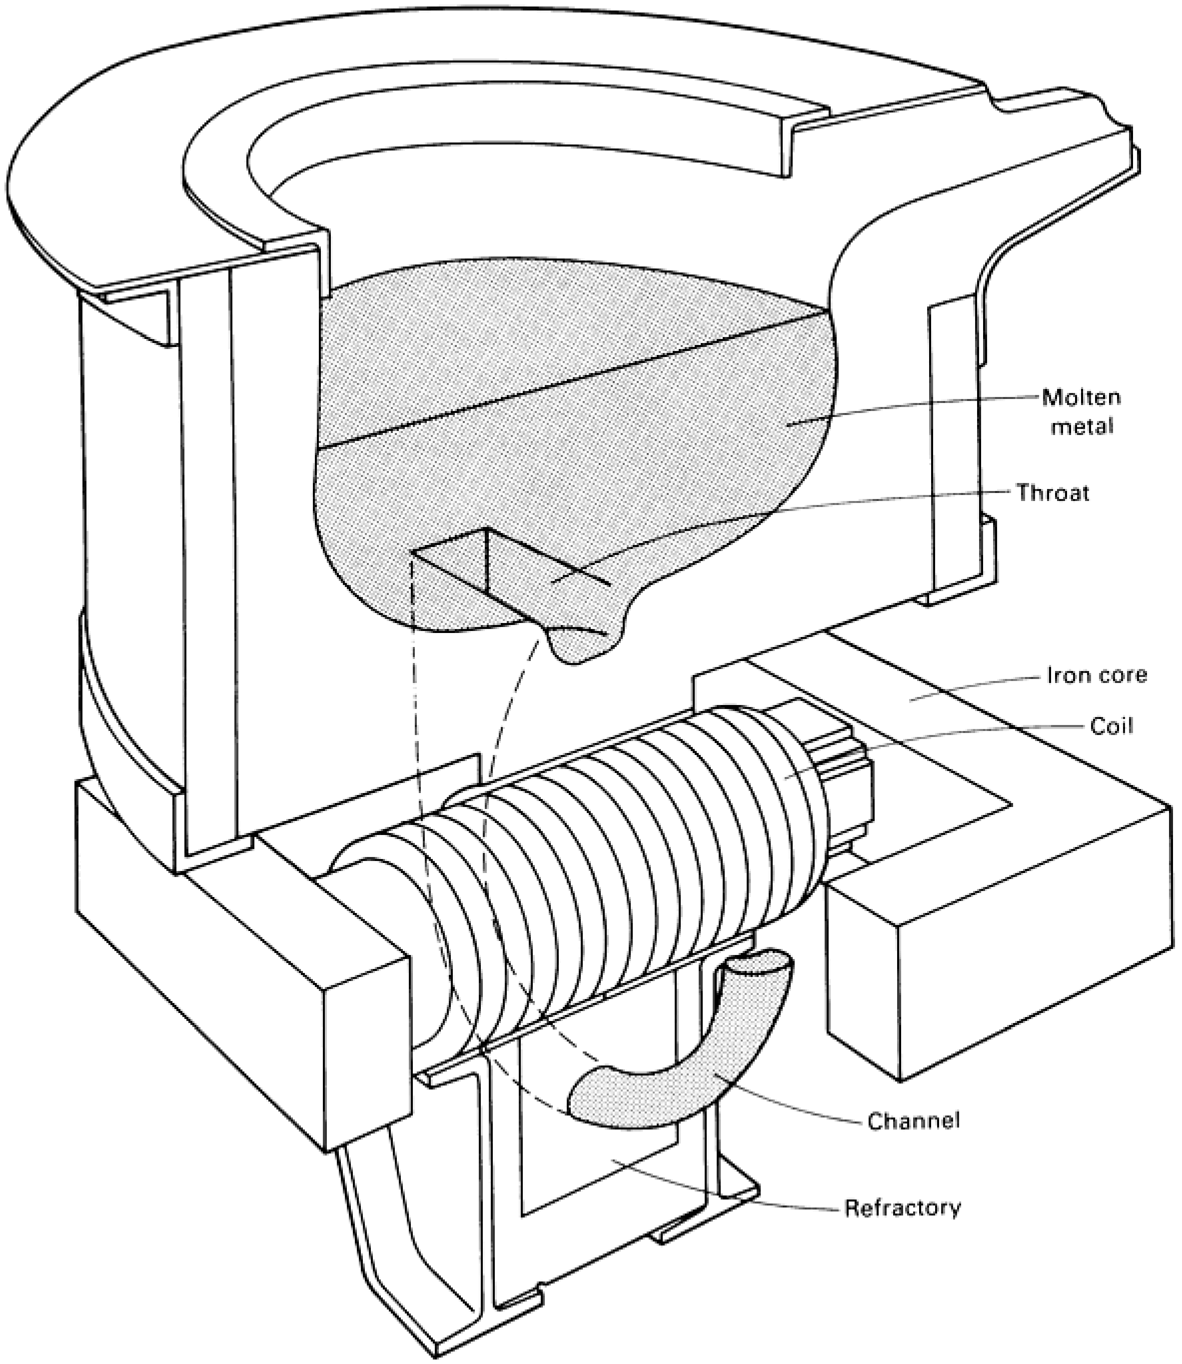

Fig. 2 A cross section of a channel-type induction furnace showing the water-cooled copper induction coil, which is located inside of a 360° loop formed by the throat and channel portion of the molten metal vessel. It is the channel portion of the loop, which serves as the secondary of the electrical circuit in which the copper coil is the primary.

In a coreless furnace, the refractory-lined crucible is completely surrounded by a water-cooled copper coil, while in the channel furnace the coil surrounds only a small appendage of the unit, called an inductor. The term "channel" refers to the channel that the molten metal forms as a loop within the inductor. It is this metal loop that forms the secondary of the electrical circuit, with the surrounding copper coil being the primary. In a coreless furnace, the entire metal content of the crucible is the secondary.

Although both employ similar electrical principles, the two types of furnaces are quite different in their capabilities and operation. The coreless furnace is more widely used for melting and superheating, whereas a channel furnace is better suited for superheating, duplexing, and holding.

The channel furnace has been used by nonferrous foundries for many years. Recently, however, this type of furnace has been increasingly replaced by the coreless and resistance furnace in aluminum-melting applications. It is still commonly used for melting copper alloys.

Technological innovations in the channel furnace have been slower in developing than advances in the coreless furnace. Only a few prototype units with a medium frequency power supply have been installed thus far. Many furnaces still rely on 60 Hz power supplies and use power-regulating autotransformers for control.

Inherent in the channel concept is the fact that only the small amount of metal in the inductor channel receives energy through the surrounding coil. This necessitates superheating the metal in the loop and pumping it out of the channel into the main vessel, where it mixes with the cold metal and heats it by convection.

The ratio of heat transfer is limited, as is the stirring action in the main vessel. This is the primary reason this type of furnace has seen only limited service as a melter. The power that can be connected to a vessel is much smaller than for a similarly sized coreless vessel. The mild stirring action also makes it difficult to get alloy and carbon additions dissolved and mixed rapidly, particularly important in the production of synthetic irons.

In addition, the channel furnace must be started with a supply of molten metal, and a metal heel must be continuously maintained in the furnace. The furnace must not be shut down even for holidays or for other extended periods, as the metal will freeze and considerable refractory damage will be incurred.

The channel furnace is more economical to manufacture in large sizes and uses electric power more efficiently than a coreless furnace. If more power is desired, additional inductors can be connected to the main vessel.

Several geometric shapes of vessels have been used. These include configurations that are described as Vertical (upright cylindrical), Drum (horizontal cylindrical), and Low Profile (spherical). Typically, all of these units are hydraulically tilted to permit the emptying of the contents.

The coreless furnace is completely surrounded by a spiral of copper tubing of a special cross section that features a water-cooling channel in its center. It must also provide good electrical coupling and strength to withstand substantial electromagnetic forces, yet with provision for thermal expansion.

Because the magnetic field is transmitted in all directions, special vertical laminations of transformer iron, which form the magnetic yokes, are evenly spaced around the circumference of the coil to provide additional strength and to pick up the stray flux that would otherwise heat up the furnace frame. Coreless furnaces are typically tilted about the spout through a 95 to 100° angle to empty their contents. The medium-frequency units can be completely emptied for alloy changes or factory shutdowns and quickly started up again with a cold charge. It is not necessary to maintain a molten heel or to use precast starter blocks, as is the case with the 60 Hz units.

Electromagnetic Stirring

When alternating current is applied to an induction coil, it produces a magnetic field, which in turn generates a current flow through the charge material, heating and finally melting it. The amount of energy absorbed by the charge depends on the magnetic field intensity, electrical resistivity of the charge, and the operating frequency.

A second magnetic field is created by the induced current in the charge. Because these two fields are always in opposite directions, they create a mechanical force that is perpendicular to the lines of flux and cause metal movement, or stirring, when the charge is liquified. The mechanical force stays perpendicular to the field only in the center of the coil; on both ends of the coil it changes direction. The metal is pushed away from the coil, moves upward and downward, and flows back. Figure 3 shows the four-quadrant stirring. It is this stirring that allows excellent alloy and charge absorption and aids in producing a melt that is both chemically and thermally homogeneous.

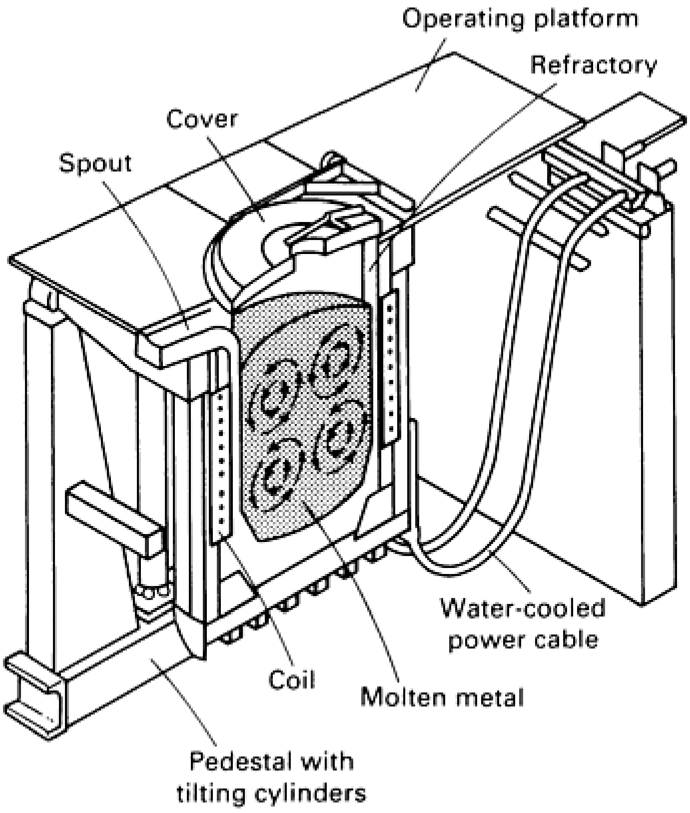

Fig. 3 A cross-sectional view of a coreless-type induction furnace illustrating four-quadrant stirring action, which aids in producing homogeneous melt

The stirring is directly determined by the amount of power induced and is inversely proportional to the square root of the frequency. Therefore, the higher the power and the lower the frequency, the more intense the stirring.

The reasons for an increased interest in induction melting for aluminum applications are many, but perhaps most significant is the question of metal loss. Because of the inherent electromagnetic stirring action in the coreless furnace, charge materials immediately become immersed in the bath, minimizing oxidation losses. This effect is particularly pronounced when melting light-gage scrap. Thus, the growing emphasis on recycling favors induction melting as a cost-effective alternative to other metal melting processes.

Electromagnetic Stirring

When alternating current is applied to an induction coil, it produces a magnetic field, which in turn generates a current flow through the charge material, heating and finally melting it. The amount of energy absorbed by the charge depends on the magnetic field intensity, electrical resistivity of the charge, and the operating frequency.

A second magnetic field is created by the induced current in the charge. Because these two fields are always in opposite directions, they create a mechanical force that is perpendicular to the lines of flux and cause metal movement, or stirring, when the charge is liquified. The mechanical force stays perpendicular to the field only in the center of the coil; on both ends of the coil it changes direction. The metal is pushed away from the coil, moves upward and downward, and flows back. Figure 3 shows the four-quadrant stirring. It is this stirring that allows excellent alloy and charge absorption and aids in producing a melt that is both chemically and thermally homogeneous.

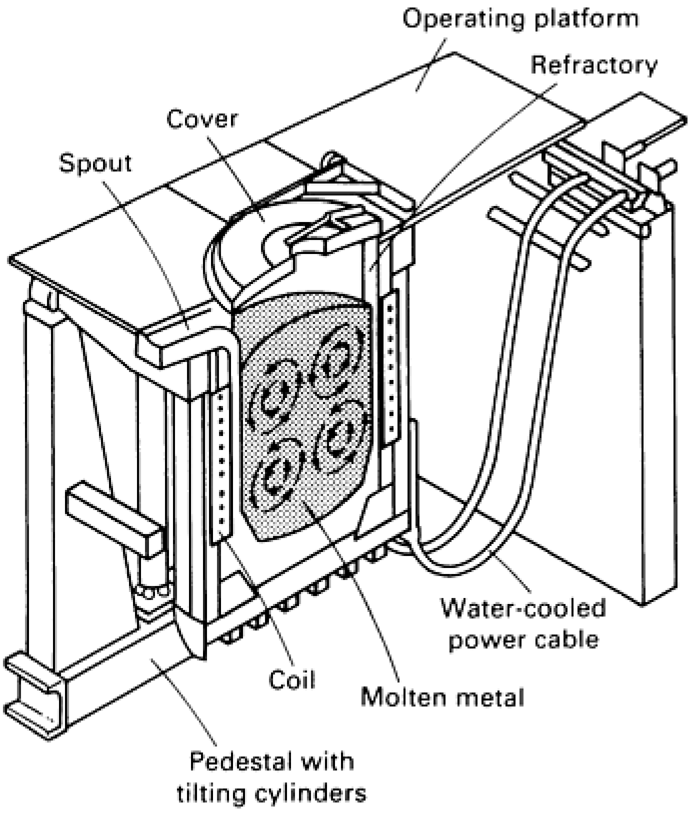

Fig. 3 A cross-sectional view of a coreless-type induction furnace illustrating four-quadrant stirring action, which aids in producing homogeneous melt

The stirring is directly determined by the amount of power induced and is inversely proportional to the square root of the frequency. Therefore, the higher the power and the lower the frequency, the more intense the stirring.

The reasons for an increased interest in induction melting for aluminum applications are many, but perhaps most significant is the question of metal loss. Because of the inherent electromagnetic stirring action in the coreless furnace, charge materials immediately become immersed in the bath, minimizing oxidation losses. This effect is particularly pronounced when melting light-gage scrap. Thus, the growing emphasis on recycling favors induction melting as a cost-effective alternative to other metal melting processes.

Power Supplies

In order to meet the range of melting needs, the proper power supply must be selected. Because the vast majority of existing furnaces use line frequency, this arrangement will be discussed first (see Fig. 4).

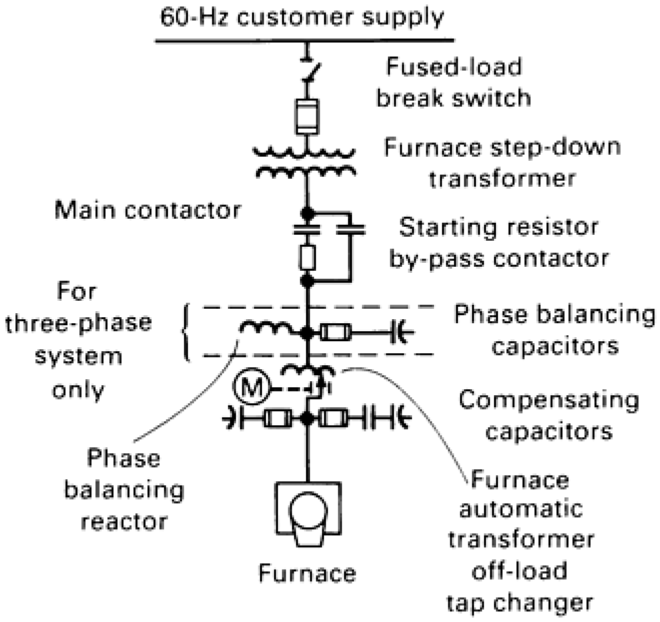

Fig. 4 Modifying 60-Hz line frequency supplied by utility company to serve as power supply for induction furnaces

Protection of the furnace and the power system, phase balancing, and power correction are required in order to operate an effective installation. The typical 60 Hz (line frequency) power supply basically consists of:

- Primary switchgear
- Furnace transformer
- Starting resistor and bypass contactor (for installations with off-load tap changers)
- Phase balancing system
- Power factor correction capacitor bank
- Instrumentation
- Controls and supervision

A primary transformation from the high-voltage grid of the local utility is usually required because the voltage applied to the coil is between 500 and 3000 V.

Because of its high inductance, an induction furnace coil has a low power factor. In order to bring the power factor to near unity, capacitors are installed and connected in parallel to the furnace coil. When starting a furnace, in order to reduce the inrush, a soft start is provided.

When the transformer with an on-load tap changer is installed, the tap changer travels down to a lower tap whenever the furnace is switched off. This provides a start with a low voltage, resulting in low inrush current. When an off-load tap changer is applied, a starting resistor bank with bypass contactors is provided.

Because the induction furnace is a single-phase furnace but its feed is commonly a three-phase line, a phase balancing system consisting of capacitors and reactors has to be provided. In ferrous applications, refractory lining wear decreases the coupling distance between the coil and charge, resulting in a power increase. Because power input is limited, the voltage has to be decreased in order to keep power from exceeding its maximum. This is typically done by using steps on a transformer tap changer. As the lining wears and the power increases, the voltage has to be reduced by going to a lower tap.

Additionally, in order to compensate for the amount of metal in the furnace and the condition of the refractory lining, a portion of the capacitor bank that is installed in parallel with the coil needs to be switched by adjusting the coarse and fine

settings on the electrical panel. In the modern medium-frequency power supplies, (see Fig. 5), many of the functions described are now performed automatically or have been eliminated altogether.

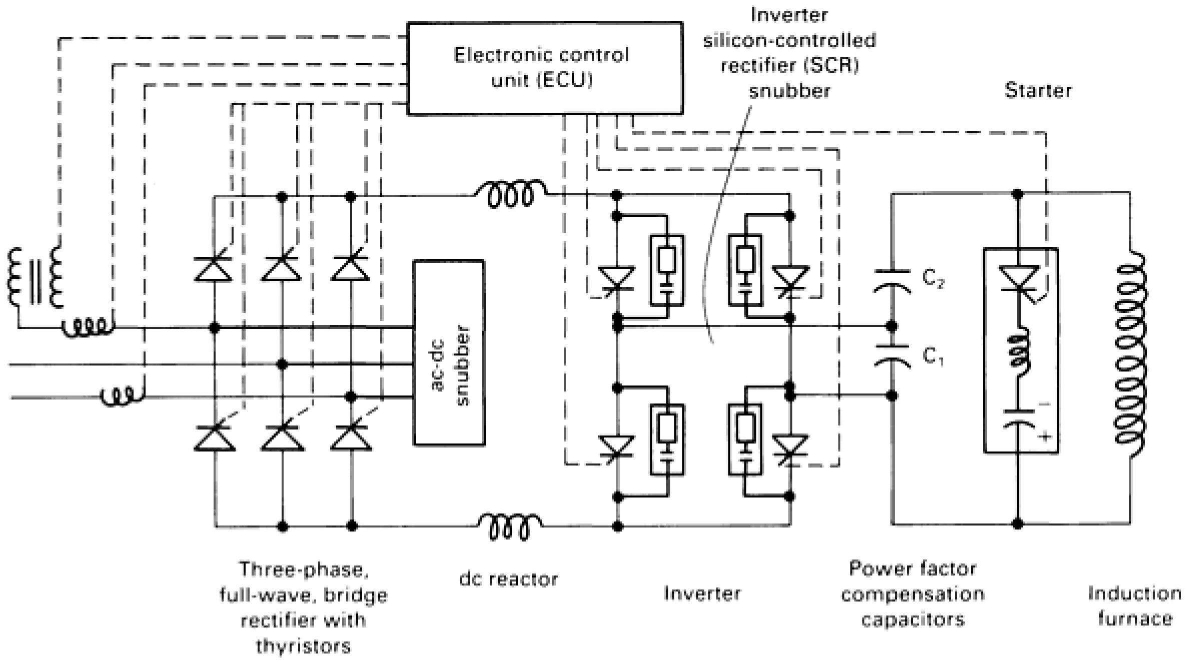

Fig. 5 A typical medium-frequency power supply incorporating a parallel inverter

The typical conversion is in an ac-dc-ac sequence. While frequency conversion entails electrical losses, modern power supplies incorporate solid-state frequency converters, and the increase in thermal efficiency usually outweighs the conversion losses. Modern converters approach an efficiency of 97%. In the power conversion commonly used, the incoming 60 Hz ac power is rectified to dc and then chopped by an inverter to a higher frequency.

Series and Parallel Inverters. Two types of inverters are typically used, namely, series and parallel. In each case the furnace and compensating capacitor bank (fixed, in this case) form part of a resonance circuit.

In a series inverter, capacitors are connected in series with the induction coil, requiring, at low power, a matching transformer. Power to the furnace is controlled by detuning the inverter. It is unnecessary to control the rectifier, thus allowing the use of diodes.

In a parallel inverter, the capacitor bank is connected in parallel with the induction coil. Power control is accomplished by detuning the inverter in the full-power range. Thyristors in the rectifier act to lower the dc voltage, if required, and provide half-cycle protection, thereby essentially becoming an electronic circuit breaker. This characteristic, coupled with the smaller number of components in the circuit, have made the parallel system the most widely used inverter in industry.

In both series and parallel circuits, it is possible to get power control that allows full power to be drawn regardless of the level of the charge in the furnace or the condition of the refractory lining. The midfrequency converters operate on a variable frequency. The load-commutated converter increases frequency as the charge contents of a furnace increase while it simultaneously compensates for lining wear. No capacitor switching is required as in the line frequency units. In addition, a single potentiometer offers stepless and infinite control, eliminating the need for tap changer systems for power control.

Modern induction furnaces take advantage of the latest technology, and many new installations are equipped with programmable controllers in lieu of relay logic. An even more recent advance has been the use of industrial computers for controlling the furnace and auxiliaries.

With the variety of software that is currently available, the operator can choose screens such as systems data, automatic lining sintering, automatic cold starting of the furnace after a prolonged shutdown, automatic melting programs for various alloys, continuous calculated-temperature monitoring, fault detection, demand limiting, tabulation of energy consumption, melting cost data, metal inventory control, and chemistry adjustment. Also, by tying the computer to support systems such as charge make-up and hot-metal delivery, the utilization of the furnace can be increased.

Packaging of Systems. Until the early 1970s, the electrical components of coreless induction furnaces were typically assembled on site in a concrete vault. Field construction costs made this installation technique financially prohibitive except for the largest of furnaces (usually above 18 Mg, or 20 tons in capacity) for which a vault is still used. Even in this size range, modern component assembly techniques have allowed for the power supply to be packaged into steel modules at the equipment manufacturing plants.

For furnaces up to 3.6 Mg (4 tons) in capacity, current practice is to completely assemble, wire, and pipe all components on a steel frame, to test, and subsequently to ship the unit as a single module, thus minimizing installation and start-up costs. This packaging concept applies to furnaces in the 4.5 to 18.1 Mg (5 to 20 ton) range, as well, although several modules may be required because of their size. Still, they are equipped with quick-connect fittings for fast and easy field assembly.

For furnaces with power above 1250 kW, a step-down transformer from the main distribution voltage is normally used. Below 1250 kW, a 480 V distribution line backed by a disconnecting device can be used. The step-down transformers, when required, can be of the oil-filled outdoor type, which is the least expensive, or the indoor dry or silicon-filled type.

Water Cooling Systems

Because the furnace coils and power supplies of the induction furnaces need to be cooled, a closed-loop water system is generally called for. In a medium-frequency power supply, the electronic components of the system contain a dc leg; it is therefore important to have clean, demineralized water circulating, typically with conductivity set at 50 μS (50 μmho) in order to prevent electrolysis from taking place.

The heat exchanger to be used depends entirely on local circumstances such as climate, availability of raw water, and so on. The most widely used are the evaporative, the water-to-water, and the air-to-water types. The latter has been frequently adapted to heat recovery systems. In those applications the hot water from the furnace power supply and coil is piped to a location in the plant where heat is required. The water is circulated through a tube bundle, and a fan dispenses the warm air to the surroundings. Considering that up to 10% of the power from a channel furnace and 20% of the power from a coreless furnace is lost to the water system, heat recovery systems for induction furnaces are very practical.

In all coreless- and channel-type furnaces, the water is circulated through the power supply and then routed through the coil and on to the heat exchanger. Typically, two pumps are provided, one as a standby with an automatic switchover, because it is extremely important to circulate water through the coil continuously, to prevent it from being damaged. To protect induction furnace equipment during momentary power interruptions or prolonged power failures, manufacturers provide a special pressure-operated valve that, when activated, allows emergency deployment of city water to circulate through the coil. Such a system is shown in Fig. 6.

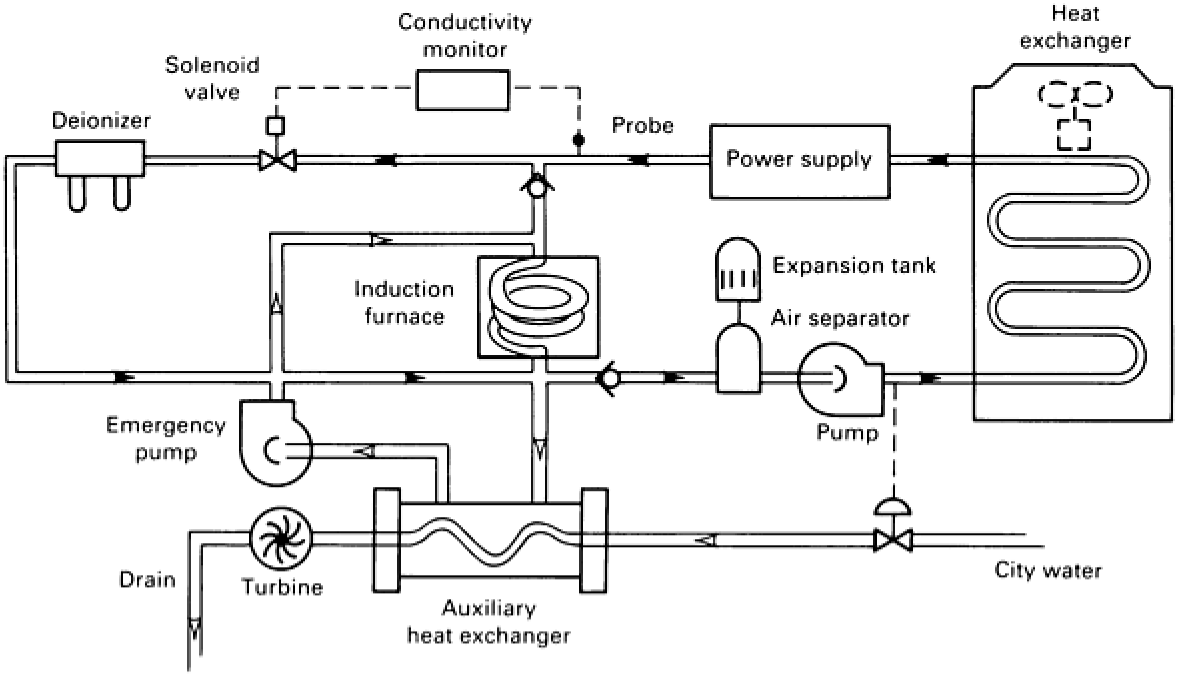

Fig. 6 A layout of a closed-loop cooling system showing routing of furnace-cooling water under both normal (black arrows) and emergency conditions (white arrows). Standby emergency pump is activated if the primary pump fails.

In addition, with channel furnaces, standby generators are often employed to maintain some power in the inductor. If the metal in the channel freezes, considerable damage to the refractory lining may occur.

Lining Material

The selection of lining material is determined by the metallurgical requirements, the operating temperatures, and the type of operation. Refractories used in induction furnaces are oxides of minerals. Typically used are silica (SiO_2), alumina (Al_2O_3), or magnesia (MgO) linings. From a chemical point of view, the silica is classified as an acid, alumina as a neutral, and magnesia as a basic material.

Silica is the clear choice in iron melting, because it does not readily react with the acid slag typically produced in high-silica iron, has an extremely forgiving expansion curve, and is easy and economical to use. Alumina is the usual choice for aluminum-melting furnaces.

Each of the refractory groups mentioned above has a different thermal expansion characteristic, as shown in Fig. 7. As can be seen, alumina and magnesia have a nearly linear expansion. Silica, however, completes its expansion at approximately 815 °C (1500 °F) and remains constant at higher temperatures. With the selection of silica lining, the furnace can be shut down, cooled, and restarted without running the risk of metal penetrating thermal cracks.

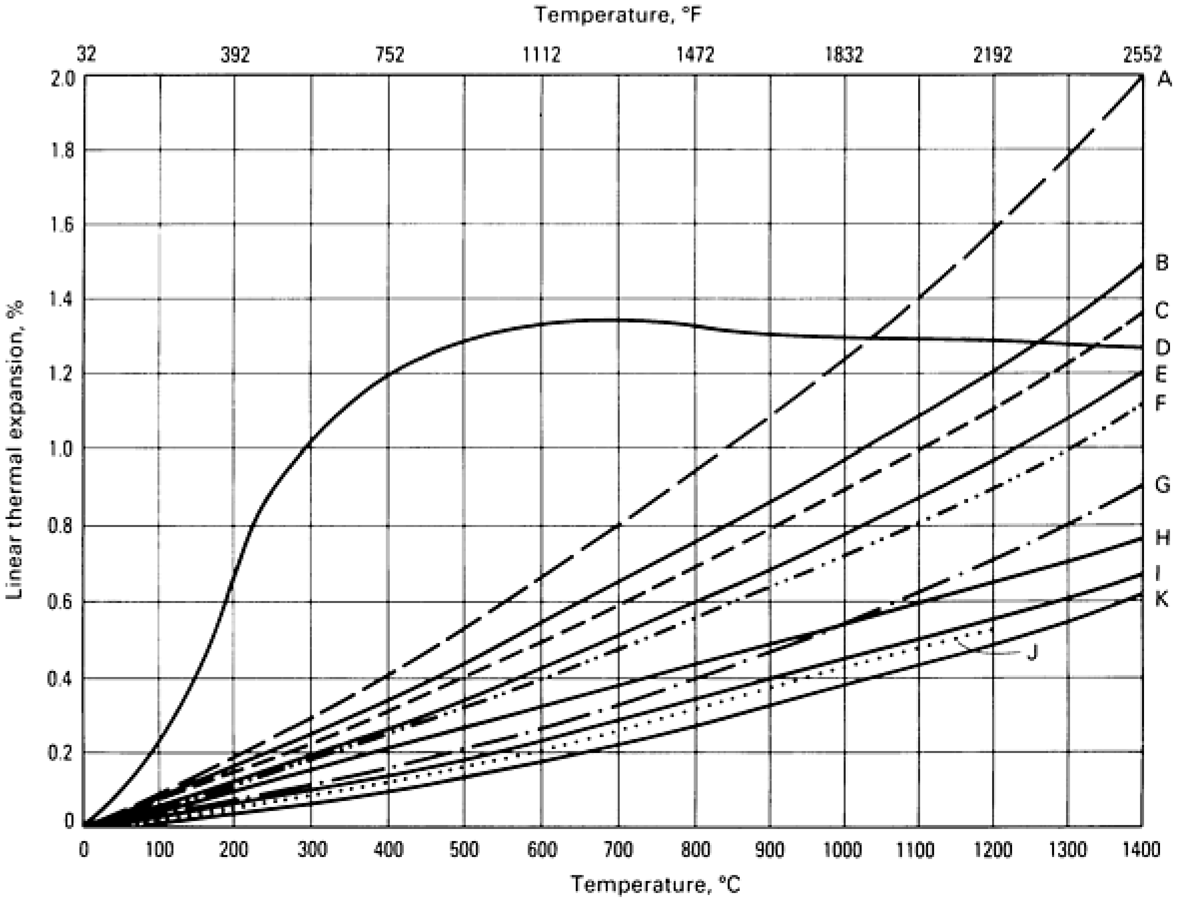

Fig. 7 Thermal expansion curves of various refractory brick oxide materials used for linings in induction furnaces: A, magnesia; B, chrome magnesia; C, chromite; D, silica; E, zirconia; F, corundum 99; G, corundum 90; H, fireclay; I, sillimanite; J, zircon; K, silicon carbide

Magnesia is very sensitive to thermal shock and has the greatest expansion. Once cracked, this type of lining is not likely to seal itself, thus resulting in metal penetration.

Alumina has approximately one-half the expansion of magnesia and is therefore less crack sensitive. It is important, however, to heat the furnace lining slowly when undergoing a cold start. This programmed start-up allows the cracks to seal before the metal adhering to the side walls melts and penetrates. This applies particularly to aluminum-melting furnaces because the metal melting temperature is relatively low.

In the case of aluminum and some copper alloys, the oxide and metal buildup on the crucible not only poses a potential refractory penetration problem, but also effectively increases the lining thickness and reduces the power that goes into the furnace. If not removed, this layer, which contains a small amount of metal, absorbs energy and becomes superheated. The superheated metal can penetrate the lining and cause premature failure. For these reasons, the furnace crucible walls must be cleaned periodically.

Crucible Wall Scrapers. The task of scraping the crucible wall has been made easier with the introduction of a patented mechanical scraper (Fig. 8), which quickly and easily cleans the sides in a full, hot furnace. The device essentially consists of a number of oscillating blades assembled on a steel frame. To start the operation, the scraper is placed on top of the furnace and the oscillating tools travel down the depth of the crucible. Radial pressure on the furnace is adjustable. The loose materials float to the top of the bath and are skimmed off.

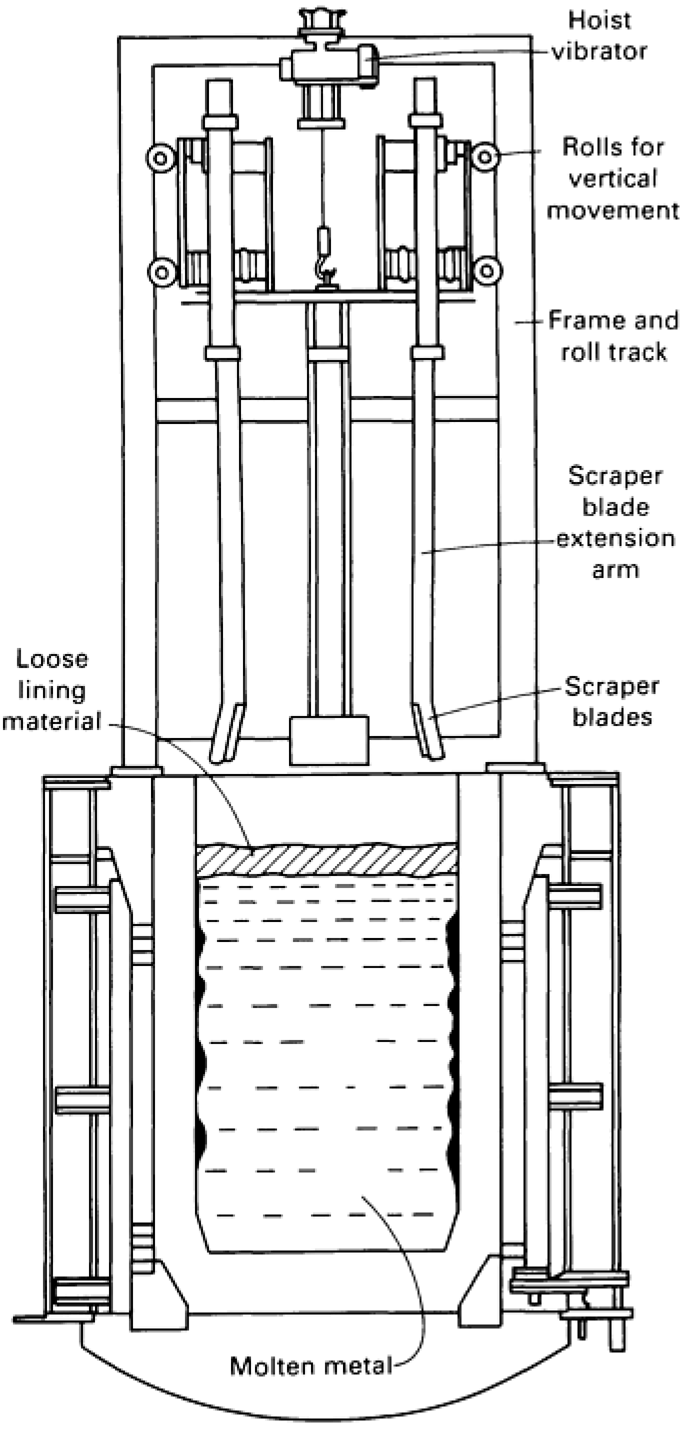

Fig. 8 A cross section of a patented mechanical scraper used to clean the refractory lining of induction furnaces that melt nonferrous metals

Ramming Mixes. Most induction furnaces operating in iron foundries are, as stated previously, lined with a silica ramming mix. Alumina, magnesia, or zircon are typically used for melting steel and alloys. Alumina is typically used for aluminum.

The current practice is to use granular materials. For example, the silica ramming mix is granular material combined with the sintering agent boric acid (H_2BO_3). The amount of boric acid depends on the operating temperature and the wall thickness of the crucible.

The flux or sintering agent fuses the silica particles to each other, forming a hard, glazed, ceramic surface. Ideally, the lining, when sintered, consists of one-third hard, sintered ceramic; one-third fritted material, in which fine particles are sintered and larger particles can still be identified; and one-third loose particles.

This loose material has its purpose. When starting up a furnace from a cold start, the lining naturally expands. The loose material provides a cushion to handle the pressure.

All granular materials are rammed on the furnace bottom using an electric vibrator equipped with a tamping plate. For the side walls, the lining material is spread behind a lining form that is vibrated with a pneumatic vibrator attached to it.

For ferrous applications, the lining form is consumed in the first heat. For nonferrous applications, the lining form can be removed and reused. It may be tapered or collapsible.

The sintering process itself takes some time because it is necessary to heat the lining at the rate of approximately 110 °C/h (200 °F/h) until a temperature of about 30 °C (50 °F) above operating temperature is achieved. This temperature is held for 1 h before the furnace is ready for production.

When the linings are to be replaced, they must be chipped out with pneumatic hammers, and the lining procedure must be repeated. A patented device is now available that eliminates the need to chip out the spent linings manually, saving both labor and time.

The key components of this device, a schematic of which is provided in Fig. 9, are a locking plate that is bolted to the bottom of the furnace and a hydraulic ram assembly that is brought into position and latched to the plate. Once activated, the hydraulic ram moves forward, exerting pressure on a specially designed refractory cone installed in the bottom of the furnace. This distributes the force over the cross section of the lining. The push-out is aided by a slip joint between the coil grout and the working lining. The whole operation takes but a few minutes, with additional time being saved because the cool-down time is cut in half.

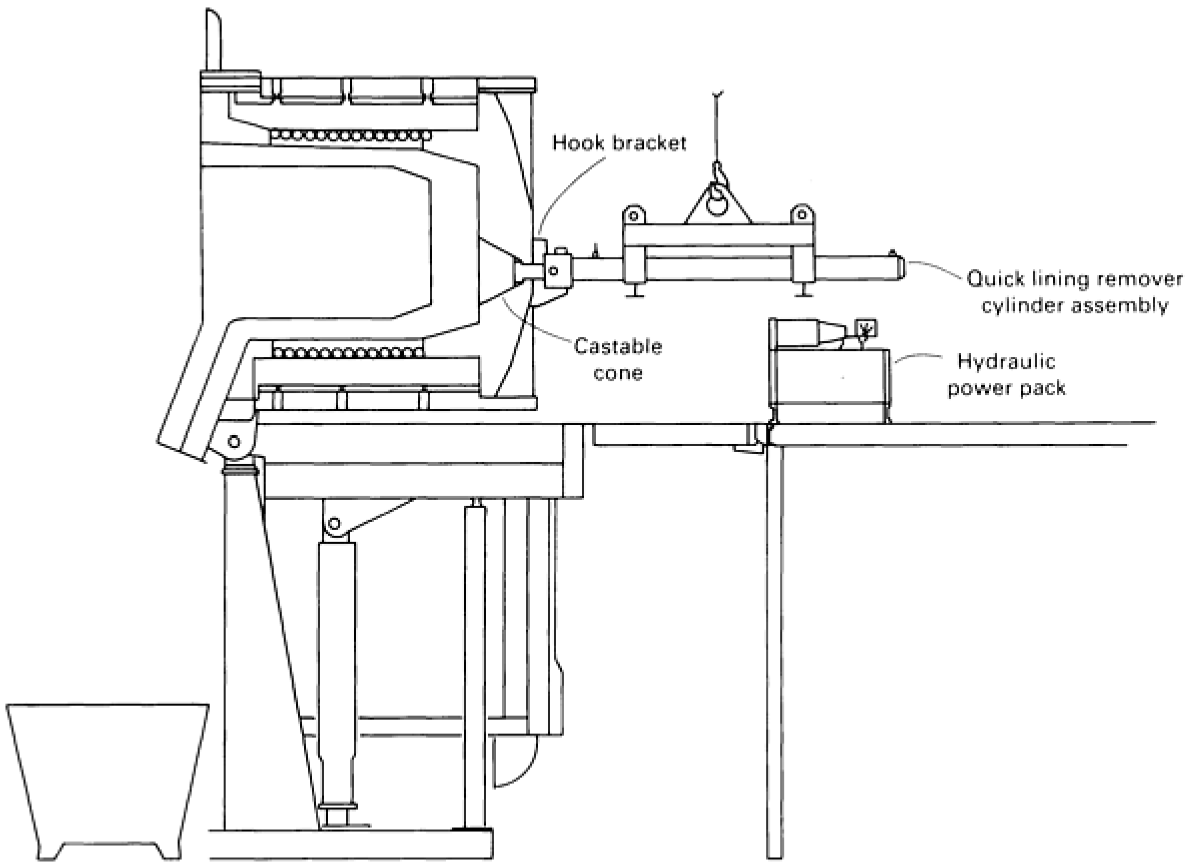

Fig. 9 The principal components of a patented push-out device used to extract deteriorated refractory lining

from coreless induction furnaces

Melting Operations

There are two distinct ways of operating a coreless induction furnace. One method is a batch operation, in which the entire contents of the furnace are emptied and the unit is recharged with solids, typically using a conveyor or bucket charger. The other, more accepted, method involves a tap-and-charge operation, in which a portion of the furnace contents, typically one-third to one-half, is tapped and the identical weight in solids is recharged using a charge bucket or charge conveyor.

Batch operation has now become feasible because medium-frequency power supplies allow the furnace to be started with ordinary scrap, rather than with starting blocks.

In terms of electrical consumption, the batch-melting method provides a $7\frac{1}{2}$% higher efficiency in iron-melting furnaces and a $4\frac{1}{2}$% higher efficiency in nonferrous-melting units over the tap-and-charge method. This is because the cold charge material couples with the magnetic flux more effectively than does molten metal. In addition to having greater electrical efficiency, a medium-frequency batch operation allows the drying of wet or oily charge material in the furnace, minimizing the need for a scrap-drying system.

The tap-and-charge operation is still the most popular approach, however, because the chemistry is much easier to control because less than one-half of the furnace contents are replenished at any one time. Additionally, the refractory lining lasts longer because of less thermal cycling. Finally, in order to use a batch operation effectively, the contents of the unit have to be quickly and completely discharged, usually into a holding furnace. This option may not be possible if small amounts of molten metal need to be taken out at defined times and the capital and operational costs of a holding furnace cannot be economically justified.

In either method of operation, it is particularly important to use the power supply efficiently and keep the cover closed to minimize potentially high radiation losses.

Utilization is calculated in terms of the time that the power is on. It is obvious that power cannot be on constantly, because certain operations, such as charging, slagging, sampling, and tapping are best and most safety done while the power is off. The objective is to keep the power on at least 75% of the time. Sometimes a second furnace added to the power supply improves utilization, because the power can be switched from one furnace to the other while the above-mentioned operations take place. Utilization can also be improved by quickly charging and tapping to minimize waiting time and heat losses as well as by increasing the charge size.

Although medium frequency has made the need for heavy charge materials obsolete, it is still good practice to choose materials that have a reasonably high bulk density, are relatively clean and dry, and are not too long. In order to avoid bridging, the length of the pieces should be no more than two-thirds the diameter of the crucible. If longer pieces such as casting gating systems and structural steel sections are available, they should be broken or cut first.

The high bulk density is important because the new charge must be contained in the space vacated by the tapped-out molten metal. If low-density charge materials are used, several charging cycles may be necessary, reducing furnace utilization.

Dry charge material is best suited for melting operations. Oils on the charge surface generate fumes from the furnace, which may need to be exhausted. Moisture on the charge also can be a problem, because a steam explosion can result. If dry materials are not readily available, a charge dryer is often employed to drive off any moisture remaining on the charge. The most common dryer consists of a refractory-lined hood equipped with gas burners, which heat the solids on a vibrating conveyor by means of forced convection of the hot gases through the material. Figure 10 shows the various major components of the system. It is important to get the preheated charge into the furnace quickly to take advantage of the thermal energy in the material and to reduce the electrical energy output required for melting. The average temperature used for drying is typically 315 °C (600 °F); for preheating, it is 540 °C (1000 °F). When applied properly,

the preheating of the charge material can increase the melt rate by 10 to 15%. Direct impingement of the flames on the charge material, particularly if it is thin, should be avoided because oxidation losses can occur.

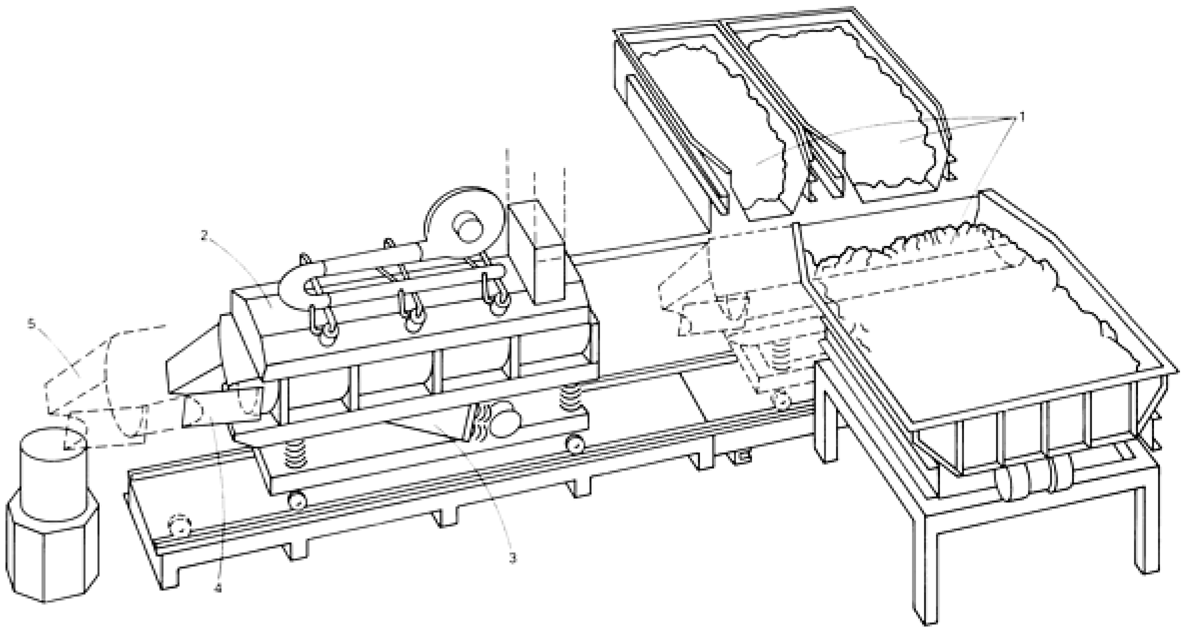

Fig. 10 The major components of a dryer used to preheat induction furnace charge material. Integrated scrap preheat process combines (1) weigh hoppers, (2) preheat hood, (3) material transfer mechanism, and (4 and 5) furnace-charging apparatus into a single automated process.

When dirty material is charged into the furnace, slag forms from the dirt and rust in the scrap as well as from the foundry return sand. Slag is undesirable in induction furnaces because it absorbs energy and erodes the lining. It is, therefore, removed each cycle with a skimmer to prevent slag accumulation.

Mechanical Skimmers. Furnace operators can increase the power supply utilization by the use of mechanical skimmers (Fig. 11). This is particularly important in large furnaces because mechanical slagging units can minimize the time that power is either turned off or reduced for skimming during each charge-to-tap cycle. A power skimmer can easily boost the output and productivity of the melting furnace.

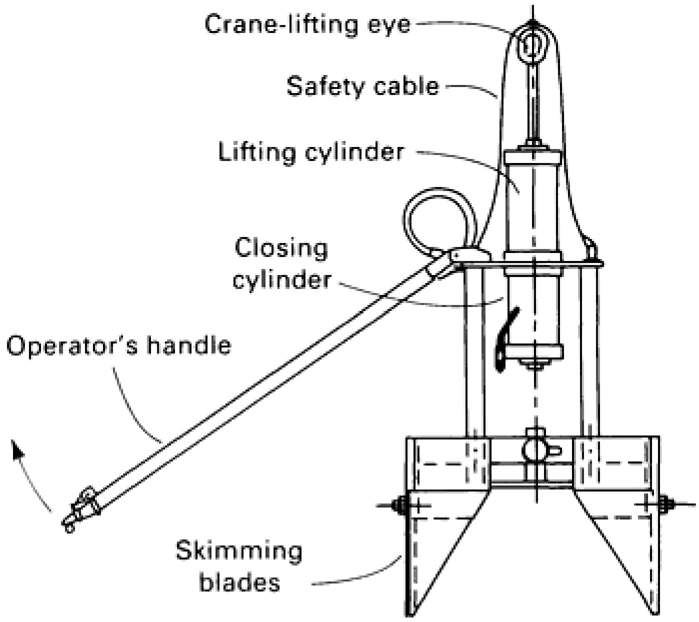

Fig. 11 A mechanical clamshell-type power skimmer used to remove slag before each tap of an induction furnace

A skimmer is typically mounted on a jib. This tool has a long handle, which keeps the operator farther away from the hot furnace. The best and most effective type of slagger is the clamshell type. The skimmer is positioned over the furnace and lowered into the slag. With an automatic raking motion, the jaws of the unit close around the slag, which is then lifted clear of the bath and deposited into a container. The blades are typically dipped into a slurry to reduce slag adhesion during the next charge-to-tap cycle.

Melting Furnaces: Reverberatory Furnaces and Crucible Furnaces

Avery Kearney, Avery Kearney & Company

Introduction

Reverberatory and crucible furnaces are extensively used for the batch melting of ferrous and nonferrous metals. This section will focus on nonferrous metals such as aluminum, copper, zinc, and magnesium, with emphasis on the melting of aluminum. Either type of furnace can individually serve as a melter or a holder or as a combined melter/holder prior to pouring the casting.

Crucible furnaces typically have a maximum holding capacity of 1.4 Mg (3000 lb) of aluminum; reverberatory furnace capacities range from 0.91 to 90 Mg (2000 to 200,000 lb) of aluminum. However, because crucible furnaces can isolate the gas or electric heat source from direct contact with the molten metal bath, they do provide the advantage of minimizing contaminants in the melt when purity is a primary concern.

Reverberatory Furnaces

Reverberatory or hearth furnaces for foundry use have been extensively redesigned since the fuel shortages of the mid-1970s. Rising fuel costs gave the industry good reason to look closely at melting techniques. Since then, many of the well-accepted ideas have been thoroughly tested and replaced with newer, better, more efficient, and more quality-oriented techniques. The answers and evaluations for determining the best technology in each specific situation are far from complete. Foundry use of hearth furnaces is primarily limited to aluminum alloys.

Types of Hearth Furnaces

The term reverberatory furnace is a throwback to the World War II era, when the most common fuels for hearth aluminum melting were coal or coke (Fig. 1). This necessitated locating the heat source or fire box at one end of the bath and the flue at the other end. The flue (stack) was designed to be strong enough to draw the flame over the bath. The roof was slanted to bounce or reverberate the flame (like sound echoes) off the ceiling, down across the metal to be melted in the molten bath, and then onto the flue. A primary objective was to heat the refractory walls and ceiling and then use these surfaces to radiate heat to melt the charge. This same flame pattern and the method of using a flame to heat the bath were implemented when the fuel used was changed from coke to oil and gas.

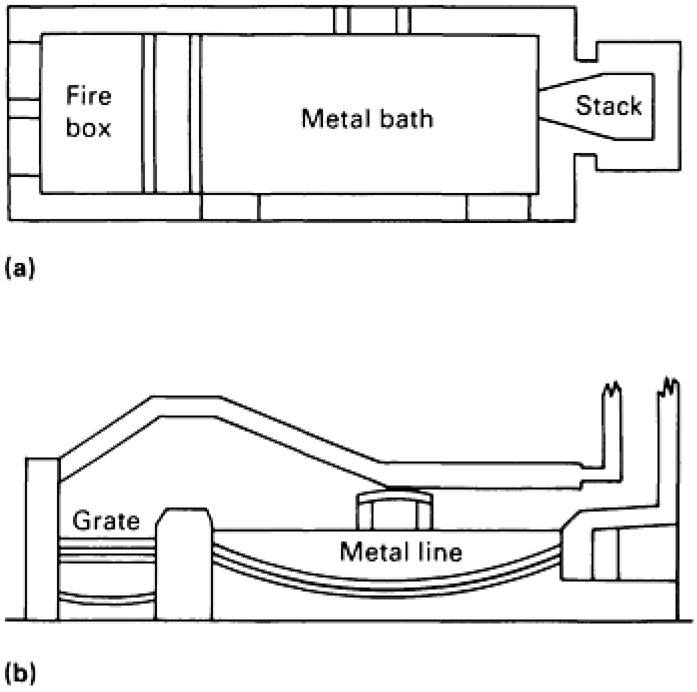

Fig. 1 An early version of a coal-fired melter hearth furnace used to produce aluminum castings. (a) Plan view. (b) Vertical cross section

This older concept of aluminum metal melting is still used in many foundries and smelters. However, the current trend is to use roof burners or side burners directed toward the metal surface. In essence, the trend is to heat the metal not the furnace for efficient operation.

Reverberatory furnaces are direct fuel fired and can be designated in either the wet hearth or the dry hearth configuration. In a wet hearth furnace, the products of combustion are in direct contact with the top of the molten bath, and heat transfer is achieved by a combination of convection and radiation (Fig. 2). In a dry hearth furnace, the charge of solid metal is positioned on a sloping hearth above the level of the molten metal so that the charge is completely enveloped by the hot gases (Fig. 3). Heat is rapidly absorbed by the solid charge, which melts and subsequently drains from the sloping hearth into the wet holding basin or chamber.

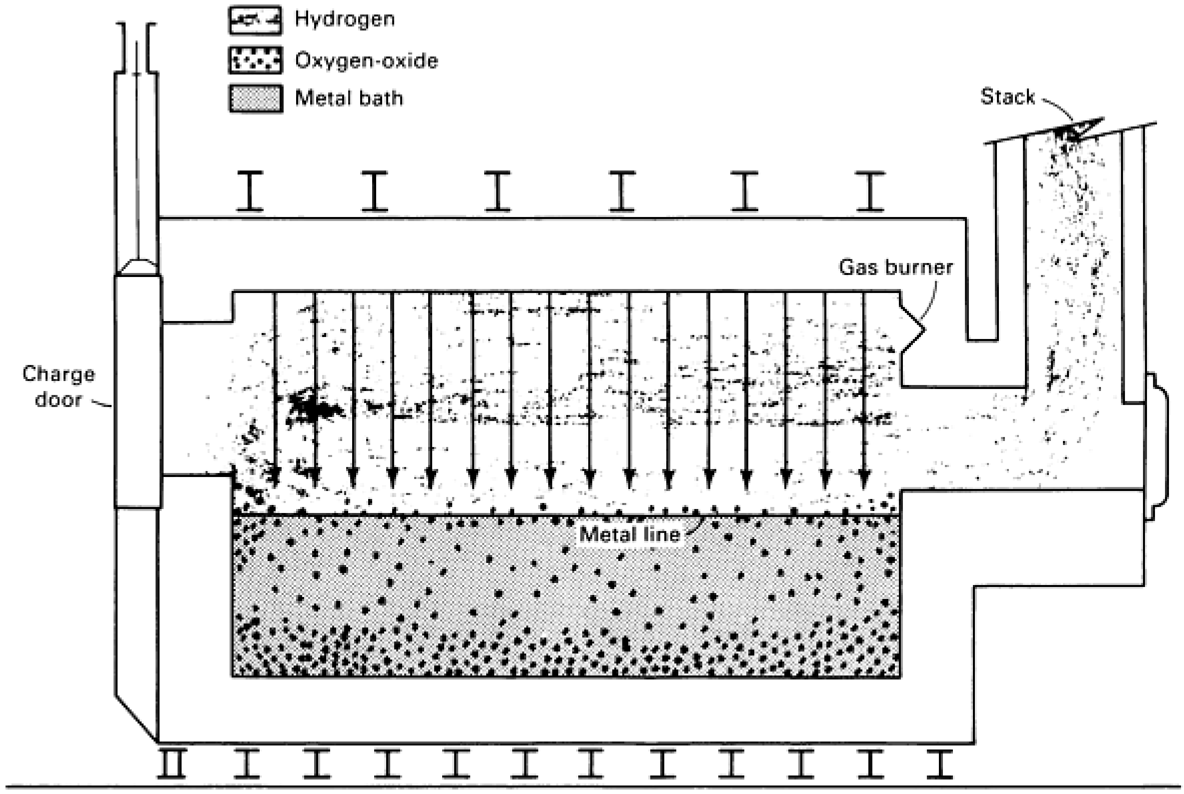

Fig. 2 Schematic of a wet hearth reverberatory furnace heated by conventional fossil fuel showing the position of the hydrogen and oxygen gases relative to the molten metal bath. Arrows indicate heat radiated from top of furnace chamber.

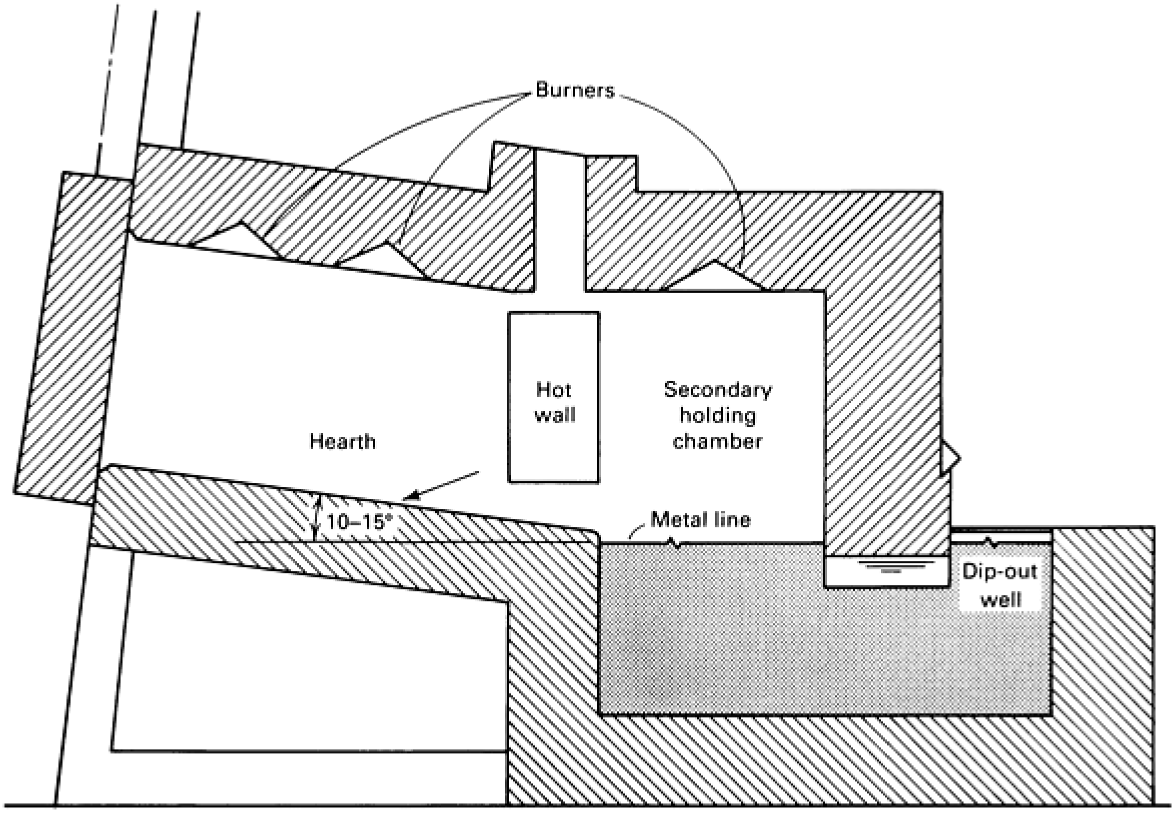

Fig. 3 Schematic of a radiant-fired dry hearth reverberatory furnace illustrating the position of the sloping hearth relative to the molten bath

Figure 4 illustrates the wide array of burner flame pattern configurations available for use in reverberatory furnaces. Electrically heated furnaces using resistance heating elements are also available.

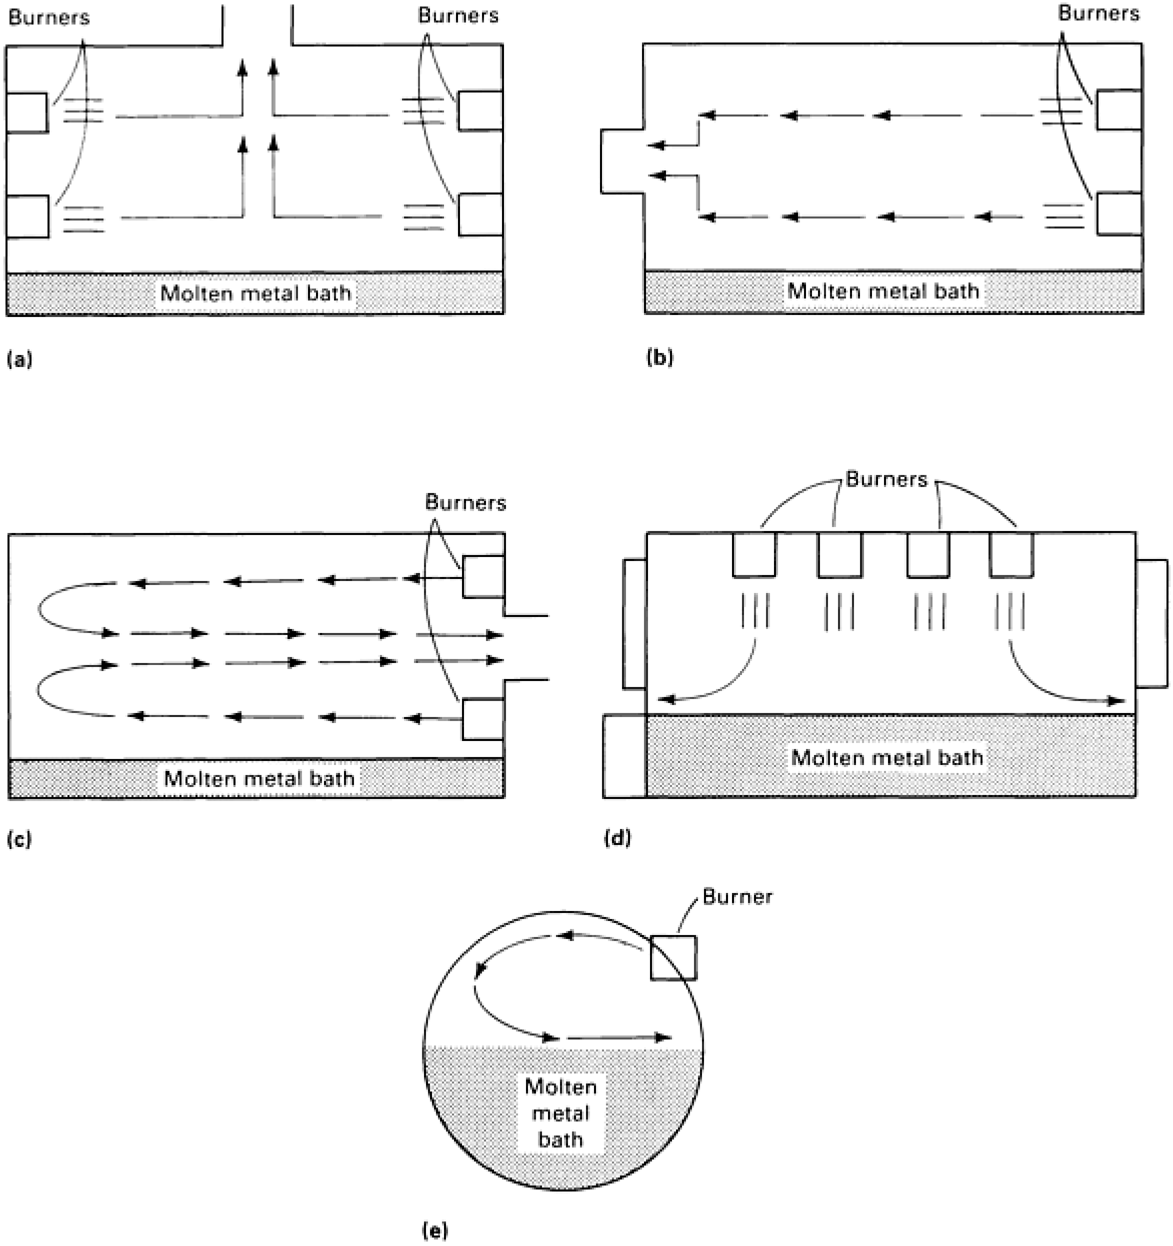

Fig. 4 Front views of the numerous types of burner flame patterns used in reverberatory furnaces. (a) Center flue arrangement. (b) Straight through firing. (c) W-fired double pass. (d) Roof mounted. (e) Barrel type

Modern aluminum foundries use numerous furnace designs. Figure 5 shows a schematic of a wet hearth reverberatory furnace charged by means of a charging ramp. In this setup, two burners are mounted in the end wall opposite the flue. In updated furnace designs, the burners are mounted on either side of the flue to increase the time that the flame remains in the furnace chamber. In this way, fuel efficiency is improved. The capacity of this type of furnace is typically 9.1 to 45 Mg (20,000 to 100,000 lb).

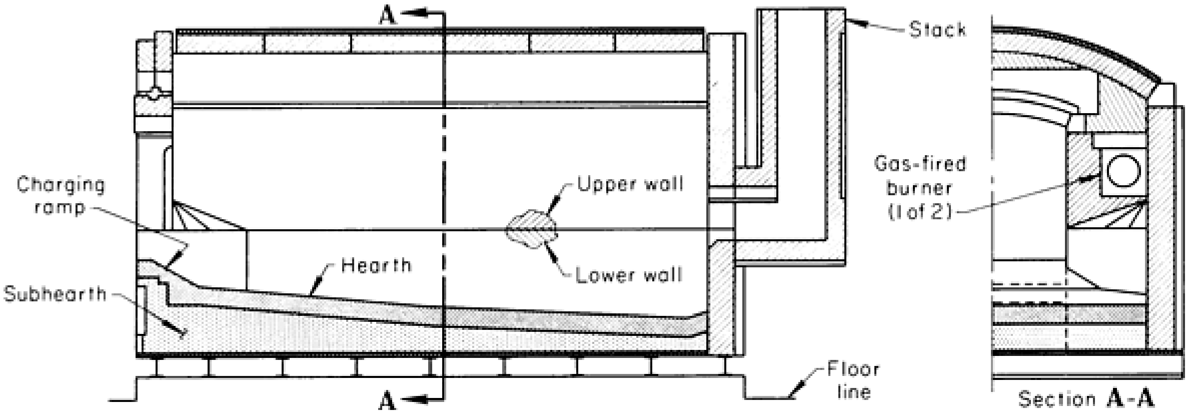

Fig. 5 Large reverberatory furnace charged through a ramp

Another widely used furnace for the melting of aluminum is the melter/holder furnace. The capacity of these units varies from 2.3 to 18 Mg (5000 to 40,000 lb). Burners in the furnace roof provide efficient heating and unobstructed floor space for furnace operation all around the perimeter of the furnace. Units of this type are often used to supply metal to several permanent mold molding stations.

Figure 6 shows a schematic of a small electric resistance melter/holder furnace for melting aluminum. Metal quality is improved with this type of unit because it eliminates the problem of combustion products and because it provides a low-temperature heating source. Practical sizes range from 0.91 to 45 Mg (2000 to 100,000 lb).

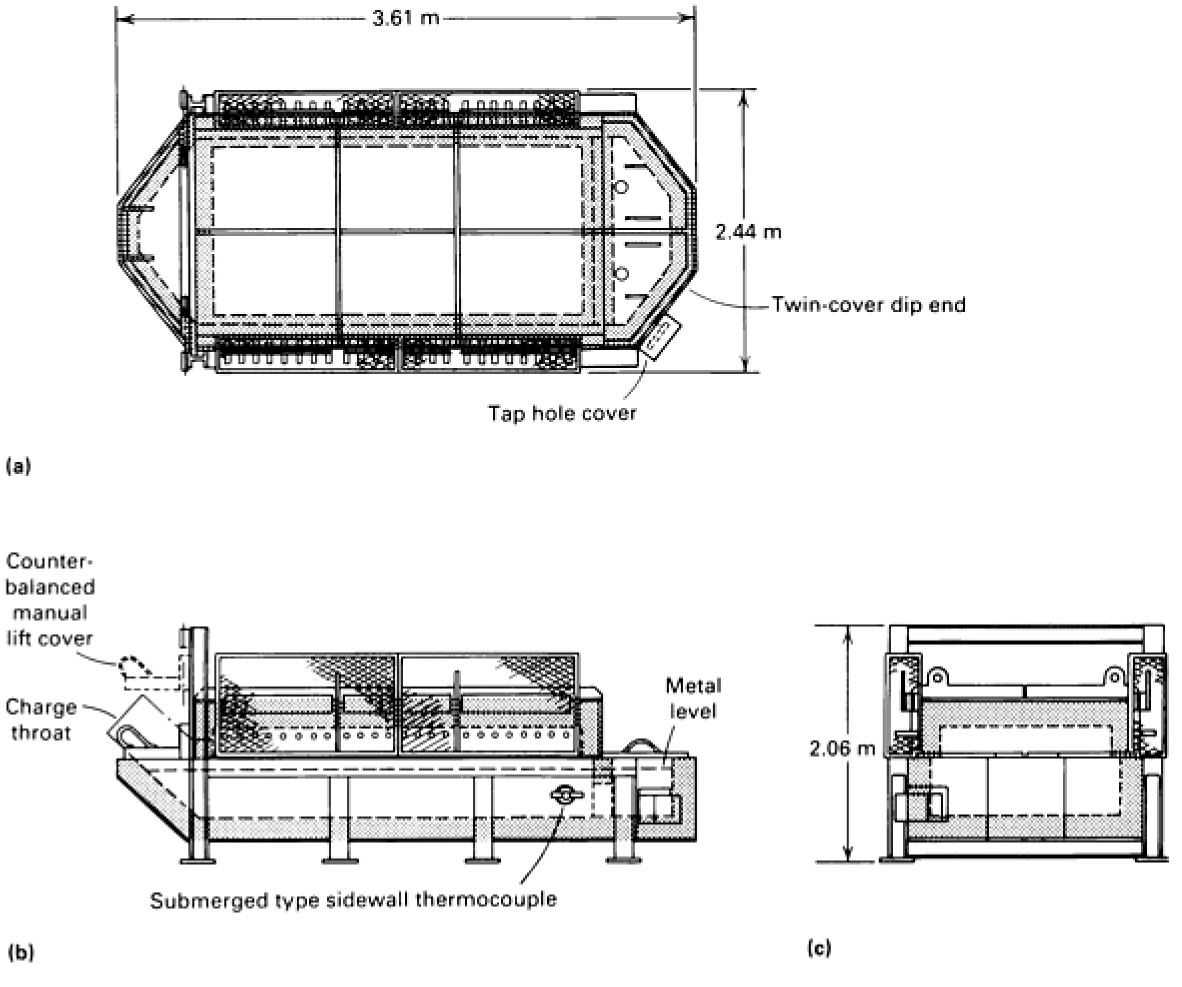

Fig. 6 Schematic of a small (4.42 Mg, or 9750 lb, capacity) electric resistance melter/holder reverberatory furnace for melting aluminum. Top (a), front (b), and side (c) views are shown.

A tilting reverberatory furnace is illustrated in Fig. 7. The burner is located on the axis of rotation at the end that is opposite to the charge well. This design provides simpler and safer tapping or metal removal than furnaces that have plugs and tap blocks. When used to melt aluminum, such a furnace typically has a capacity of 2.0 to 9.1 Mg (4400 to 20,000 lb) and can melt at a rate of 1.8 Mg/h (4000 lb/h).

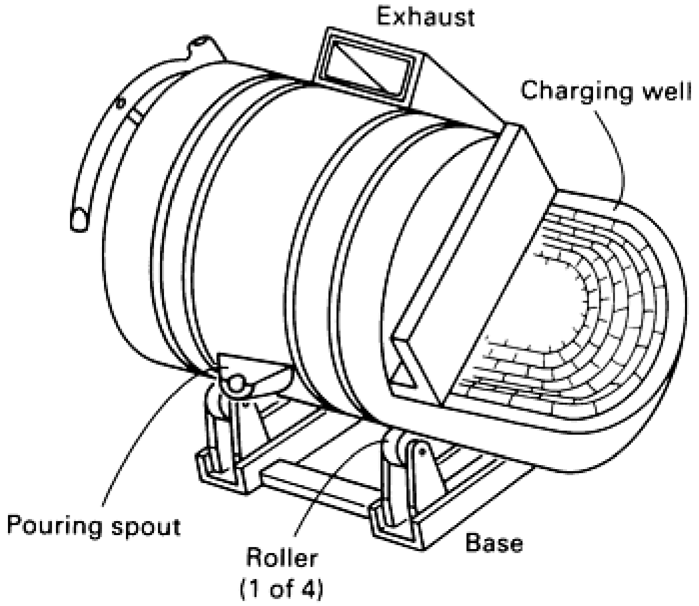

Fig. 7 Simplified view of a small tilting reverberatory furnace

Figure 8 shows a cutaway view of a dry hearth melting/holding furnace that serves as a metal supply to casting units. These furnaces supply excellent-quality metal. The fact that the molten metal does not get heated above the pouring temperature avoids many problems encountered in other types of melting. These units are extensively used in automobile wheel foundries and other high-volume quality foundry applications. One problem area relates to cleaning of the dry hearth. The flame and high temperatures can cause oxide and other melt residue to accumulate into large refractory deposits on this hearth. Regular and thorough cleaning will easily control this problem. Capacities of this style of furnace range from 1.8 to 9.1 Mg (4000 to 20,000 lb).

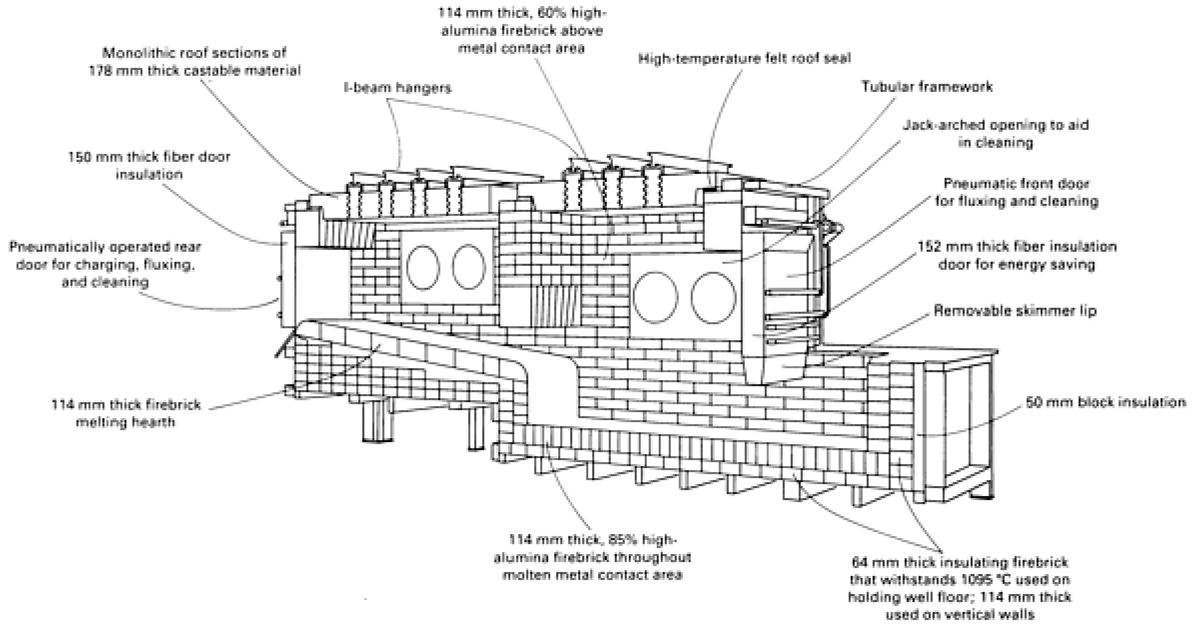

Fig. 8 Cutaway view of a combination of dry hearth/holder reverberatory furnace used as a source of molten metal for the production of aluminum castings

A unique hearth design that carefully addresses many of the hearth operation and design problems that are encountered in small furnaces is shown in Fig. 9. This melter/holder furnace has a hinged roof, which facilitates access for hearth cleaning. A stack ingot and heavy scrap preheater arrangement provides high fuel efficiencies, good metal temperature control, and charging safety features. The optional dry hearth provides the metal quality advantage offered by melter/holder furnaces. The roof-mounted burner system yields maximum use of floor space around the furnace. As with many of the other newer furnaces, a high-efficiency insulation provides a cool furnace exterior. Capacities range from 0.91 to 6.8 Mg (2000 to 15,000 lb).

Aluminum Alloy Melting Practice

The equipment and processes required for melting aluminum alloys vary widely and take into consideration the unique requirements of aluminum alloy melting. The following list describes equipment, energy, and metal property requirements that must be considered to melt aluminum cost effectively.

Energy Requirements for Melting. Very large quantities of heat are required for the melting of aluminum alloys. Table 1 compares the energy per unit mass needed to heat and to melt various metals when the furnace is operated from a cold start. It is interesting to note that the amount of heat required to melt 0.45 kg (1 lb) of aluminum (at 660 °C, or 1220 °F) is over 85% as much heat as that required to accomplish the same task with 0.45 kg (1 lb) of iron at 1260 °C (2300 °F). Careful consideration of the heat transfer problem in the design and operation of equipment is required to provide efficient melting.

Table 1 Heat required for melting various alloys

Metal	Heat required	
	kJ/kg	Btu/lb
Iron	1240	534
Aluminum	1060	457
Copper	675	290
Zinc	280	120
Tin	116	50

Table 2 lists the amounts of heat and the percentages of total heat required to heat aluminum to various temperatures. From a practical standpoint, this indicates the importance of preheating; that is, it takes 41% of the furnace energy to heat aluminum to 425 °C (800 °F). Therefore, with heated charges, one can almost double the capacity of the melt furnace. At the same time, much shorter meltdown times are developed.

Table 2 Heat input as a function of aluminum alloy temperature

Temperature rise		Specific energy required		% of total	Cumulative %
°C	°F	kJ/kg	Btu/lb		
20-425	70-800	484	208	41	41
425-660	800-1220	186	80	16	57

Liquid to solid	Liquid to solid	395	170	33	90
660-770	1220-1420	116	50	10	100

High Chemical Activity. This property of aluminum requires special precautions, including:

- Careful isolation from moisture and water; under certain conditions, violent explosions can occur
- Consideration of possible thermite reactions; silicon, iron, and other metallic oxides are often reduced by molten aluminum, resulting in bath contamination and other problems that require special consideration in refractory selection
- Heavy firing and/or direct flame impingement, under some conditions, will cause thermiting or aluminum oxidation on the bath surface

Bath Stratification. The hot molten metal, being less dense, tends to float toward the top of the bath, while the cooler molten metal and the unmelted solids remain on the furnace bottom. Variations of up to 110 °C (200 °F) between the top and bottom of a 686 mm (27 in.) deep furnace have been documented.

Natural circulation or convection currents in aluminum baths are very poor. Cold molten metal is denser or heavier than hot molten metal. For this reason, there is no natural tendency to develop circulation. By design, many furnaces are heated through the surface, and the surface tends to get hotter. In addition, with the cold charge at the bottom, the molten metal there tends to stay cold. This is an inherent problem in the design and operation of hearth furnaces that must be solved to provide efficient heating of the molten metal.

Refractory deposits are classified as furnace floor deposits and melt line deposits. Both are discussed below.

Furnace Floor Deposits. Upon melting, the solid first becomes a slush or a solid liquid mixture. The more fluid component of this slush will drain off and often will leave a residue or sludge consisting of iron, manganese, chromium, silica, and copper. These high melting temperature alloy components are the last to become liquid. If substantial quantities or substantial depth of this unmelted alloy or sludge is allowed to collect on the furnace bottom, this sludge will slowly change into an insoluble, highly refractory monolithic growth on the furnace floor. With such continuous abusive furnace operation, the deposit can seriously decrease the furnace capacity. Solutions to this problem include limiting bath depth, frequent stirring, and the use of mechanical or electromagnetic circulators. Circulating pumps can reduce the temperature differential between the top and bottom of a 686 mm (27 in.) deep bath to about 4 °C (7 °F) and can increase melting rate by 30%.

Melt Line Deposits. Many aluminum oxides, sand charged with scrap, and other light materials will float and collect on the top of the molten aluminum bath. Often, refractory slag compositions are formed and deposited on the furnace walls at the metal line. Regular periodic cleaning (once per shift) is usually required to control this problem in furnaces in which considerable metal melting is done.

Dross By-Product. The melting of aluminum results in a residue of oxides or dross that must be controlled. This residue varies in density. Some of it floats, and other forms remain either in the bath or sink to the furnace bottom.

This dross accumulation is minimized where dry hearth melting is used. Here the newly melted liquid that separates from the oxides flows into the bath, leaving most oxides and other insoluble material on the dry hearth.

However, in melting in which solids are charged into the bath, oxides lighter than the melt will float; those heavier or the same weight as the bath will remain in the bath to be removed later. Dross causes four serious problems:

- Molten aluminum in small beads becomes entrapped in floating dross and is often lost at heavy costs; recovery processes (fluxing) can be used to reduce this loss
- With surface-fired furnaces, the floating drosses can become hot enough to light-off or start the burning of aluminum; this burning or thermiting of aluminum can result in large melt loss costs. Aluminum burning releases

considerable heat and can produce foundry data that would indicate low fuel costs; in reality, all commercial fuels are less costly than aluminum as heat sources

- Large surface oxides in the surface-fired furnaces aggravate the furnace sidewall deposit or buildup problem
- Depending on metal quality requirements, excessive melt drossing often makes the subsequent fluxing, degassing, filtration, and other quality improvement processing more difficult and less reliable

Optimizing metal quality and prolonging furnace life involve consideration of five factors. These are temperature control, refractory temperature variations, furnace charging techniques, burner maintenance, and general preventive maintenance.

Temperature Control as Related to Metal Quality. Aluminum, being very active chemically, becomes even more active as the temperature of the molten metal is increased. Therefore, aluminum foundries should use the lowest practical melt temperatures at all times. The general rule is to heat the bath to no more than 60 °C (100 °F) above pouring temperature; it should be noted that the oxidation rate of aluminum doubles between 770 to 800 °C (1420 to 1470 °F). Melt quality control procedures are often substantially reduced in effectiveness when they are used at higher-than-necessary temperatures. This includes procedures for hydrogen porosity control, grain refinement, silicon constituent modification, and loss of highly active alloy additives such as magnesium, beryllium, boron, sodium, and lithium.

An example of this temperature-dependent activity is shown in Fig. 10. The melt temperature and melt hydrogen content are related to the time when the furnace flame is on and when it is off. Figure 10 clearly shows that a repeating sequence occurs. First, the heat or flame comes on, and then within a couple of minutes, the temperature begins to rise. Shortly after that, the hydrogen content of the bath increases. The reverse occurs after the flame is turned off. Hydrogen content is increased by 50% (from 0.24 to 0.36 mL/100 g, or 0.07 to 0.1 in.^{3}/lb), with the temperature cycle between 740 and 770 °C (1365 and 1420 °F). It is interesting that the gas content is also instantaneously lost as the temperature is lowered.

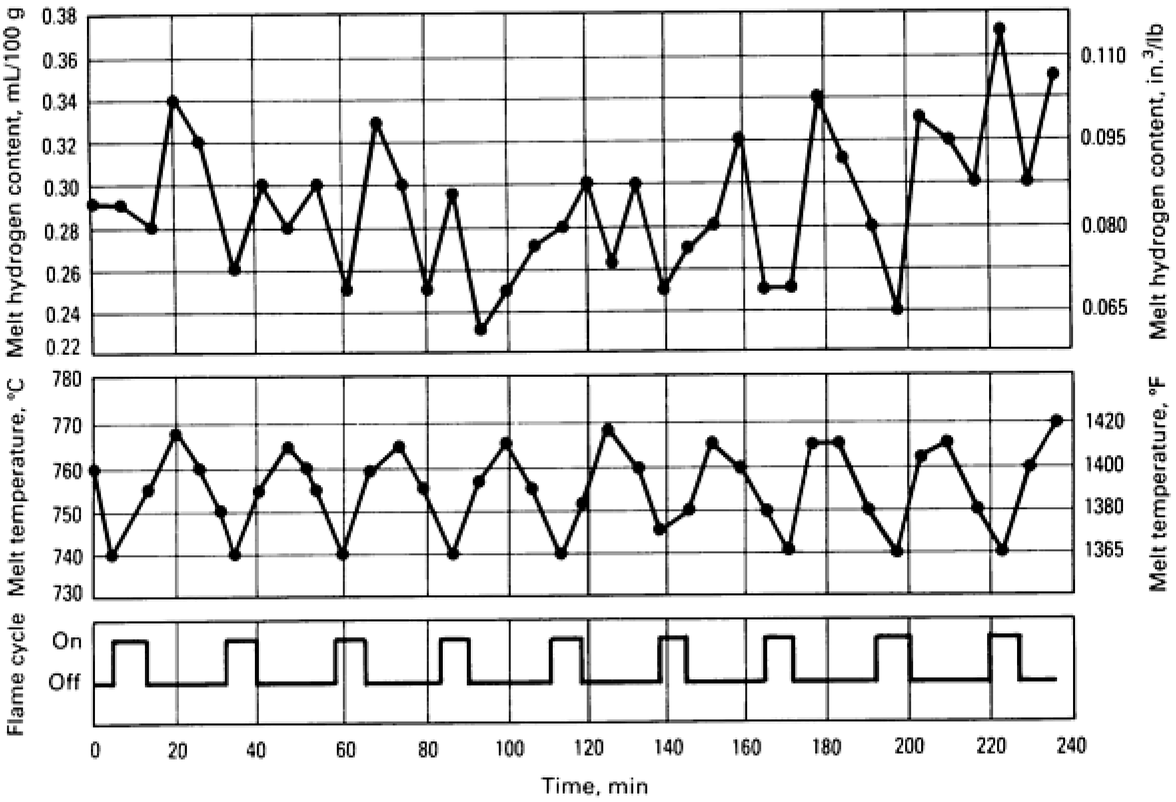

Fig. 10 Effect of metal temperature and hydrogen content on casting porosity

Similarly, the beneficial effects of grain refiners and silicon constituent modifiers fade more rapidly or are lost sooner at high temperatures than at lower temperatures. Unlike hydrogen porosity, fading grain refinement or modification is not regained simply by lowering melt temperatures.

Effect of Refractory Temperature Variations on Furnace Life. Continuous operation without weekend or other frequent cool-down periods does much to extend furnace life and to minimize maintenance problems. Cooling of the refractory from operating temperatures to room temperatures causes considerable damage, such as cracks and loosening of anchors.

The best preventive maintenance procedure is close and careful condition examinations during weekly drain and clean operations. Holes or weaknesses in the refractory and wall or hot spots in the floor are usually obvious. Contact temperature indicators are useful. Use of optical or photo infrared equipment to monitor external furnace surface temperatures is an excellent method of keeping a record of developing hot spots or weak furnace wall, floor, and roof areas.

The start-up procedure for cold furnaces should always include heating of the empty furnace to a high temperature prior to charging. This allows the refractory to heat, to expand, and to close all cracks that have opened during cooling. If the metal is melted in a cold furnace, these cracks will be filled with molten metal and will weaken the refractory. This can substantially reduce the life of the furnace.

Effect of Furnace Charging Techniques on Melt Quality. The rough or aggressive charging of sharp ingot, sow, or scrap into an empty furnace can and often does cause considerable damage to furnace floors and walls. Light scrap is often charged first to cushion and to protect the furnace floors and walls.

It is essential that water and moisture in furnace charges be avoided. Serious and even fatal accidents have resulted when metal that contains water was loaded into hearth furnaces. To prevent this and to reduce fuel costs substantially, preheated charges should be used as often as possible. Preheating of the scrap can reduce melt time by as much as 60%.

Alloy additions often require special care. Furnace charging techniques for alloy additions are covered in the four points that follow.

First, active light metal additions will float and, without care, will burn on the surface without producing the intended effect. Alloy additions such as magnesium, sodium, calcium, and lithium should be submerged with a tool to prevent excessive losses.

Second, silicon will also float and needs to be stirred into the melt before excessive surface oxidation occurs. This can oxidize to a protective surface that will not allow the silicon metal to dissolve.

Third, heavy metals such as copper and lead will sink to the bottom of the furnace (the coldest part of hearth furnaces) and will often be difficult to dissolve. For the fastest alloying cycle, these should be suspended high in the bath (using a basket, for example).

Finally, zinc and tin cause special problems because they are both heavy and have low melting and vaporization temperatures. Improper charging of these metals can drill a hole in the furnace floor (zinc drilling). Large slabs that are charged directly will go to the melt floor; the zinc then melts and vaporizes. The vapor then escapes into the porous refractory and condenses when it gets to the cooler portions of the floor. Here it condenses, solidifies, and expands to crack the refractory. This process can and will bore a hole through the furnace floor and cause furnace failure. To prevent this, metals such as zinc and tin should be charged using a steel basket held high above the melt furnace floor.

Burner Maintenance to Optimize Metal Quality. As a result of past fuel shortages and increased fuel costs, many important improvements have been made in the design and operation of melt furnace burners. In most cases, these improvements have resulted from better air-fuel mixing, flame control, and the use of preheated, constant air temperature feed to the burners. A particularly interesting burner development uses a pulsating flame on the metal surface for more efficient heat transfer. Contrary to past practice, very significant efficiency and quality gains have been realized by directing the flame on the bath surface.

Careful maintenance is often required in order to reap benefits of these improvements. Clean burner blocks are particularly important, because these units usually control air flow and flame shape. The furnace air-to-fuel mixture or furnace atmospheric condition is also very important.

Particular maintenance effort should be directed toward burners and related components in order to achieve efficient furnaces that produce quality aluminum alloys for good castings. A neutral or reducing atmosphere should be used because an oxidizing atmosphere will cause a dramatic increase in metal loss if the gases impinge directly on the metal surface.

A regular preventive maintenance program should include operation and condition checks on the following items:

- Burner block and refractory conditions
- Burner systems. Particular attention should be paid to deposits on and in the burners
- Fuel-to-air ratios. Unless constant-temperature air is used for combustion, fuel-to-air ratios should be checked carefully. With any major difference in air temperature (for example, seasonal changes), air volume must be adjusted to supply the proper amount of oxygen for efficient fuel use and melting
- Tap hole condition (inside and out)
- Flue or stack condition, particularly at the exit from the furnace chamber
- Housekeeping in the working and safety lane areas

Safety

All operations dealing with molten metal must involve careful consideration of operator safety. A thorough discussion of the safety precautions involved in foundry melting is highly recommended for any and all melt room activities. The three areas of metal melting that require special attention (furnace operation, furnace design, and personnel protection) are discussed below.

Furnace Operation. Most accidents occur during the charging and removal of molten metal. Worker exposure to splashes and potential explosions should be examined closely. Training programs are often required so that operators have a good understanding of all necessary precautions and safety measures. Such measures include the following:

- Whenever possible, carefully preheated charges should be used. This will avoid the possibility of loading water- or moisture-containing charges
- All areas around a melting furnace should be clear of obstructions to provide quick evacuation or escape routes in case of emergency
- Clean, dry, and carefully coated ladles and other tools should be used at all times
- Thorough preheating procedures should be followed before any tool is used in the bath
- Safety equipment and instructions for its use should be prominently displayed in case of furnace leaks or failures
- A well-conceived plan should be implemented to minimize potential hazards and to prepare personnel for any emergency
- Few of the materials used in most foundry hearth furnace operations can be considered hazardous. National Institute of Occupational Safety and Health programs require that Material Safety Data Sheets be readily available and used

Furnace Design. A principal consideration in furnace design should be to minimize worker exposure to splashing or exploding metal. Most furnace designers avoid floor-level charging wells as a concession to this safety consideration; instead, they use dip-out and charge wells that are waist high or higher. This enables the operator to avoid most splashes and spills of molten metal.

In the past, the furnace-tapping operation was a high-risk activity. Today, however, with the availability of insulated fiber cones or plugs, much of the problem has been overcome. Protective clothing should be worn, and at least two well-protected operators should be on hand when a furnace is being tapped. When an oxygen lance is used to open a tap hole, extreme care and full protective clothing and head gear should be used.

Personnel Protective Equipment and Clothing. Protection from flying molten metal due to splashes and minor explosions is the key to the selection of proper clothing and safety equipment. The use of wool shirts and trousers is a long-standing solution to these hazards. A metal splash causes the apparel to emit the odor of burning wool, and quicky warns the wearer of a potential problem. Clothes made of acrylic and other synthetic fibers should never be worn in the melting area, because they easily burn or form a hot liquid that can produce very serious burns. A 0.5 kg (1 lb) quantity of aluminum at 675 °C (1250 °F) that is plunged directly into water will produce an explosion equivalent to 1.4 kg (3 lb) of TNT.

Crucible Furnaces

Few if any metallurgical or industrial processes have a more distinguished history than the crucible melting of metals. Crucibles or earthenware smelting pots that were used to refine copper from King Solomon's mines can still be found in that area of ancient Israel. Some pots had capacities of up to 0.40 m^3 (14 ft^3) . The Wootz steels of India, the famous Damascus sword blades, and the equally famous steels of Toledo, Spain, were produced all using crucible melting processes.

The modern crucible process offers industry a great deal of flexibility and a wide variety of options with regard to metals, melt sizes, fuels, smelting, and processing techniques. Aluminum, brass, bronze, copper, ductile or gray iron, steel, magnesium, Monel, nickel, refractory alloys, steel, and other metals and alloys are produced using the crucible melting processes. Crucible capacity can vary from mere ounces for laboratory melts to 1.4 Mg (3000 lb) for the melting of aluminum alloys. Fuel choices include coal, coke, electricity, commercial gases (natural, propane, producer, and so on), and fuel oil. Crucible liners are often used for low- or high-frequency electric induction furnaces.

Foundry metal melting and handling operations that utilize crucible equipment include furnace melting, pouring ladle equipment (either separately heated or as a ladle liner), and liners for electric induction melting furnaces. Metal-processing operations include in-line filtration, fluxing, and hydrogen gas content control. Crucible melting can also be used as a component of quality adjustment equipment between melter and casting furnaces to alter the chemistry and temperature of the melt for control of such factors as porosity content prior to casting. Crucible melting is a simple and flexible process. Crucible furnaces can generally be started or shut down at a moment's notice. Normally, there is no stand-by charge for labor costs between uses of this equipment.

Furnace Types

Foundry crucible furnaces can be classified as stationary, tilting, or movable.

Stationary furnaces utilize a crucible set inside a refractory-lined shell that has heating equipment attached. Normally, molten metal is dipped out with hand ladles, or the crucible containing the molten metal is removed from the shell for the casting operation.

A stationary crucible furnace built to accommodate a lift-out crucible is shown in Fig. 11. By using tong and shank tools to lift and carry the bilge-shaped crucible to the mold, pouring of the casting is done directly from the crucible without the need for potentially damaging metal transfers. The maximum crucible size normally used in this manner holds 140 kg (300 lb) of aluminum or copper. The weight and the strength of the crucible limit this type of operation. A similar stationary crucible furnace designed for use with a bowl shape and for hand ladle dip out has a capacity of up to 1.4 Mg (3000 lb) of aluminum alloy. The double pushout furnace shown in Fig. 12 uses induction coils instead of fuel gases to heat the melt and hydraulic cylinders to raise and lower the crucibles within the coils.

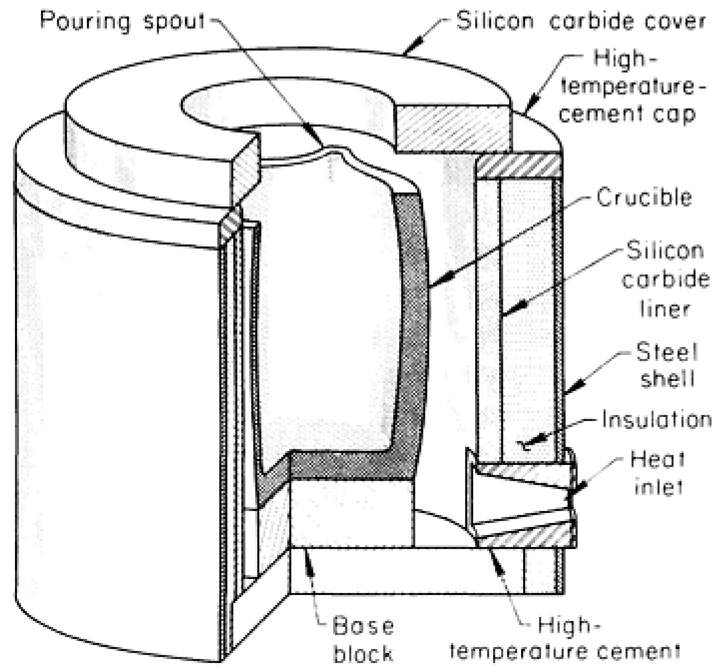

Fig. 11 Typical lift-out version of a stationary crucible furnace specifically adapted to the foundry melting of small quantities (<140 kg, or 300 lb) of copper alloys.

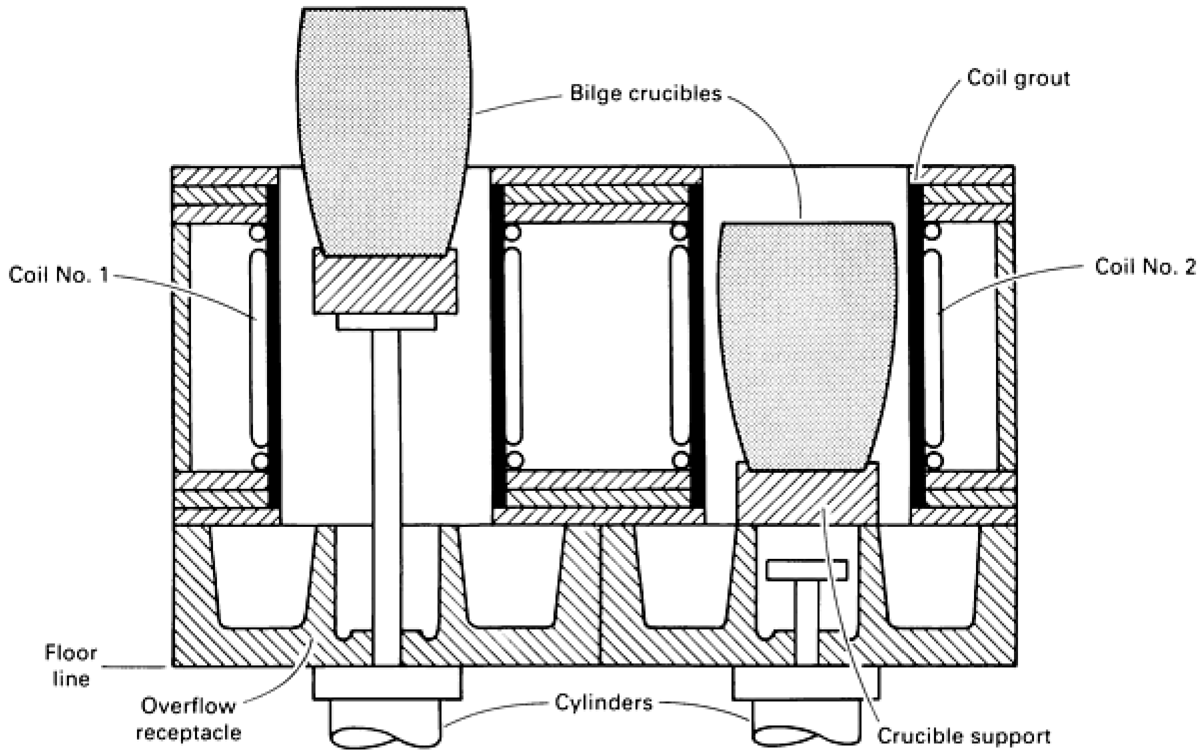

Fig. 12 Cross section of a double pushout stationary crucible furnace

Some stationary crucible furnaces are equipped for hand-ladle dip-out pours. For most metals, it is imperative that the flame and flue gases do not contact the charge. Two methods of controlling this critical factor are illustrated in Fig. 13. The first is the side flue configuration used in an aluminum melter installation (Fig. 13a), and the second is the cover plate configuration used for a brass foundry furnace (Fig. 13b). The cover plate setup incorporates holes on the outside

diameter of the crucible top. Also shown is the extensive use of highly insulating fiber refractory material. This material has a low heat content and serves to conserve fuel and to minimize the temperature override that often occurs with the heavier refractory furnace linings. The added refractory flame face is required to accommodate the higher melt temperature.

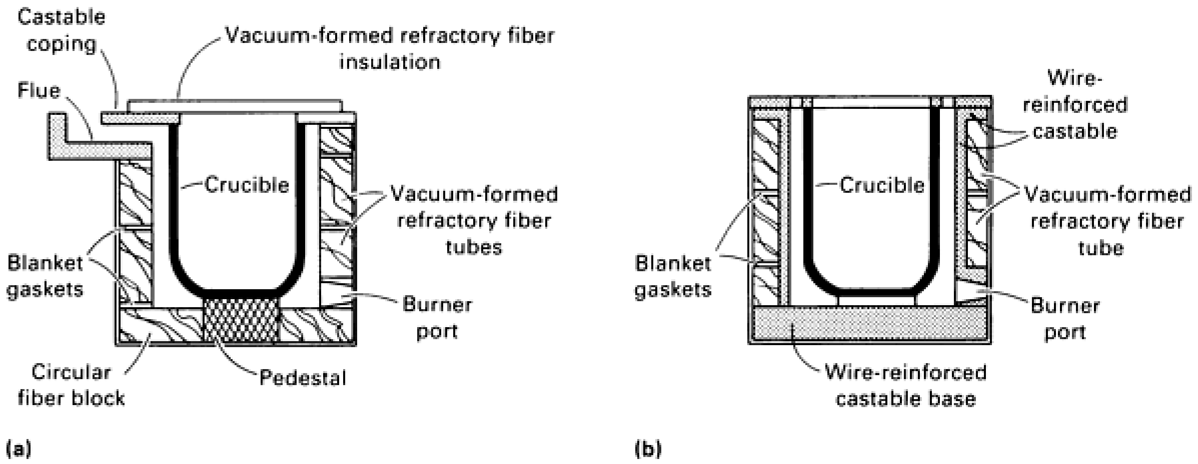

Fig. 13 Stationary crucible furnaces equipped for hand-ladle dip-out pours. (a) Side flue configuration. (b) Configuration with cover plate openings on outside diameter of crucible top

Steel crucibles can also be used in stationary crucible furnaces, as shown in Fig. 14. The high heat conductivity of the steel offers fuel and meltdown time savings. Steel and ductile iron crucibles are extensively used for magnesium and zinc melting. In these molten alloys, there is little attack of the crucible walls.

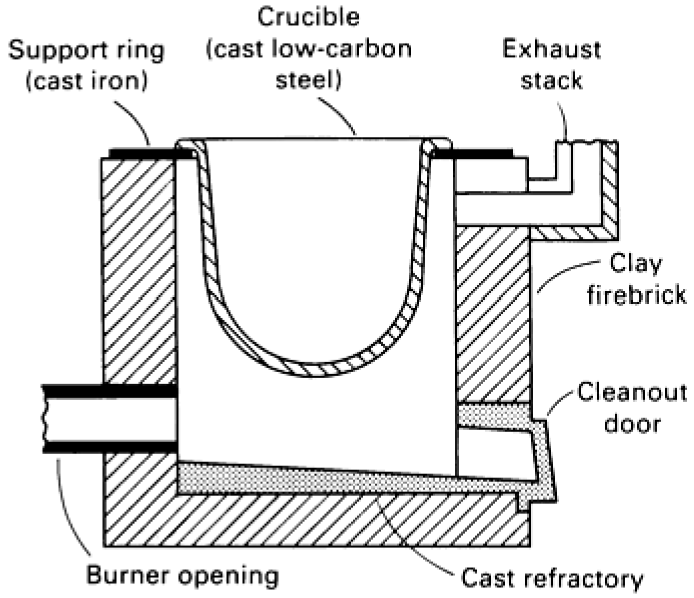

Fig. 14 Cross section of a stationary fuel-fired furnace used for the open crucible melting of magnesium alloys

On the other hand, aluminum alloys will attack the steel crucible walls by forming sludge (combination of iron, manganese, and chromium), which eventually causes hot spots in the castings produced from this melt. However, there have been successful aluminum foundry uses of steel crucibles. This requires a thorough refractory coating on the crucible surfaces in contact with molten metal and careful cleaning of the rust that tends to accumulate in the firing

chamber (for example, flame contact with the crucible causes rust and scaling). This can collect in the firing chamber. A special clean-out door is used to remove this residue.

Both aluminum and magnesium can react explosively with iron oxide. The use of electrical resistance furnaces and steel crucibles reduces the seriousness of this problem, and long-term use of steel crucibles and resistance furnaces has been successful in the casting of aluminum alloys.

Tilting furnaces incorporate a crucible that is supported in the shell such that both are free to rotate on an axis. This allows the molten metal to be poured into ladles or molds. The axis of the pour can be either at the center of gravity or at the lip of the furnace. This design simplifies the handling of molten metal in many foundries.

Tilting crucible furnaces are designed to simplify metal removal and have been extensively used in numerous foundries for many years. Figure 15(a) illustrates a center-axis furnace; Fig. 15(b) shows a cross section of a lip-axis furnace. Tilting crucible furnaces are useful where castings require more metal than can be easily handled by stationary crucible furnaces. These units are more flexible and can easily handle production requirements that are too small for the efficient operation of larger hearth furnaces.

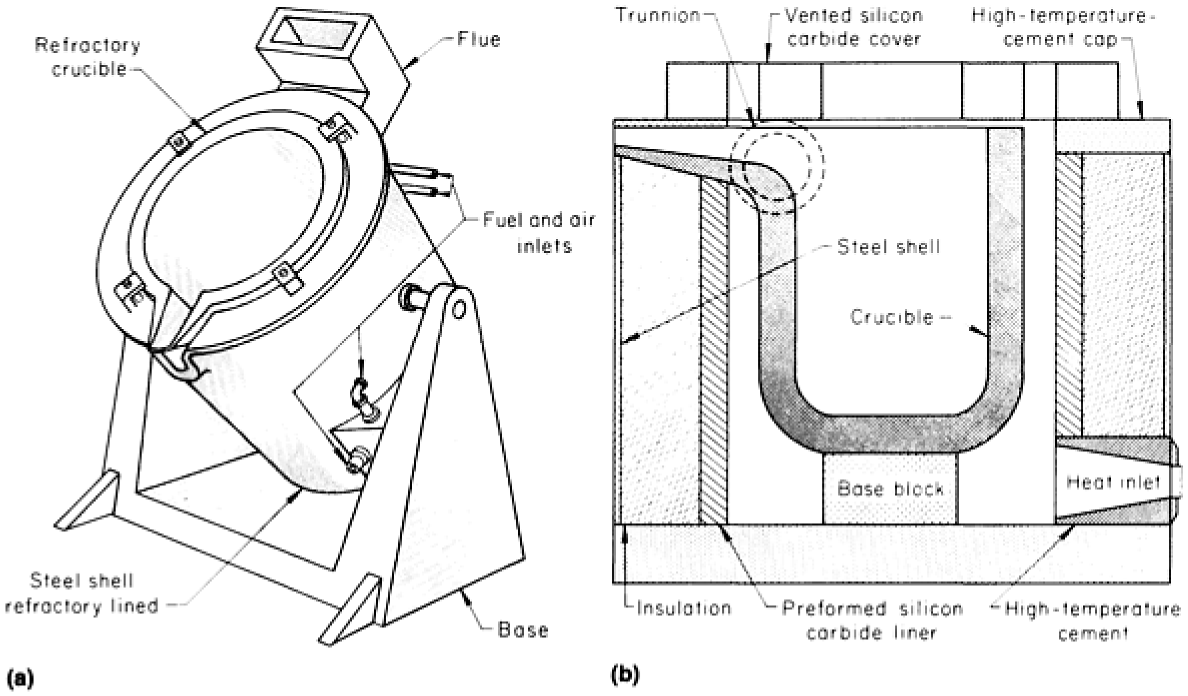

Fig. 15 Two variations of a tilting crucible furnace. (a) Center axis. (b) Lip axis

Figure 16 illustrates the use of a crucible liner for an induction melting tilt furnace. Use of the crucible liner overcomes the problems that would occur as a result of the strong erosive currents existing at the crucible sidewalls. The low electrical conductivity of clay-graphite crucibles makes them ideal for use in such applications. A gradual buildup of molten metal in the heel and voids in the backup refractory, both caused by repeated tilting of the furnace, are detrimental to crucible life (see the section "Furnace Design Considerations" in this article.)

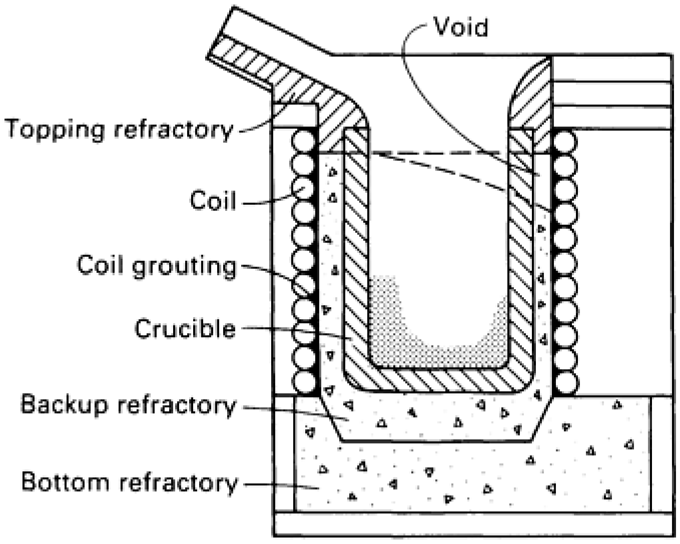

Fig. 16 Cross section of a tilt furnace for the high-frequency induction melting of brass and bronze alloys. Crucible is of clay-graphite composition. Also shown are the locations of the molten metal buildup and the voids in the backup refractory, which shorten crucible life.

Crucible liners, which provide a durable wear-resistant surface for molten metal, are often used in the brass, steel, and ductile iron foundry industries. This application for the foundry use of crucibles is similar to that for the induction furnace liners shown in Fig. 16.

Movable Furnaces and/or Pouring Ladles. In this category, either melter or holder furnaces are cycled between the in-line pouring station and the melt and/or the postmelting temperature and quality adjustment operation. The requirements of new highly automated pouring methods have encouraged new thinking in many areas. The modular melting method is particularly interesting. This method uses two-, three-, or four-crucible melters that are arranged on either a shuttle or a turntable, as diagrammed in Fig. 17. In operation, one furnace is always in a holding mode. This furnace is considered to be in the pour position. The remaining furnace positions are used alternately for recharging, stabilizing, and metal treatment. This method eliminates the need for the transfer of molten metal within the foundry. When automatic pouring is used, temperature stability of ±3 °C (±5 °F) can be maintained while casting with robotic pouring equipment. A three-crucible modular melter is capable of preparing, melting, and delivering up to 650 kg/h (1425 lb/h) of molten metal to the casting unit.
